Freshly voided and diarrheic fecal samples should be examined. Detection of trophozoites can be improved by collecting samples using a fecal loop⁵² and by examining multiple fecal smears. Trichomonads will not survive refrigeration and are not observed after fecal flotation or sedimentation. Survival of trophozoites in feces can be extended from 0 to 4 days by removal of adherent litter and dilution of the sample with normal saline to avoid desiccation (3 ml 0.9% saline per 2 g of feces).⁴⁴ Concurrent antibiotic therapy will diminish the number trophozoites present in feces, a fact that should be considered in cats with negative fecal smear results.⁴⁹ The sensitivity of direct fecal smear examination for diagnosis of trichomoniasis is low (2% in cats with experimentally induced infection and 14% in cats with spontaneous disease).^{52,54}

Infectious Diseases of the Dog and Cat, 3rd Edition

78.5.4.2 Fecal Protozoal Culture

If repeated direct microscopic examination results are negative for trophozoites, feces may be cultured in-house using a commercially available system marketed for diagnosis of *T. foetus* infection in cattle (In Pouch™ TF, Biomed Diagnostics, San Jose, Calif.)⁵⁰ (Fig. 78-15). For diagnosis of feline *T. foetus*, pouches should be inoculated with 0.05 g (approximately the size of a peppercorn) of freshly voided or loop-collected feces and incubated at room temperature (25° C [77° F]) in an upright position. Before microscopic examination, pouches are tapped against a bench-top to dislodge adherent organisms and then placed within a manufacturer-provided clamp that allows the pouch to be mounted onto the stage of a light microscope. 748
Pouch contents should be examined every other day for motile trophozoites using a light microscope with 20 × or 40 × objective and discarded if still negative after 12 days. Fecal culture using In Pouch™ TF has a detection limit of greater than 1000 *T. foetus* organisms per 0.05 g feces and is superior to direct fecal smear examination for diagnosis of *T. foetus* infection.^{50,54} Neither *Giardia* nor *P. hominis* organisms can survive in In Pouch™ TF for longer than 24 hours; thus positive cultures results are strongly suggestive of *T. foetus* infection.⁵⁰ Strictly speaking, however, the types of trichomonads potentially hosted by cats and the specificity of In Pouch™ TF with regard to these other types of trichomonads is unknown. Positive In Pouch™ TF culture results do not preclude the possibility of co-infection with *P. hominis* or *Giardia*. 749

Fig 78-15 The In Pouch™ TF system consists of two chambers of culture medium connected by a channel. To inoculate the In Pouch™ TF, the upper chamber is opened by tearing off a plastic strip along the top of the pouch. Approximately 0.05 g of feces is inoculated into the upper chamber and mixed with the culture contents. The top edge is then rolled down to seal the opening and forces the contents into the lower chamber for cultivation. (Courtesy Jody Gookin, Raleigh, N.C.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fecal samples can also be cultured in antibiotic-fortified, modified Diamond's medium.⁴⁸ Such cultivation requires shipment of feces to a research laboratory, preparation and maintenance of sterile medium, and 37°C (99°F) incubation. Minimal evidence exists to suggest that modified Diamond's medium culture provides any greater diagnostic sensitivity than does in-house fecal culture using In Pouch™ TF.

78.5.4.3 Polymerase Chain Reaction

A sensitive and specific single-tube nested PCR based on amplification of a conserved portion of the *T. foetus* internal transcribed spacer region (ITS1 and ITS2) and 5.8S rRNA gene from feline feces has been described.⁴⁸ The PCR test is superior to fecal culture for diagnosis of naturally infected cats⁵⁴ and is commercially available. Refer to [Appendix 6](#) for more information on this test.

78.5.4.4 Exclusion of Coexisting Disease

Coexisting systemic or enteric disease should be excluded in cats with trichomonas infection. Studies of experimental feline infection suggest that coexisting intestinal infection (e.g., cryptosporidiosis) worsens clinical signs of diarrhea and increases the shedding of *T. foetus* organisms.⁵² Further diagnostic evaluation of infected cats may include complete blood count; serum biochemical analysis; urinalysis; tests for feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and feline enteric coronavirus; fecal flotation; *Giardia*-specific antigen testing; fecal direct FA for *Cryptosporidium*; fecal gram stain for clostridia; and colonic mucosal biopsies. Commercial ELISA kits to detect fecal *Giardia*-specific antigen do not cross-react with *T. foetus*.

78.5.5 Pathologic Findings

Hematologic and serum biochemical analysis results from cats with *T. foetus* infection are invariably normal. Coexisting enteric infection by recognized feline pathogens (e.g., *Giardia*, *Cryptosporidium*, internal parasites) is not a consistent feature. Infected cats usually test negative for FeLV antigen and FIV antibody.⁴⁹ Histopathologic changes in colonic mucosal biopsies from infected cats have been consistent with mild to severe lymphoplasmacytic colitis. Because trichomonads are noninvasive and extremely fragile, they are unreliably preserved in intestinal biopsy specimens ([Fig. 78-16](#)), although immunohistochemistry may be used to enhance their detection.⁵²

78.5.6 Therapy

P. hominis is reportedly exquisitely responsive to treatment with metronidazole at the dosages that are effective for *Giardia*. An effective antimicrobial treatment for feline *T. foetus* infection has not been identified. Attempts to identify an effective treatment for economically important bovine trichomoniasis have failed; therefore specific therapy for feline infection in the near future seems unlikely.

Cats infected with *T. foetus* have failed treatment with recommended (and in many cases higher) dosages of numerous antimicrobial drugs, including metronidazole, fenbendazole, albendazole, sulfadimethoxine, trimethoprim-sulfadiazine, furazolidone, tylosin, enrofloxacin, amoxicillin, clindamycin, paromomycin, and erythromycin.⁴⁹ Furthermore, in vitro studies of feline *T. foetus* in culture have revealed multiple drug resistance (e.g., to paromomycin, furazolidone, metronidazole, anisomycin, azithromycin, ciprofloxacin, chloroquine,

Infectious Diseases of the Dog and Cat, 3rd Edition

doxycycline, tinidazole, and clotrimazole).⁸² Although nitazoxanide inhibited growth of *T. foetus* in culture, rapid resistance to the drug was acquired in vivo.⁵² In contrast to prior reports, paromomycin is not an effective treatment for *T. foetus* infection and has precipitated acute renal failure in infected cats.⁵³

Despite antibiotic failure to eradicate the infection, some cats have improved fecal consistency while receiving antimicrobial drugs.⁴⁹ This improvement may be related to a dependence of trichomonads on endogenous bacterial flora and host secretions for acquisition of essential nutrients. Prolonged use of antibacterial drugs has not been uniformly useful for long-term control of diarrhea and may delay the onset of clinical remission. Ronidazole, a nitroimidazole, was effective in curing infected cats with monitoring of up to 13 weeks post-treatment.^{49a}

In a study of long-term outcome in 26 cats with diarrhea and *T. foetus* infection, clinical signs resolved a median of 9 months after the onset of diarrhea (range, 4 months to 2 years).⁴⁴ Relapses of diarrhea were common and associated with dietary change, medical treatments unassociated with *T. foetus* infection, and travel. Based on fecal PCR, *T. foetus* was undetectable in more than 50% of cats when tested 2 to 5 years after diagnosis. Thus cats with *T. foetus* may have a good long-term prognosis for spontaneous resolution of disease.⁴⁴

Infectious Diseases of the Dog and Cat, 3rd Edition

78.5.7 Public Health Considerations

In light of the poor host specificity of *T. foetus* and the intimate association between infected cats and their human companions, the potential for zoonotic transmission should be considered. Only a single case of human infection with *T. foetus* appears in the literature. The infected individual had epididymitis and meningoencephalitis following immunosuppression and peripheral blood stem cell transplantation.¹⁰¹

79 CHAPTER 79 Nonenteric Amebiasis: Acanthamebiasis, Hartmannelliasis, and Balamuthiasis

Craig E. Greene

Elizabeth W. Howerth

79.1 ETIOLOGY

Acanthamoeba is a genus of ubiquitous free-living amoebas found in fresh and salt water, soil, dust, and sewage.^{1,14,18} The classification of the genus *Acanthamoeba* and separation from the closely-related genus *Hartmannella* has had a confusing history that is becoming resolved only with the use of molecular techniques.^{31,37} *Hartmannella* and *Acanthamoeba* are classified as distinct genera based on morphologic differences in the trophozoite shape and cyst wall structure, nutritional requirements, and serologic responses by infected hosts. *Acanthamoeba* has been further divided into three morphologic groups (I, II, and III) based on trophozoite and cyst size and structure. Although this morphologic classification is used, genetic comparisons have suggested the need for additional taxonomic reevaluation.³¹ *Balamuthia mandrillaris* is another free-living amoeba that can cause fatal granulomatous amebic encephalitis.

Acanthamoeba has a relatively simple life cycle with two stages, one as a dormant free-living cyst in the environment and the other as a vegetative feeding form in host tissues. The vegetative replicating trophozoite has two distinct phagotrophic niches: (1) feeding on bacteria in aquatic habitats and (2) acting as opportunists of host cells in the body. The cyst phase is often able to resist adverse environmental conditions, including desiccation¹⁴ and possibly host immune responses. The cyst can also survive exposure to temperatures between –20°C and +42°C and a pH of 3.9 to 9.75.¹

751

In the environment, *Acanthamoeba* species are omnipresent and abundant. They have been isolated from all water sources. In the atmosphere, they are carried on pollutants, and their concentrations have been used as potential monitors of air quality.

Several *Acanthamoeba* species are pathogenic for animals and people. They can subclinically colonize superficial epithelial surfaces but can also produce ocular surface infections and may disseminate in immunocompromised individuals. Disseminated infections usually involve the central nervous system (CNS). *Acanthamoeba castellanii*, *Acanthamoeba culbertsoni*, and *Acanthamoeba* sp. genotype T1 have been causes of canine infections.^{3,26}

In addition to *Acanthamoeba* species, *Hartmannella vermiformis*, another free-living but potentially pathogenic amoeba, can be isolated from the ocular surfaces of people. As with *Acanthamoeba* species, *Hartmannella* have been found in corneal biopsies of people with keratitis. Clinically healthy cats have been shown to harbor *Hartmannella* on their ocular surfaces; however, compared with clinically healthy cats, those with ocular disease were more likely to harbor amoebic DNA of *Hartmannella* and its endosymbiont rickettsiae *Neochlamydia hartmannellae*.^{35,36} The significance of *Hartmannella* infection as a cause of ocular surface infections in cats or dogs needs additional study. Finding a greater prevalence of *N. hartmannellae* and its amoebic host in cats with ocular disease suggests a causal association (see Chlamydial Infections, Chapter 30).

Several other forms of amoebic meningoencephalitis exist, which can be a source of confusion. Two related amoebae, *Naegleria fowleri* and *Balamuthia mandrillaris* (previously, *Leptomyxida amoebae*), also cause

Infectious Diseases of the Dog and Cat, 3rd Edition

meningoencephalitis in people and nonhuman primates; *B. mandrillaris* caused disseminated infection with granulomatous nephritis and meningoencephalitis in a dog.¹⁴ Systemic infections with *Acanthamoeba* species develop in immunocompromised people; however, those caused by *Naegleria* and *Balamuthia* species can affect immunocompetent people. Infection with *Naegleria* and *Balamuthia* organisms is acquired through swimming in contaminated waters, with the infection spreading through the olfactory neuroepithelium to the CNS. *Acanthamoeba* and *Hartmannella* species have spikelike (acanth) projections, which help differentiate them from the genus *Naegleria*, *Balamuthia*, or other amoebae.

79.2 EPIDEMIOLOGY

Acanthamoeba organisms cause pneumonia and encephalitis in people^{14,18,34} and animals^{2,11,14,15,26} and disseminated dermatitis and chronic keratitis in people.^{20,22} Although rare, rhinosinusitis, osteomyelitis, and disseminated infection have been developed in human infections.

Primarily solitary cases of acanthamebiasis in dogs have been reported, although in greyhound kennels, multiple dogs have been infected.^{14,15} Acanthamebiasis has not been described in cats.

In dogs, epizootics of acanthamebiasis have been observed in greyhounds,^{14,15} whereas single cases were described in a German shepherd dog² and an immunosuppressed Akita.²⁶ Young dogs appear to be most susceptible. Affected greyhounds ranged from 4 to 13 months of age. During outbreaks, organisms are thought to be acquired from a common environmental source rather than from other animals. The source of infection and the incubation period in dogs are unknown.

Immunosuppressed persons, such as those who have had organ transplants, have the acquired immunodeficiency syndrome, abuse alcohol, have diabetes, or have other debilitating conditions, are at high risk for infection and particularly susceptible to acanthamebiasis.^{18,38} In people who are critically ill or debilitated, *Acanthamoeba* species typically cause a chronic granulomatous meningoencephalitis that may last for weeks or months before causing death.¹⁸ Disseminated *B. mandrillaris* infection developed in a dog given immunosuppressive doses of glucocorticoids.¹⁴ Amebic keratitis has been seen in otherwise healthy people who wear contact lenses or have minor corneal trauma.^{20,22} Using tap water to make saline solutions for contact lenses has been suggested as a source of infection.¹⁶

79.3 PATHOGENESIS

The pathogenesis in dogs is unknown; however, in people, routes of infection may include inhaling organisms from water while swimming or from contaminated air. The organisms can replicate in the upper or lower respiratory tract after inhalation or in skin or other tissues after penetrating injuries. They then spread to the CNS by hematogenous means. Alternatively, infection of the cornea and nasal passage might lead to a retrograde spread to the nervous system via optic and olfactory nerves, respectively.

79.4 CLINICAL FINDINGS

Clinical manifestations of canine acanthamebiasis and canine distemper are remarkably similar.^{15,26} Initial signs include mild oculonasal discharge, anorexia, and lethargy. Rectal temperature varies from normal to as high as 40.5°C (105°F). Respiratory distress and neurologic signs then develop. Most dogs eventually develop neurologic

Infectious Diseases of the Dog and Cat, 3rd Edition

dysfunction. Neurologic signs include incoordination, head tilt, stumbling, dysmetria, and seizures. Coughing and dyspnea may be observed after a few days. Severely affected dogs are tetraplegic and in lateral recumbency without the ability to right themselves. Less severely affected greyhounds have permanent disabilities that preclude performance racing. In one dog, progressive neurologic disease was caused by the meningoencephalitis; however, the brain damage also induced a syndrome of inappropriate antidiuretic hormone secretion (SIADH).⁷ SIADH was associated with impaired water excretion and normal sodium excretion leading to peripheral edema, serum hyposmolality, and an inappropriately high serum sodium concentration.

The dog with disseminated balamuthiasis developed lethargy and hematuria followed by neurologic dysfunction, including intermittent seizures, rotary nystagmus, recumbency and coma.¹⁴

Cats with *Hartmannella* species infection may be more likely to have clinical manifestations of keratitis or conjunctivitis such as photophobia, lacrimation, conjunctival hyperemia, and ocular discharge. However, a direct causal association between this amoeba and ocular surface inflammation has not been proven.

79.5 DIAGNOSIS

The clinical laboratory abnormalities in animals with systemic acanthamebiasis are nonspecific. Leukopenia in greyhounds is a result of marked lymphopenia¹⁵ and in other breeds is caused by a reduction in all types of blood leukocytes.^{2,26} The cause of the leukopenia is unknown but may be concurrent infectious disease, stress, or specific factors produced by the *Acanthamoeba* organisms. No laboratory findings are available for the dog that developed *B. mandrillaris* infection.

751

Identification of amoebae in animals with keratitis is best accomplished using corneal scrapings or biopsy. Swabs are not suitable. The specimen should be inoculated as soon as possible onto specialized media (Page's agar). Specimens can be transported to the laboratory in a sterile vial containing a few drops of sterile saline. The organisms can be visualized in the specimen by microscopy, although trophozoites do not always stain predictably.

752

Premortem diagnosis of *Acanthamoeba* encephalitis in dogs or people has been rare. Culture or biopsy of affected tissues would be the most specific means of confirmation. Although lung and CNS tissues are not readily accessible, the possibility of finding organisms in cerebrospinal fluid (CSF) and tracheal washings has not been evaluated.

Amoebas can be cultured from lesions by special methods that are not done in most laboratories³⁴ because biocontainment facilities are needed.⁴ Organisms grow sparingly on potato dextrose agar, where amoebas grow as individual colonies with many cysts, or on non-nutrient agar seeded with bacteria, where they grow more rapidly as a confluent expanding ringlike mass of trophozoites with cysts at the central portion. Organisms can also be isolated in cell culture, where they cause cytopathic effects. Mouse inoculation can be used to test the pathogenicity of isolated strains. Polymerase chain reaction analysis of corneal epithelial and tear samples has been used in the diagnosis of *Acanthamoeba* keratitis.¹⁷ Similar genetic evaluation of CSF or blood samples for diagnosis of systemic infections has not been done in human or animal infections.

79.6 PATHOLOGIC FINDINGS

In dogs with acanthamebiasis, lung and brain lesions have been observed grossly in all cases. Lung lesions vary from light-tan to deep-red, raised, semisolid nodules distributed uniformly throughout all lobes.^{2,3,26} The nodules have a tendency to coalesce, and intralesional cavitations have been noted. Brain lesions may be large, multifocal,

Infectious Diseases of the Dog and Cat, 3rd Edition

and visible on the meningeal surfaces of the cerebrum and cerebellum and vary from red to tannish brown as a result of recent hemorrhage or necrosis.

Microscopically, multifocal necrotizing and often hemorrhagic meningoencephalitis and pneumonia with purulent, pyogranulomatous or granulomatous inflammation are seen. Trophozoites and occasional cyst forms of *Acanthamoeba* are seen within alveolar spaces and terminal bronchioles (Figs. 79-1 and 79-2). In brain lesions the amoebas are best visualized in perivascular and subarachnoid spaces, because in the neural parenchyma they are often masked by the presence of infiltrating inflammatory cells. Similar necrotizing and purulent to granulomatous foci containing amoeba may be seen in other tissues, including kidney, heart, liver, adrenal, and pancreas.^{2,3,26}

Histologic and direct fluorescent antibody (FA) methods are used to demonstrate and identify the organism in tissues.³⁴ Free-living pathogenic amoebas are difficult to differentiate microscopically from certain mammalian cells, especially macrophages.¹⁰ The diagnostic feature of *Acanthamoeba* in histologic sections is the centrally located nucleolus^{14,34} (*targetoid karyosome*) and vacuolated cytoplasm. Periodic acid–Schiff and Gomori's methenamine silver methods stain only the cyst wall. Trophozoites are 15 to 45 μm in diameter, and cysts are 15 to 20 μm . Direct FA staining is specific and reliable on deparaffinized sections of formalin-fixed tissue and with specific conjugates can be used to distinguish among the various species of *Acanthamoeba*.

In the dog with *B. mandrillaris* infection, grossly visible granulomas were found in the kidneys and brain (Figs. 79-3 and 79-4). In the kidneys, marked interstitial edema and necrosis with perivascular granulomatous inflammation was found (Fig. 79-5). Cyst and troph forms of amoebae were admixed with these infiltrates. Trophs were 15 to 45 μm in diameter and round to oval, with short cytoplasmic pseudopodia (Fig. 79-6). The cysts were 15 to 20 μm in diameter and surrounded by a double wall (Fig. 79-7).

752

753

Infectious Diseases of the Dog and Cat, 3rd Edition

79.7 THERAPY

Information on treating topical and systemic amoebic infections in animals is lacking. No therapeutic regimen for systemic acanthamebiasis in people has been well established, and drug susceptibility has been inconsistent. Drugs active against *Acanthamoeba* in vitro include polyene antifungals (amphotericin B), imidazoles (ketoconazole [KTZ]), and the antitubercular drug rifampicin, among others.¹² Rifampicin was effective in treating mice with meningitis.¹² In one immunocompromised person with disseminated skin lesions from *Acanthamoeba rhysodes* infection, successful treatment involved topical chlorhexidine gluconate and KTZ cream and systemic treatment with pentamidine followed by itraconazole (ITZ).³⁰ Treatment was likely successful in this case because it was instituted before spread to the CNS. Combination therapy with intravenous pentamidine, oral fluconazole, flucytosine (FCY), and sulfadiazine is recommended in people with disseminated and CNS infections.²¹ Sulfadiazine has been beneficial in treating experimental infection in mice,¹⁰ and trimethoprim-sulfonamide cured a child with meningoencephalitis after 8 weeks of therapy.²⁸ When used in combination with ITZ, 5-FCY transiently halted progression of disseminated *Acanthamoeba* infection in a person infected with human immunodeficiency virus.⁹ A dog diagnosed with *Acanthamoeba* infection should be treated with one or more of these drugs. As a first choice, and because of its CNS penetration, trimethoprim-sulfonamide could be instituted at a dosage of 30 mg/kg given every 12 hours. (See Drug Formulary, [Appendix 8](#), for additional information and dosages on the relevant drugs.)

Fig 79-4 Focal necrotizing lesion in right occipital lobe of cerebral cortex of dog with *B. mandrillaris* infection. (From Foreman O, Sykes J, Ball L, et al. 2004. Disseminated infection with *Balamuthia mandrillaris* in a dog, *Vet Pathol* 41: 506-510.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 79-5 Kidney from dog with *B. mandrillaris* infection. Small cluster of organism cysts on right and trophozoite stages (arrowheads) are accompanied by mononuclear infiltration and multinucleated giant cell (arrow; H and E stain, bar = 33 μ m). (From Foreman O, Sykes J, Ball L, et al. 2004. Disseminated infection with *Balamuthia mandrillaris* in a dog, *Vet Pathol* 41:506-510.)

For ocular surface or dermal infections in people, topical treatment with propamidine isethionate has been used; however, acquired drug resistance has developed. Chlorhexidine is the most available amebicidal compound for topical therapy and can be combined with propamidine. A standard treatment schedule has been 0.02% weight per volume (w/v) chlorhexidine digluconate in sterile isotonic saline and 0.1% w/v propamidine isethionate. The solution is applied at a decreasing frequency for a total of 6 months.²⁷ Concurrent topical antiinflammatory therapy may be needed for a brief period to control the surface inflammation caused by dying amoebae. Topical treatment with polyhexamethylene biguanide (a swimming pool amebicidal disinfectant) has also been effective, especially combined with propamidine, in treating human amoebal keratitis.^{19,32}

753

754

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 79-7 Dog kidney containing cystic stages of *B. mandrillaris* infection. Note outer undulating membrane and prominent karyosomes (Giemsa stain, bar = 15 µm). (From Foreman O, Sykes J, Ball L, et al. 2004. Disseminated infection with *Balamuthia mandrillaris* in a dog, *Vet Pathol* 41:506-510.)

79.8 PREVENTION

Dogs may be exposed to low numbers of *Acanthamoeba* organisms throughout their lifetimes. Because they are free-living amoebae, infection prevention involves avoiding access to contaminated water. Pathogenic, free-living amoebae are found more frequently in thermally enriched and polluted discharge water from industrial plants, lakes, and swimming pools.¹⁸ Nonthermally enriched water contains fewer amoebae. A 0.5% solution of sodium hypochlorite is a satisfactory aqueous disinfectant. Because *Acanthamoeba* species feed on bacteria, water sources can be screened for amoebae initially by testing for coliforms.

79.9 PUBLIC HEALTH CONSIDERATIONS

No transmission of infection between hosts is known, and infections are thought to originate solely from environmental sources.³³ However, the dog is sentinel for human infection because of common environmental exposure.

80 CHAPTER 80 Toxoplasmosis and Neosporosis

J.P. Dubey

Michael R. Lappin

80.1 TOXOPLASMOSIS

80.1.1 Etiology

Toxoplasma gondii is an obligate intracellular coccidian parasite that infects virtually all species of warm blooded animals, including people.^{93,319} Domestic cats and other Felidae are the definitive hosts that excrete oocysts. All nonfeline hosts are intermediate hosts that harbor tissue cysts. Three infectious stages have been noted: sporozoites in oocysts, tachyzoites (actively multiplying stage), and bradyzoites (slowly multiplying stage) enclosed in tissue cysts. Oocysts are excreted in feces, whereas tachyzoites and bradyzoites are found in tissues. Most isolates of *T. gondii* can be grouped into three genetic lineages that can be used in epidemiologic monitoring. The three predominant genotypes likely resulted from a single cross between two parenteral strains approximately 10,000 years ago.^{119a,319}

80.1.2 Epidemiology

The three major modes of transmission are congenital infection, ingestion of infected tissues, and ingestion of oocyst contaminated food or water (Fig. 80-1). Other minor modes of transmission include lactational,²⁷⁸ transfusion of body fluids, or transplantation of tissues or organs.^{26,93}

Toxoplasmosis and seroreactivity to *T. gondii* are more prevalent in older animals as a factor of increasing exposure with aging and in animals from a rural or feral environment that are more apt to hunt small mammals.²⁵¹ A higher frequency of disease and exposure is found in dogs or cats that are fed raw meat instead of commercial diets.^{130,131,245a} Seroprevalence is highest in older cats, and in those that are kept outdoors, are homeless, or found in shelters.^{69,140,235,294a,339a} Outdoor cats in the Bangkok metropolitan area had a relatively low infection rate, presumably because they were predominantly fed well-cooked fish and rice.³²¹ Exotic cats in zoologic gardens have a high prevalence of infection, presumably from eating raw meat diets.^{229,307,307a} *T. gondii* has also been identified as a cause of morbidity and mortality in marine mammals.¹²⁷ Presumably, these animals become infected from contaminated runoff water that enters the ocean.^{91a,244b} Mollusks or marine invertebrates may act as transfer hosts. *T. gondii* can survive in and sporulate in seawater and remain viable for at least 6 months at a temperature range of 4° to 24° C.²¹⁴ Contaminated oocysts may enter the marine environment by entering storm water drainage or sewage systems by being flushed from toilets and in open public drainage.^{119a}

80.1.2.1 Enteropithelial Life Cycle

This cycle is found only in the definitive feline host (see Fig. 80-1). Most cats are thought to become infected by ingesting intermediate hosts infected with *T. gondii*. Bradyzoites are released in the stomach and intestine

from the tissue cysts when digestive enzymes dissolve the cyst wall. Bradyzoites penetrate the epithelial cells of small intestine and initiate the five types of predetermined asexual stages (Fig. 80-2). These types, A to E, are equivalent to schizonts of other intestinal coccidia.^{314a} After an undetermined number of generations, merozoites released from type D or E form male (micro) or female (macro) gamonts, respectively. The microgamont divides and forms several biflagellate microgametes, which are released and swim to and penetrate macrogamonts.^{314a} A wall is formed around the fertilized macrogamont to form an oocyst. Oocysts are round to oval, $10 \times 12 \mu\text{m}$, and are unsporulated (uninfective) when passed in feces (Fig. 80-3). After exposure to air and moisture for 1 to 5 days, oocysts sporulate and contain two sporocysts, each with four sporozoites. Sporozoites are banana shaped, approximately $8 \times 2 \mu\text{m}$, and can survive in the oocyst for many months, even under harsh environmental conditions. These sporozoites are the infectious form of the oocyst.

756

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 80-1 Life cycle of *T. gondii*. **A**, Enteropithelial replication occurs in the cat intestine after ingestion of oocysts from fecal contamination or bradyzoites within tissue cysts. Following tachyzoite formation, some systemic spread to other tissues may occur with encystment. Ingested bradyzoites can also undergo merogony to form micro- and macrogamonts. An unsporulated oocyst is eventually formed following union of gamonts. **B**, The oocyst is excreted unsporulated in the feces and is noninfectious. It sporulates in the environment, becomes infectious, and then can be ingested by a variety of intermediate hosts. **C**, Muscle and tissue encystment occur in the intermediate host. In females infected for the first time during pregnancy, congenital infection of the fetus occurs. (Courtesy University of Georgia, Athens, Ga.)

Fig 80-2 Enteroepithelial stages of *T. gondii* in the small intestine of cats (H and E stain, $\times 1000$). **A**, Merozoite (arrow) above the epithelial cell nucleus. **B**, Type B meront (arrow). **C**, Type C (arrow) in banana-shaped merozoites. The epithelial cell nucleus (arrowhead) is hypertrophied. **D**, Two gamonts on right (arrow), each with one nucleus, and a male gamont on the left. **E**, Unsporulated oocyst in intestinal lumen.

The entire enteroepithelial (coccidian) cycle of *T. gondii* can be completed within 3 to 10 days after ingestion of tissue cysts and occurs in up to 97% of naïve cats. However, after ingestion of oocysts or tachyzoites, the formation of oocysts is delayed until 18 or more days, and only 20% of cats fed oocysts will develop patency.^{81,83,89} The differences in the life cycle that account for this delay and resistance are uncertain, but bradyzoites are probably precursors of enteroepithelial replication, allowing for more rapid development. Bradyzoites are more infective to cats as compared with oocysts because much fewer of the former are needed to establish patent infections.⁸⁸

Dogs have been infected by feeding on tissue cysts.²¹⁷ Experimentally, dogs have been fed sporulated oocysts from cat feces, which passed through into their feces for 2 days postinoculation (PI).²¹⁸ Although these dogs seroconverted, no clinical signs of infection or enteroepithelial replication occurred. Dogs ingesting cat litter would serve as potential mechanical vectors for transmission to people as they shed ingested sporulated oocysts in their stool.²¹⁸

80.1.2.2

Extraintestinal Life Cycle

The extraintestinal development of *T. gondii* is the same as it is for all hosts, including rodents, dogs, cats, and people, and is not dependent on whether tissue cysts or oocysts are ingested. After the ingestion of oocysts, sporozoites excyst in the lumen of the small intestine and penetrate intestinal cells, including the cells in the lamina propria. Sporozoites divide into two by an asexual process known as endodyogeny and thus become tachyzoites. Tachyzoites are lunate in shape, approximately $6 \times 2 \mu\text{m}$ (Figs. 80-4 and 80-5), and multiply in almost any cell of the body. If the cell ruptures, they infect new cells. Otherwise, tachyzoites multiply intracellularly for an undetermined period and eventually encyst. Tissue cysts grow intracellularly and contain numerous bradyzoites (Figs. 80-6, 80-7, and 80-8). Bradyzoites resemble tachyzoites in structure except that they are thinner and the nucleus is located at the posterior (nonconoidal) end of the parasite.

756

757

Infectious Diseases of the Dog and Cat, 3rd Edition

Biologically, bradyzoites differ from tachyzoites in that they can survive the digestive process in the stomach, whereas tachyzoites are usually killed. Tissue cysts vary in size from 15 to 60 μm and usually conform to the shape of the parasitized cell. Tissue cysts are separated from the host cell by a thin (less than 0.5 μm) elastic wall (see Fig. 80-8). Tissue cysts are formed in the central nervous system (CNS), muscles, and visceral organs and probably persist for the life of the host. Some variation in tissue tropism for cyst formation has been observed.⁸³

Tachyzoites are separated from the host cell cytoplasm by a parasitophorous vacuole (PV). One tachyzoite has divided into two progeny that are still attached at the posterior end. Note central nucleus (N), rhoptries (R), and micronemes (M) anterior to the nucleus ($\times 10,000$). (Courtesy C.A. Speer, Montana State University, Bozman, Mont.)

Toxoplasma-encysted organisms can injure the CNS of infected mice and rats, resulting in impaired learning and memory and behavioral abnormalities. *T. gondii*-infected rodents become less neophobic, leading to decreased aversion to the odor of cats.²⁴ This behavior might help ensure that rodents would be eaten by cats and the life cycle would be preserved; however, the neurologic signs were transient and corresponded with peak development of tissue cysts in the brain.¹⁶⁷ Wild mice (*Mus domesticus*) have been shown to transmit the infection congenitally at a rate of 75% or greater.²³⁴ This may serve as a mechanism, other than involving cats, of maintaining the infection in nature.

80.1.2.3

Congenital Transmission

Parasitemia during pregnancy can cause placentitis followed by spread of tachyzoites to the fetus. In people or sheep, congenital transmission usually occurs when the woman or ewe becomes initially infected during pregnancy. High levels of congenital transmission have also been observed in natural urban populations of mice,²³⁴ which may help maintain infection in these rodents in the absence of cats. Bitches fed sporulated

757

758

Infectious Diseases of the Dog and Cat, 3rd Edition

oocysts at 56, 40, and 32 days of gestation showed evidence of congenital infection and aborted.³⁵ The prevalence of congenital toxoplasmosis in dogs is thought to be less common than that in sheep and goats. Many kittens born to queens infected with *T. gondii* during gestation became infected transplacentally or via suckling as tachyzoites are shed in milk.* Clinical illness was common, varying with the stage of gestation at the time of infection, and some newborn kittens shed oocysts.¹⁰⁸ Lactational or transplacental transmission may predispose kittens to the development of ocular toxoplasmosis.²⁸⁰

Ferguson, Oxford University, England.)

* References: 44, 96, 106, 108, 278, 297.

80.1.3 Pathogenesis

The type and severity of clinical illness with *T. gondii* infections depend on the degree and localization of tissue injury. Tachyzoites are the invasive asexual forms of the parasite that require intracellular existence for replication and survival. All cell types appear susceptible. Cell necrosis is caused by the intracellular growth of *Toxoplasma*. *T. gondii* does not produce a toxin. In infections acquired after the ingestion of tissue cysts or oocysts, initial clinical signs are caused by the necrosis of intestine and associated lymphoid organs caused by tachyzoites. Enteroepithelial stages in the cat appear to have unique antigens.³²⁵ Antibodies of the IgA class, specific for *T. gondii* enteroepithelial stages, increase in the intestinal secretions as part of the immune response to terminate the phase of intestinal replication.^{259,294} *T. gondii* also spreads to extraintestinal organs via blood or lymph, and focal necrosis may develop in many organs (Fig. 80-9). The brain, liver, lungs, skeletal muscle, and eyes are common sites of initial replication and chronic persistence of infection. The clinical outcome is determined by the extent of injury to these organs, especially vital organs such as the heart, lung, liver, and adrenal glands. Although acute disseminated infections can be fatal, the host often recovers. Interferon (IFN)- γ -dependent cell-mediated immunity and humoral factors are important in resistance to *Toxoplasma* encephalitis as studied in experimentally infected rodents.³²³ Resistance is caused by inter-play among T and B lymphocytes, IFN- γ -producing non-T cells, microglia, astrocytes, and dendritic cells. The classical complement pathway of cats is not activated after exposure to *T. gondii*,¹⁷⁸ a feature that appears unique to the definitive host.

Fig 80-9 Liver of a kitten congenitally infected with *T. gondii*. Numerous white yellowish areas of discoloration are caused by necrosis produced by tachyzoites.

By approximately the third week after infection, tachyzoites begin to disappear from visceral tissues and may localize as tissue cysts (as bradyzoites). This phase is associated with a systemic immune response, which inhibits the parasitemia. These tissue cysts may persist in the host for life. Tissue cysts may rupture, and released bradyzoites may initiate a clinical relapse during immunosuppression, such as with antitumor or glucocorticoid therapy (Fig. 80-10). The mechanism of reactivation is not known.

The reason why some infected dogs or cats develop clinical toxoplasmosis while others remain well is not fully understood. Age, sex, host species, strain of *T. gondii*, number of organisms, and stage of the parasite ingested may account for some of the differences. Postnatally acquired toxoplasmosis is generally less serious than is prenatally acquired infection. Stress may also aggravate *T. gondii* infection. Concomitant illness or immunosuppression may make a host more susceptible because *T. gondii* proliferates as an opportunistic pathogen. Clinical toxoplasmosis in dogs is often associated with canine distemper or other infections, such as ehrlichiosis, or with glucocorticoid therapy or vaccination with live attenuated vaccines.^{122a} In some cases, however, predisposing disorders cannot be found. Historically, the prevalence of canine toxoplasmosis has decreased with the routine use of canine distemper vaccines.⁹⁸ Some cases of clinical feline toxoplasmosis have been observed concomitantly with glucocorticoid or cyclosporin therapy, hematotropic mycoplasmal infection (haemobartonellosis), feline leukemia virus (FeLV) and immunodeficiency virus (FIV) infections, and feline infectious peritonitis.* In one serosurvey of urban stray cats, cats infected with FIV were more likely to have seropositive test results for *T. gondii*, whereas no association with concurrent FeLV infection was found.⁷⁵

Preexisting FIV infection can produce more severe *Toxoplasma* infection in cats that are subsequently challenged with FIV.^{65,197} FIV-infected cats that were subsequently co-infected with *T. gondii* had suppressed CD4+ and CD8+ lymphocyte expression of interleukin (IL)-2, IL-6, IFN- γ and IL-12 when compared with cats infected with *T. gondii* alone.²⁰⁷ IL-10 levels were increased in FIV-infected cats before and after infection

Infectious Diseases of the Dog and Cat, 3rd Edition

with *T. gondii* and may have suppressed the T1 helper cytokine response to *T. gondii* infection. In contrast to these experiments, experimental FIV and FeLV infections in cats did not produce reactivated or more severe acute infections in cats already or simultaneously inoculated with *T. gondii*.^{194,199,268} Regardless of the difference in these experimental studies or which infection precedes the other, clinically, cats with FIV and *T. gondii* co-infections are more difficult to treat effectively (see sections to follow).

758

759

Fig 80-10 Tachyzoites and tissue cysts in section of brain (immunohistochemical stain).

IL-6 activity is greatly elevated in cats with uveitis suspected to be a result of their *Toxoplasma* infection,¹⁹⁶ and cats with toxoplasmosis have circulating *T. gondii*-containing immune complexes²⁰⁰ that may play a role in development of ocular toxoplasmosis. Feline herpesvirus 1 and *Bartonella henselae* co-infections failed to activate ocular toxoplasmosis in congenitally infected kittens.²⁷⁹ Toxoplasmosis has been associated with dissemination and mortality in cats and dogs receiving immunosuppression with cyclosporine.^{1,26,341b} Therefore animals to receive such therapy should be prescreened by serologic testing for the risk of reactivating a chronic infection.

* References: 21, 65, 95, 96, 157, 210, 260, 330.

80.1.4 Clinical Findings

80.1.4.1 Cats

Naïve cats ingesting bradyzoites from tissues can develop self-limiting, small-bowel diarrhea as a manifestation of enteroepithelial replication. Otherwise, this phase of the illness, which lasts up to 10 days, can be clinically silent and unimportant. Immunosuppressed cats can have simultaneous systemic manifestations with extraintestinal spread of tachyzoites. However, clinical toxoplasmosis from systemic spread is most severe in transplacentally or lactationally infected kittens because tachyzoite replication can

Infectious Diseases of the Dog and Cat, 3rd Edition

be overwhelming.^{96,108,117} Affected kittens may be stillborn or may die before weaning. Kittens may continue to suckle until death. Clinical signs reflect inflammation of the liver, lungs, and CNS (Fig. 80-11). Lethargy, depression, hypothermia, and sudden death can occur. Affected kittens may have an enlarged abdomen because of enlarged liver and ascites. Encephalitic kittens may sleep most of the time or cry continuously. Kittens born to infected queens develop chorioretinitis, sometimes in the absence of other signs of clinical illness.²⁸⁰ Some kittens develop transient concurrent anterior uveitis.

Clinical signs in older cats can be the result of spread of tachyzoites following initial acute exposure or reactivation of a chronic encysted infection by release of bradyzoites following immunosuppression. Anorexia, lethargy, and dyspnea caused by pneumonia have been commonly recognized features of postnatal toxoplasmosis (Table 80-1). Other clinical signs include persistent or intermittent fever, anorexia, weight loss, icterus caused by hepatitis or cholangiohepatitis, vomiting, diarrhea, abdominal effusion, hyperesthesia on muscle palpation, stiffness of gait, shifting leg lameness, neurologic deficits, dermatitis, and death.^{95,159,202,4a,225a} In 100 cats with histologically confirmed toxoplasmosis, clinical syndromes were diverse, but infection of pulmonary (97.7%), CNS (96.4%), hepatic (93.3%), pancreatic (84.4%), cardiac (86.4%), and ocular (81.5%) tissues were most common.⁹⁵ Clinical signs may be sudden or have a slow onset. The disease may be rapidly fatal in some cats with severe respiratory or CNS signs. Anterior or posterior uveitis involving one or both eyes is common.^{*} Iritis, iridocyclitis, or chorioretinitis can occur alone or concomitantly. Aqueous flare, keratic precipitate, lens luxation, glaucoma, and retinal detachment are common manifestations of uveitis. Chorioretinitis, which can be unifocal or multifocal, may occur in both tapetal and nontapetal areas (Fig. 80-12) (see Toxoplasmosis, Chapter 93). Ocular toxoplasmosis occurs in some cats without polysystemic clinical signs of disease. In experimental *T. gondii* in cats, those infected concurrently with FIV developed severe pneumonitis and hepatitis, whereas those not infected with FIV developed multifocal chorioretinitis and anterior uveitis.^{63,65} Neurologic and ocular manifestations that occur in the absence of other systemic signs are more common with reactivated infection rather than acute infection. Nodular pyogranulomatous dermatitis has developed in dogs and cats with disseminated infection resulting from immunosuppressive drug therapy.^{4a,205a}

80.1.4.2

Dogs

Clinical signs may be localized in respiratory, neuromuscular, or gastrointestinal (GI) systems, or they may be caused by generalized infection.^{93,98} The neurologic form of toxoplasmosis may last for several weeks without involvement of other systems, whereas severe disease involving the lungs and liver may kill dogs within a week.⁹³ Generalized toxoplasmosis is seen mostly in dogs younger than 1 year and is characterized by fever, tonsillitis, dyspnea, diarrhea, and vomiting. Icterus usually results from extensive hepatic necrosis.²⁸⁶ Myocardial involvement is usually subclinical, although arrhythmias and heart failure may develop as predominant findings in some dogs. Occasionally, there is dermatitis.^{341b}

The most dramatic clinical signs in older dogs have been associated with neural and muscular systems.¹⁵³ Neurologic signs depend on the site of lesion in the cerebrum, cerebellum, or spinal cord. Seizures, cranial nerve deficits, tremors, ataxia, and paresis or paralysis may be seen. Dogs with myositis may initially show abnormal gait, muscle wasting, or stiffness. Paraparesis and tetraparesis may rapidly progress to lower motor neuron paralysis. Canine toxoplasmosis is clinically similar to *Neospora caninum* infection, which was previously confused with toxoplasmosis (see Neosporosis later in this chapter).²⁶⁶ Canine CNS toxoplasmosis may occur concurrently or be predisposed by canine distemper virus infection.^{68,98} Although these diseases are similar, toxoplasmosis appears to be more prevalent in cats and neosporosis more prevalent in dogs.

Infectious Diseases of the Dog and Cat, 3rd Edition

Only a few reports have been submitted of ocular lesions associated with toxoplasmosis in dogs. Retinitis, anterior uveitis, iridocyclitis, ciliary epithelium hyperplasia, and optic nerve neuritis have been noted (see Toxoplasmosis, [Chapter 93](#)).

80.1.5 Diagnosis

80.1.5.1 Clinical Laboratory Findings

Routine hematologic and biochemical parameters may be abnormal in cats and dogs with acute systemic toxoplasmosis. Nonregenerative anemia, neutrophilic leukocytosis, lymphocytosis, monocytosis, and eosinophilia are most commonly observed. Leukopenia of severely affected cats may persist until death and is usually characterized by an absolute lymphopenia and neutropenia with an inappropriate left shift, eosinopenia, and monocytopenia. In experimentally infected cats, neutropenia and lymphopenia persist for 5 to 12 days. Leukocytosis was seen in the recovery phase of illness.¹⁹⁹ Lymphocyte counts greater than 7000 cells/ μ l were common from 28 to 154 days after primary inoculation.¹⁹⁹ Secondary exposure of cats to *T. gondii* did not result in significant changes in leukocyte numbers.¹⁹⁹

Biochemical abnormalities during the acute phase of illness include hypoproteinemia and hypoalbuminemia. Hyperglobulinemia has been detected in some cats with chronic toxoplasmosis.²⁰² Marked increases in serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) activities have been noted in animals with acute hepatic and muscle necrosis. Dogs generally have increased serum ALT and alkaline phosphatase (ALP) activities with hepatic necrosis, but this occurs less frequently in cats. Serum creatine kinase activity is also increased in cases of muscle necrosis. Serum bilirubin levels have been increased in animals with acute hepatic necrosis, especially cats that develop cholangiohepatitis or hepatic lipidosis. Cats or dogs that develop pancreatitis may show increased serum amylase and lipase activities, although these are inconsistent. Cats often show protei-nuria and bilirubinuria. Cats with pancreatitis may have reduced serum total calcium with normal serum albumin concentrations.⁹⁵

80.1.5.2 Cytology

Tachyzoites may be detected in various tissues and body fluids by cytology during acute illness (see [Fig. 80-4](#)). They are rarely found in blood, cerebrospinal fluid (CSF), fine needle aspirates, and transtracheal or bronchoalveolar washings^{36,128,155} but are more common in the peritoneal and thoracic fluids of animals developing thoracic effusions or ascites.

Inflammatory changes are usually noted in body fluids. In suspected feline toxoplasmosis of the nervous system, CSF protein levels were within reference ranges to a maximum of 149 mg/dl, and nucleated cells were a maximum of 28 cells/ml.²⁰² Lymphocytes predominate, but a mixture of inflammatory cells may be found.

80.1.5.3 Radiology

Thoracic radiographic findings, especially in cats with acute disease, consist of a diffuse interstitial to alveolar pattern with a mottled lobar distribution ([Fig. 80-13](#)).²⁹⁶ Diffuse symmetric homogeneous increased density caused by alveolar coalescence has been noted in severely affected animals. Mild pleural effusion

Infectious Diseases of the Dog and Cat, 3rd Edition

can be present. Abdominal radiographic findings may consist of masses in the intestines or mesenteric lymph nodes or homogeneous increased density as a result of effusion. Loss of contrast in the right abdominal quadrant can indicate pancreatitis. Abdominal ultrasonographic changes can indicate organ or tissue enlargement as a result of inflammation or granuloma formation. Lesions within the CNS may be detected by myelography, computed tomography, or magnetic resonance imaging.

760

761

80.1.5.4

Fecal Examination

Despite the high prevalence of serum antibodies in cats worldwide, the prevalence of *T. gondii* oocysts in feces is low. In the United States, approximately 1% of cats shed oocysts on any given day.^{93,160,314} Because cats usually shed *T. gondii* oocysts for only 1 to 2 weeks after their first exposure, oocysts are rarely found in routine fecal examination. Moreover, cats are usually not clinically ill and do not have diarrhea during the period of oocyst shedding. Although cats are considered immune to reshedding of oocysts, they may shed a few oocysts after rechallenge with different strains more than 6 years later.⁸⁰ Cats that are immune have partial asexual development of *T. gondii* in their intestines compared with complete development cycle in naïve cats.⁶⁶ Immunosuppression with high dose (10 to 80 mg/kg, daily by mouth or intramuscularly (IM) once a week) of prednisolone will cause chronically infected cats to reexcrete oocysts, whereas a lower dose (5 mg/kg IM for 4 weeks) will not.¹⁹⁵

T. gondii oocysts in feline feces are morphometrically indistinguishable from oocysts of *Hammondia hammondi*, *Besnoitia orcytofelisi* and *Besnoitia darlingi*, which also occur in cats (see [Chapter 81](#)). Oocysts of these coccidians can be differentiated only by ultrastructural and molecular examination, sporulation, and subsequent animal inoculation.^{124,316} If 10 µm-sized oocysts are found, they should be considered to be *T.*

Infectious Diseases of the Dog and Cat, 3rd Edition

gondii until proved otherwise. Because of the infectious nature of this organism, further inoculations should be attempted only in a diagnostic laboratory with competence in this procedure.

Because of their small size, oocysts of *T. gondii* are best demonstrated by centrifugation using Sheather's sugar solution. See [Chapter 70](#) for a discussion of this technique. Examine 1 to 2 drops removed from the meniscus at low power ($\times 100$) magnification. *T. gondii* oocysts are approximately one fourth the size of *Isospora felis* and one eighth the size of *Toxocara cati* ([Fig. 80-14](#)).

80.1.5.5

Serologic Testing

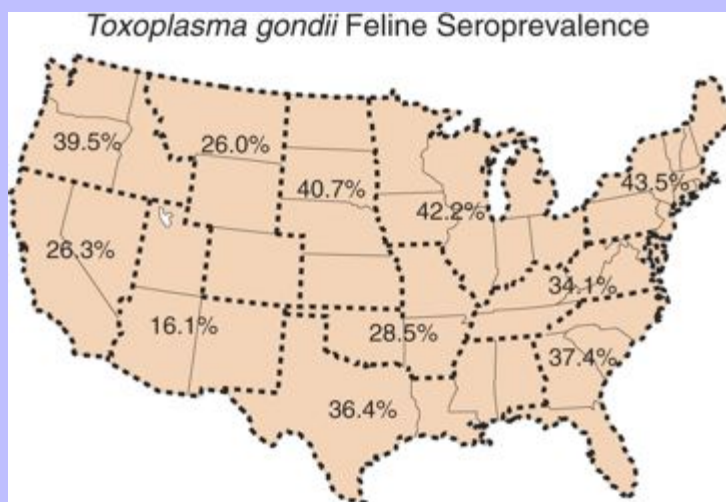

Once infected, animals harbor toxoplasmic tissue cysts for life, which stimulates a long-term humoral immune response in infected adults. Serologic surveys indicate that *T. gondii* infections are prevalent worldwide. Approximately 30% of cats and dogs in the United States have *T. gondii* antibodies ([Fig. 80-15](#)).^{69,93,339} The prevalence of seropositivity increases with age of the cat or dog because of the chance of exposure rather than susceptibility.

Fig 80-14 Unsporulated oocysts of *T. gondii* (T), *I. felis* (F), and *I. rivolta* (R), and an egg of the roundworm *T. cati* (C) in a flotation of feline feces (unstained, $\times 410$). (From Dubey JP. 1976. A review of *Sarcocystis* of domestic animals and of other coccidia of cats and dogs, *J Am Vet Med Assoc* 169:1061–1078. Reprinted with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 80-15 Seroprevalence of *T. gondii* in cats in the continental United States. (Modified from Voltaire MR, Radecki SV, Lappin MR. 2005. Seroprevalence of *Toxoplasma gondii* antibodies in clinically ill cats in the United States, *Am J Vet Res* 66:874–877.

Multiple serologic tests for the detection of antibodies have been used in the diagnosis of toxoplasmosis (Table 80-2). The use of these tests in cats has been reviewed.¹⁸⁸ No single serologic assay exists that can definitively confirm a diagnosis of toxoplasmosis. The Sabin Feldman dye test is highly sensitive and specific for human toxoplasmosis but not necessarily for cats. Moreover, the test is too technical to perform in diagnostic laboratories, and it uses live *T. gondii*.

The indirect fluorescent antibody (FA) technique is comparable to the dye test but does not require live antigen. Some false positive polar staining that can occur with the indirect FA test has been attributed to Fc receptors on the surface of *T. gondii* tachyzoites that nonspecifically bind Ig. The indirect FA can be adapted to detect IgM, IgG, or IgA using whole or immunoblotted antigen (see later discussion).³²⁴

761

762

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 80-2 Serologic Tests for Feline Toxoplasmosis

TEST	EARLIEST DETECTION (WEEKS)	ANTIBODY CLASS	TITER (LEAST SIGNIFICANT LEVEL OF REACTIVITY ^a)	GUIDELINES FOR ACTIVE INFECTION
Sabin-Feldman	1–2	IgG, IgM	16	Fourfold rise over 2–3wk
Indirect FA				
IgM	1–2	IgM	64	Titer > 1:64 with or without concurrent IgG
IgG	2	IgG	64	Fourfold rise over 2–5wk
Indirect hemagglutination	2	IgG	64	Fourfold rise over 2–3wk; insensitive
Latex agglutination	2	IgG	64	Fourfold rise over 2–3wk
Modified Agglutination Test				
Acetone-fixed antigen	1–2	IgG	100	Fourfold rise over 2–3wk or high titer with low formalin-fixed; titers remain high for 3 mo
Formalin-fixed	2	IgG	—	Fourfold rise over 2–3wk; titers remain high for years
ELISA				
IgM	1–2	IgM	64	Titer > 1:64 with or without concurrent IgG
IgG	2	IgG	64	Fourfold rise over 2–3wk

For additional information on test availability, see Laboratory Listings, [Appendix 5](#). Modified from references 211 and 188.

a Titers may vary between laboratories on the basis of individual methodologies. Whenever comparisons are being made, both samples should be processed at the same time by the same laboratory.

Agglutination tests have the advantage of being species independent and are available in commercial kits that have been developed for use in people. The indirect hemagglutination (IHA) test (TMP test, Wampole Labs, Carter Wallace Inc., Cranbury, N.J.) does not require live antigen but is less sensitive compared with the dye test, indirect FA test, and enzyme-linked immunosorbent assay (ELISA).²⁰⁴ The main drawback is that it primarily measures IgG and is usually not positive during acute infection.

The latex agglutination test (LAT) (Toxo test, Eiken Chemical Co., Tokyo, Japan; Synkit Inc., Chatsworth, Calif.) is somewhat more sensitive for serologic screening; however, it cannot be used to distinguish immunoglobulin classes. The modified agglutination test (MAT) (Toxo Screen DA, Biomerieux, Marcy l'Etoile, France) detects only IgG but is extremely sensitive compared with the other available assays.²²⁶ The MAT has been improved in its sensitivity and specificity in distinguishing acute and chronic *Toxoplasma* infections in people and cats by using acetone- or methanol-fixed and formalin fixed trophozoites, respectively.¹⁰⁹ Antibodies to acetone fixed antigen are elevated only during acute (under 3 months)

Infectious Diseases of the Dog and Cat, 3rd Edition

infection, whereas antibodies to formalin fixed antigen may remain high for several years.¹²⁶ For additional information on commercial laboratory testing and test kits, see [Appendices 5](#) and [6](#), respectively.

ELISA, with and without immunoblotting, has been adapted for the detection of IgM, IgG, and IgA class anti-bodies against *T. gondii* in feline sera.* ELISA methods are as sensitive as is indirect FA³¹ and more sensitive compared with LAT or IHA. As a result, ELISA may be less specific at lower dilutions of sera. Immunoblots of separated antigens, reacted with an animal's sera and ELISA, can be used to identify specific target antigens and improve specificity. Comparison of antigen recognition patterns by serum from infected queens and their kittens by immunoblot aids in the diagnosis of neonatal toxoplasmosis.⁴⁴ ELISA has also been compared with indirect FA and IHA tests in the kinetics of the humoral immune response in dogs experimentally infected with *T. gondii*.³⁰⁵ Specific IgM was detected from day 7 PI and began decreasing by day 27 PI, with the ELISA showing slightly earlier and longer detection of IgM. Specific IgG was detected from day 7 PI throughout the 62 days of the study. IgM may constitute an indicator of recent or active infection in dogs.

80.1.5.5.1

Investigational Assays

An ELISA incorporating a recombinant-produced immunodominant surface antigen (SAG)1 and P30 was developed to measure antibodies in experimentally infected cats and in experimentally and naturally infected dogs.^{181,305,306} The antigen is stage specific, being secreted by tachyzoites, and might be of consideration in the diagnosis of active clinical infections.¹⁸¹ Use of recombinant SAG2 in ELISA allowed for discrete detection of experimentally infected cats with the same specificity as that for the LAT.^{168,169} The test has also been adapted to an immunochromatographic method.¹⁶⁸ The SAG2 ELISA appears to be specific because no cross-reaction occurred between sera of *Neospora*- and *Toxoplasma*-infected mice.¹⁸¹ In studies in people, IgG binding avidity for *Toxoplasma* antigens is low soon after primary antigenic challenge.²⁰⁸ The IgG avidity increases during subsequent months of infection from chronic humoral immune stimulation. Assays that quantitate the degree of antibody avidity might be used as a single assay to discriminate between recently acquired and chronic encysted infections.

80.1.5.5.2

Antibody Kinetics

Soon after inoculation, approximately 80% of experimentally inoculated cats develop detectable IgM titers; 100% develop detectable IgA and IgG titers. Chronic persistence of high IgG titers thereafter merely reflects continued presence of *Toxoplasma* antigen. Documentation of a positive IgM titer or an increasing IgG or IgA titer (fourfold) can verify recent infection but not necessarily oocyst shedding.²⁵⁵ Some cats do not develop detectable IgM titers, and positive IgM titers can persist in some cats for months to years after infection. Persistent IgM titers have been observed in experimentally infected cats that were co-infected with FIV, after repeat exposure to *T. gondii*, or from exposure to glucocorticoids. Thus this antibody class does not accurately predict the oocyst-shedding period. Some cats may not develop IgG titers to *T. gondii* for 4 to 6 weeks, well after the completion of the oocyst-shedding period. Following the initial detection of IgG or IgA antibodies in serum, maximal titers are often reached in 2 to 3 weeks, leaving a narrow window for the documentation of an increasing titer.¹⁸⁹ Thus failure to document a changing IgG titer does not exclude a diagnosis of recent infection. Optimally, sequential serum samples should be assessed at the same time in the assay to avoid interassay variation. After experimental

Infectious Diseases of the Dog and Cat, 3rd Edition

inoculation of cats, IgG titers greater than 1:30,000 are commonly detected by MAT for 6 years after inoculation; thus high IgG titers do not prove recent or active infection.¹⁰⁹ Some seropositive cats will shed lower numbers of oocysts after oral inoculation with *T. gondii*, and therefore the presence of serum antibodies does not prove intestinal immunity.⁸⁰ Because of these findings, the measurement of serum antibodies in healthy cats cannot accurately predict the oocyst-shedding period. IgG in kittens born to chronically infected queens is transferred in colostrum and persists for 8 to 12 weeks after birth.²⁵⁷

80.1.5.5.3

Public Health Risk Assessment

In general, for *assessing human health risk*, serologic test results from healthy cats can be interpreted as follows:

1. A seronegative cat is not likely currently shedding oocysts but will likely shed oocysts if exposed to the organism for the first time. This cat poses the greatest public health risk.
2. An IgG test seropositive cat is probably not currently shedding oocysts and is less likely to shed oocysts if reexposed or immunosuppressed. Recommendations are that potential exposure to oocysts be minimized.

Following initial exposure, IgM levels increase followed by increases in IgG levels. An increased IgM titer by itself may indicate very recent exposure and infection correlating with a period of oocyst shedding. Any concurrent increase in IgG would indicate that the shedding period had already passed and would also be expected in a chronic reactivated infection.

80.1.5.5.4

Disease Assessment

A *tentative antemortem diagnosis* of clinical toxoplasmosis in dogs or cats can be based on the following combination of serology and clinical parameters:

1. Serologic evidence of recent or active infection consisting of high IgM titers, or fourfold or greater, increasing or decreasing, IgG or other antibody titers (after treatment or recovery, or both)
2. Exclusion of other causes of the clinical syndrome
3. Beneficial clinical response to an anti *Toxoplasma* drug

Because antibodies occur in the serum of both healthy and diseased cats, results of these serologic tests do not independently prove clinical toxoplasmosis. Antibodies of the IgM class are commonly detected in the serum or aqueous humor of clinically ill or FIV infected cats but not healthy cats, and they may be a better marker of clinical disease than IgG or IgA.^{197,199,202,203} *T. gondii*-specific IgM is occasionally detected in the serum of cats with chronic or reactivated infection and does not always correlate with recent exposure.

Cats with uveitis or meningoencephalitis often have seropositive test results for other ocular pathogens such as FeLV, FIV, and feline infectious peritonitis virus. These co-infections may be responsible for immunosuppressing cats and allowing *Toxoplasma* infections to reactivate. Given that these infections have been associated with uveitis, positive serologic tests may also confuse exact determination of the

Infectious Diseases of the Dog and Cat, 3rd Edition

underlying cause. For this reason, determination of *Toxoplasma*-specific antibodies in aqueous and CSF has been recommended.

80.1.5.6 Aqueous Humor and Cerebrospinal Fluid Assessment

In dogs and cats with toxoplasmic encephalitis or uveitis, both protein and leukocytes may be increased in CSF or aqueous humor.²⁰⁵ Cells are usually a mixed population of large and small mononuclear cells and neutrophils; the organism is rarely seen.

When assessing specific antibodies in aqueous humor or CSF, those produced locally must be differentiated from those passively diffusing across a damaged vascular barrier. As with serologic testing for other CNS or ocular infections, a comparison of antibody in CSF or aqueous humor can be made with that of serum for *Toxoplasma* and another nonocular infectious agent such as calicivirus.^{161,205} (See also Immunologic Testing, Canine Distemper, [Chapter 3](#).) This coefficient is calculated by the following:

$$\text{Antibody coefficient} = \frac{\text{Toxoplasma-specific antibody aqueous (or CSF)}}{\text{Toxoplasma-specific antibody serum}} \times \frac{\text{Other agent-specific antibody serum}}{\text{Other agent-specific antibody aqueous (or CSF)}}$$

Titers or equivalent numerical values from ELISA or other assays are substituted in the formula.

Antibody coefficient values greater than 1, and especially greater than 8, are considered stronger evidence for local production of *Toxoplasma* antibody and associated infection compared with nonselective leakage from inflammation.²⁰⁵ Ideally, to avoid variables inherent in test sensitivity, the same methodologies (e.g., ELISA, indirect FA, agglutination) should be employed in the assays for both infectious agents. For examination of CSF and CNS infection, the other agent should be a pathogen that is likely to have a serum titer such as a vaccine antigen but does not cause CNS infection. Calicivirus is also suitable for this purpose in cats. In some experimentally infected cats, high *T. gondii*-specific IgG antibody coefficients can be detected for 3 to 4 months after inoculation.⁵⁰ Caution must be exercised in assuming that this increased value always correlates with CNS or ocular replication of organisms. In some cats previously exposed to *T. gondii*, nonspecific immune stimulation resulted in an increased antibody coefficient (greater than 1) on CSF or aqueous humor.²¹⁷ Analysis of IgM in aqueous humor shows better discrimination in cats with uveitis.²⁰⁵

Transient local production of *T. gondii*-specific antibodies in the eyes (IgG and IgA) and CNS (IgG) of cats has been documented after primary and secondary experimental inoculation.^{50,191,210,247} Local production of *T. gondii*-specific IgM has been detected only in client owned, naturally exposed cats with uveitis or clinical signs of encephalitis, suggesting that this antibody class in CSF or aqueous humor may be a marker of

763

764

clinical disease.^{188,205} *T. gondii*-specific antigens can be detected in the aqueous humor of some cats with uveitis.^{205,217}

80.1.5.7 Organism Detection

Identification of *T. gondii* in body tissues or fluids is definitive for infection. The presence of *T. gondii* can be confirmed by bioassays in animals or cell culture inoculation. Laboratory mice are the most susceptible animals. Homogenized suspensions of tissues or body fluids obtained at necropsy or biopsy may be used to infect laboratory mice or tissue culture. Cleaned, sporulated oocysts obtained from feces similarly may be

Infectious Diseases of the Dog and Cat, 3rd Edition

used to infect mice. Generally, mice are inoculated subcutaneously or intraperitoneally (IP). Beginning 4 to 6 days PI, peritoneal exudates of mice are examined for tachyzoites of *T. gondii* in IP inoculated mice. Tissue cysts are present 4 to 6 weeks PI mostly in neural tissue. *Toxoplasma* antibodies in mice have developed by 6 weeks PI and can be demonstrated by any one of the serologic tests mentioned. Lack of parasite demonstration does not mean that the mice are not infected with *T. gondii*, and serologic verification is necessary.

ELISAs that detect *T. gondii* antigen, both free and bound in immune complexes, have been studied in naturally and experimentally infected cats.^{200,201} Clinically ill cats and those with ocular involvement were more likely to have immune complexes in serum. Although this finding may have a role in disease development, the detection of circulating antigen does not confirm that *T. gondii* is responsible for clinical illness in a given animal. Research is being conducted in cats with acute *Toxoplasma* infections to clinically evaluate detection in blood of two antigens (H4 and P18) known to be only secreted by tachyzoites.^{47,162}

Polymerase chain reaction (PCR) can be used to verify the presence of *T. gondii* in biologic specimens.^{*} PCR was more sensitive than the mouse inoculation bioassay was in detecting infection in the blood of experimentally infected cats.⁴¹ The PCR results were positive for the entire time period after primary challenge up to 140 days and after rechallenge. Therefore, being so sensitive, it can detect infected cats but cannot distinguish whether they have acute or chronic subclinical encysted infection. PCR has been performed to detect *T. gondii* in the blood of people with acute toxoplasmosis.¹⁵⁰ False negative results occur, and chronically infected people may not be identified. PCR followed by restriction analysis can also be used to determine genotypes of infecting strains.¹⁶⁶ PCR has detected *T. gondii* in the intestine¹³² and aqueous humor³⁸ of experimentally infected cats. In the aqueous humor, *T. gondii* was detected transiently by PCR after primary and secondary inoculation of cats.^{40,190} The organism was commonly identified before the detection of specific antibody in the aqueous humor of cats with and without uveitis. In client owned, naturally exposed cats, the organism was detected in the aqueous humor from 8 of 43 cats with uveitis and 2 of 23 healthy cats.^{40,190} Because *T. gondii* can be detected without the clinical signs of uveitis, positive PCR results in aqueous humor do not prove that the ocular signs are from toxoplasmosis. A multiplex PCR was developed that can detect and distinguish between *Neospora* or *Toxoplasma* DNA in CSF, skeletal muscle, or neural tissue of cats and dogs.³⁰¹

* References: 41, 170, 190, 231, 318.

80.1.6 Pathologic Findings

80.1.6.1 Cats

The gross and microscopic findings may be similar to those seen in dogs; however, in feline toxoplasmosis, necrosis is predominantly in the liver (see Fig. 80-9), mesenteric lymph nodes, pancreas, and lungs.^{95,117} CNS lesions are similar to those found in dogs. Granulomas may be present in intestines and mesenteric lymph nodes. Tissue cysts in naturally infected cats have always been identified as *Toxoplasma* and not *Neospora*. Cholangiohepatitis, found in cats infected with *Toxoplasma*, has not been reported in any other host. The bile ducts are hyperplastic and plugged with desquamated bile duct epithelium and exudate. *T. gondii* schizonts (not tachyzoites) were seen in the biliary epithelium in both naturally occurring and experimentally induced disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

80.1.6.2 Dogs

Grossly, necrosis is the predominant lesion, particularly in the brain, lung, liver, and mesenteric lymph nodes.⁹⁸ Pulmonic lesions consist of gray white nodular foci up to 5 mm in diameter and are found in the subpleura and in the parenchyma. The bronchial lymph nodes are often enlarged and necrotic. Grossly visible necrotic foci are also seen in pancreas, liver, kidneys, and spleen. Multiple ulcers up to 10 mm in diameter are observed in the stomach and small intestines. In the CNS, areas of discoloration and necroses up to 12 mm in diameter and cerebellar atrophy have been observed.

Myositis involving the muscles of the limbs has been observed in dogs with *T. gondii* infections. The affected muscles are pale and reduced in mass and, in severe, chronic cases, are grossly replaced by connective tissue. Fibrosis and scarring are usually not as prominent as those occurring with neosporosis (see later discussion).

Microscopically, pulmonic lesions consist of fibrinous exudation and necrosis involving alveolar walls, blood vessels, and bronchioles. The alveolar lumina are filled with fibrin and occasionally with lymphocytes, neutrophils, and eosinophils. The alveolar lining and terminal epithelial cells are hypoplastic and infiltrated with lymphocytes, plasma cells, and multinucleated giant cells. Necrosis, the predominant muscular lesion, involves myofibers, small blood vessels, and surrounding connective tissues. Necrotic myofibers are replaced by fibrosis. Neural lesions consist of necrosis, gliosis, and vasculitis and are characteristic of multifocal nonsuppurative meningoencephalomyelitis. Lesions seen early in blood vessels consist of endothelial cell proliferation, necrosis, and perivascular cuffing. Neuronal necrosis, mild malacia, and some astrogliosis may be seen. Multifocal leptomeningeal infiltrates of macrophages, plasma cells, and some lymphocytes and neutrophils are found. In dogs with *T. gondii* polymyositis, noninflammatory degenerative changes are observed in peripheral nerves and nerve roots. Immunoperoxidase staining can be used to demonstrate *T. gondii* definitively in tissues to distinguish it from *N. caninum*. Electron microscopy can also be used for this purpose.³¹⁵

80.1.7 Therapy

Available drugs usually suppress replication of *T. gondii* and are not completely effective in killing the parasite. Dosages for these drugs are summarized in [Table 80-3](#).

Clindamycin is the drug of choice for treating clinical toxoplasmosis in dogs and cats.^{147,202} Because of clindamycin's good intestinal absorption, oral and parenteral dosages are similar. Clindamycin dosages for treating toxoplasmosis are greater than those for treating anaerobic infections for which the drug is marketed.

Clinical signs of systemic illness usually begin to resolve within 24 to 48 hours after institution of therapy. Appetite improves, hyperesthesia disappears, and fever usually subsides. Lower motor neuron deficits and muscle atrophy may take weeks to resolve in animals with polymyositis. Clindamycin has been effective in crossing the blood brain and blood vascular barriers in *Toxoplasma* infected animals and people. Neurologic deficits improve, but signs may not totally resolve because of permanent damage caused by CNS inflammation. Active chorioretinitis generally subsides within 1 week. Some cases of anterior segment inflammation thought

to be from toxoplasmosis have resolved with the administration of clindamycin alone.^{49,202} However, because intraocular inflammation commonly leads to lens luxation and glaucoma, cats with anterior segment inflammation should be treated with topical, oral, or injectable glucocorticoids (see Toxoplasmosis, [Chapter](#)

764

765

Infectious Diseases of the Dog and Cat, 3rd Edition

93). Antiinflammatory doses of glucocorticoids are not likely to exacerbate systemic disease, although treating first with topical antiinflammatory therapy in conjunction with systemic clindamycin is better.^{62,195} Clindamycin, given by itself early in the course of acute experimental infection of cats, caused increased inflammatory reaction and tumor necrosis factor- α levels.⁶⁴ These effects have not been substantiated in naturally infected cats and may be related to the increased killing of actively replicating parasites, decreased IgM titer development, or decreased phagocytic activity caused by the drug. Cats with concurrent FIV infections do not respond as well as FIV naïve cats to therapy.

Table 80-3 Therapy for Toxoplasmosis

DRUG ^a	SPECIES	DOSAGE (mg/kg) ^b	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Extraintestinal Cycle (Systemic Infection)					
Clindamycin	D	3–13 ^c	PO, IM	8	4
	D	10–20	PO, IM	12	4
	C	8–17	PO, IM	8	4
	C	10–12.5	PO, IM	12	4
Sulfonamides ^d and Pyrimethamine ^e	B	30	PO	12	4
Trimethoprim-sulfonamide	C	0.25–0.5	PO	12	4
Trimethoprim-sulfonamide	C	15	PO	12	4
Enteropathelial Cycle (Oocyst Shedding by Cats)					
Clindamycin	C	50	PO, IM	24	1–12
	C	12.5–25	PO, IM	12	1–2
Sulfonamides ^d and Pyrimethamine ^e	C	100	PO	24	1–2
Pyrimethamine ^e		2.0	PO	24	1–2

D, Dog; C, cat; B, dog and cat; PO, by mouth; IM, intramuscular

- a See [Appendix 8](#), Drug Formulary, for more information on these drugs.
- b Dose per administration at specified interval. See Therapy, in text, for other drugs being investigated to treat systemic infections.
- c Use proportionally higher doses per kilogram in small (<5kg) dogs.
- d Twice this dosage is used if sulfonamides are used alone.
- e Available only in 25-mg tablets. For proper dosing of cats, must be divided. More effective than trimethoprim.
- f Mixed as 0.02% (w/w) concentration in dry weight of food.

Oral clindamycin can cause anorexia, vomiting, and diarrhea in dogs and cats, especially at higher doses.¹⁴⁸ These side effects appear to be related to local GI irritation because parenteral therapy at similar doses does not cause them in the same animals. The side effects stop soon after the dose is reduced or therapy is discontinued. *Clostridium difficile* overgrowth has not been documented in dogs and cats as it has been in people treated with clindamycin (see Drug Formulary, [Appendix 8](#), and Macrolides and Lincosamides, [Chapter 34](#)).

Although less suitable compared with clindamycin, the combination of pyrimethamine and rapid acting sulfonamides, such as sulfadiazine, sulfamethazine, sulfamerazine, and triple sulfas, is synergistic in the therapy of systemic toxoplasmosis. Pyrimethamine has greater efficacy than trimethoprim has when used in combination. Because mental depression, anemia, leukopenia, and thrombocytopenia from bone marrow

Infectious Diseases of the Dog and Cat, 3rd Edition

suppression develop rapidly in antifolate treated cats compared with dogs, frequent hematologic monitoring is required, especially if therapy lasts longer than 2 weeks. Although trimethoprim sulfonamide crosses the blood brain barrier well, it has been reported to be ineffective in treating a dog with severe uveitis and optic neuritis.¹⁰³

Bone marrow suppression can often be corrected with the addition of folinic acid (5.0 mg/day) or brewer's yeast (100 mg/kg/day) to the animal's diet. Baker's yeast, which contains folic acid, is inexpensive and as effective as is folinic acid. The parasite uses preformed folic acid better than does folinic acid. Nevertheless, pyrimethamine and sulfonamides inhibit folic-folinic acid metabolism in *T. gondii* to a greater extent than it does in the mammalian cell; therefore supplementation with folic acid does not completely reverse therapeutic efficacy when used in combination with pyrimethamine and sulfonamides.

Doxycycline and minocycline have been shown to be effective in vitro and in vivo in experimental infections in mice and on cerebral toxoplasmosis in people,²⁴⁶ and they have been used to treat related intestinal coccidiosis. Doxycycline and minocycline might be considered when side effects are noted with clindamycin or antifolates or with co-infections of other pathogens that are susceptible to the tetracyclines.

Several new drugs, such as trimetrexate and piritrexim (antifolates), roxithromycin (a macrolide), atovaquone (a hydroxynaphthoquinone), and aprinocid (a purine analog and an anticoccidial drug), have been effective in treating experimental toxoplasmosis in mice,³⁰² but they have limited availability for clinical use in cats or dogs. Azithromycin and clarithromycin are newer macrolides that are licensed for human use and show in vitro and in vivo activity against *T. gondii*⁷⁰ (see Drug Formulary, [Appendix 8](#)). The combination of pyrimethamine and azithromycin was as effective as pyrimethamine and sulfadiazine was in treating ocular toxoplasmosis in people with the advantage of fewer side effects.³³ Trioxane derivatives have been shown to be effective against *T. gondii* in vitro. Spiramycin, used in Europe for prevention of transplacental transmission of *Toxoplasma*, has not been as effective in treating postnatally infected people.

765

766

In addition to pyrimethamine sulfonamide combinations, pyrimethamine has been administered in combination with clindamycin or dapsone. Limited clinical and experimental studies have shown synergy with azithromycin pyrimethamine, clarithromycin minocycline, clarithromycin or azithromycin and sulfonamides, and atovaquone with pyrimethamine or sulfonamides.^{8,346} Biologic response modifiers such as INF γ have been given synergistically in combination therapy with antimicrobials.⁹

80.1.7.1

Oocyst Shedding in Cats

Oocyst shedding has been partially controlled only when high doses of pyrimethamine and sulfonamide have been provided (see [Table 80-3](#)). Oocyst excretion also has been reduced by the doses of clindamycin recommended for systemic chemotherapy.

Monensin, an anticoccidial drug used in poultry and cattle feeds, is effective in suppressing oocyst shedding when placed in dry cat food within 1 to 2 days PI. It did not prevent infected cats from developing immunity against shedding of oocysts in subsequent exposure to *Toxoplasma*. Toxicity in cats was not noted when the drug was fed for extended periods, despite its known tendency to produce a myopathy in dogs and horses. Toltrazuril has been highly effective when given on a daily basis in preventing oocyst shedding after infection or reshedding after glucocorticoid induced immunosuppression. These drugs may be beneficial in treating cats owned by pregnant women to reduce the risk of potential exposure of the fetuses to oocysts.

Infectious Diseases of the Dog and Cat, 3rd Edition

80.1.8 Prevention

Preventing toxoplasmosis in dogs and cats involves measures intended to reduce the incidence of feline infections and subsequent shedding of oocysts into the environment (see also [Chapter 99](#)). Kittens raised outdoors usually become infected shortly after they are weaned and begin to hunt. Cats should preferably be fed only dry or canned, commercially processed cat food. The prevalence of canine and feline toxoplasmosis has been higher in countries where raw meat products are fed to pets. Freezing or γ ray irradiation can kill tissue cysts without affecting meat quality.^{79,125} Household pets should be restricted from hunting and eating potential intermediate hosts or mechanical vectors, such as cockroaches, earthworms, and rodents. If meat is provided, it should always be thoroughly cooked, even if frozen before feeding.^{311,348} Cats should be prevented from entering buildings where food producing animals are housed or where feed storage areas are located. Toxoplasmosis has developed in people and experimental animals after transfusion of contaminated blood products, making donor screening an important consideration.

The development of protective immunity in toxoplasmosis appears to be strain or stage specific, or both.²⁵³ An oral vaccine containing live bradyzoites of a mutant strain (T 263) was reported for reducing oocyst shedding by cats.^{82,136,137} The vaccine strain itself does not produce oocyst shedding.¹³⁶ Although not commercially available, the value of a vaccine for cats would be to reduce the environmental contamination in areas of human habitation and food production. In actual and experimental modelings, vaccination of cats living on commercial swine farms reduced oocyst shedding of the resident cats and significantly reduced the *T. gondii* seroprevalence of finishing pigs.^{236,237}

80.1.9 Public Health Considerations

Worldwide, nearly 500 million people have *T. gondii* antibodies. The seroprevalence of *T. gondii* is highest (approaching 100%) in warm, moist, or tropical climates and lowest in the arid and the frigid regions of the world.^{93,327} In the United States, prevalence is highest in the East and in the Appalachian Mountain regions and is lowest in the southwestern arid regions and northwestern mountain regions. Approximately 25% to 50% of people tested in the United States have antibodies to *Toxoplasma*.

People become infected with *T. gondii* by ingesting viable cysts in raw or undercooked meat or by ingesting oocysts shed in the feces of a recently infected cat. In the United States, estimates are that at least 50% of acquired infections are associated with ingestion of meat.^{43,291} Oocyst-induced infections in people may be more severe than those acquired from ingestion of tissue cysts.^{91a} Water-borne outbreaks can occur sporadically related to contamination of water supplies by domestic or wild cat feces.⁷ Transplacental infection of the fetus occurs via tachyzoite spread when a pregnant woman is infected for the first time. The rate of congenital infection varies among countries, being higher in continental Europe and South America than in North America.⁹³ The fetus can become infected from an immunocompromised or human immunodeficiency virus-infected woman who is also chronically infected with *Toxoplasma*. The fetus is affected most severely when infection takes place during the first half of gestation. Retinochoroiditis is the primary clinical disease in congenitally infected children. Prenatal detection of fetal infection and treatment of the pregnant mother have greatly reduced the morbidity of disease in newborn infants.

Clinical disease in postnatally infected people is similar to that in other infected intermediate hosts, such as dogs.¹³⁴ Postnatally acquired infections are generally asymptomatic and self limiting, usually persisting 1 to 12

Infectious Diseases of the Dog and Cat, 3rd Edition

weeks. Such infections with persistent or recurrent lymphadenomegaly may resemble infectious mononucleosis or Hodgkin's disease and are usually not fatal unless the host is severely immunosuppressed and the infection becomes disseminated. Reactivation of chronic latent (encysted) infection also is possible. Reactivated disease has been seen in patients with acquired immunodeficiency syndrome (AIDS) when *Toxoplasma* encephalitis is the predominant illness.²² *Toxoplasma* encephalitis also occurs in non-AIDS immunosuppressed people. High-dose trimethoprim-sulfonamide has been used to reduce the risk for development of CNS inflammation.²⁸⁸ Many studies have linked *T. gondii* infections in people to neuropsychiatric disorders and decreased psychomotor performance.¹⁵⁴ In particular, a link has been made with a high prevalence of *T. gondii*-specific serum antibodies or strong correlation of obtaining a cat during childhood in people with schizophrenia.³³¹ However, these studies have been serologic; one examining the presence of *T. gondii* by PCR of cortical brain tissue from psychiatric patients was not incriminating.⁵⁶

Ingestion of undercooked meat, or contamination of uncooked foods by cutting boards used to prepare raw meat, is a common source of *Toxoplasma* infection for people. On farms housing food-producing animals, cat populations should be controlled, and pigs should be reared on concrete or indoors when feasible.³⁴² In France, where eating undercooked meat and toxoplasmosis is prevalent, exposure to undercooked beef, cat ownership, consumption of raw vegetables, and eating undercooked lamb were found to be risk factors, in decreasing order, for infection in pregnant women.¹⁷ Although people generally become infected by ingesting bradyzoite infected meat,^{52,230,348} ingestion of raw goat's milk may be an additional source of human toxoplasmosis. Laboratory accidents, blood transfusions, and organ transplants are additional sources of infection.

766

767

Oocyst survival is an important determinant of the distribution and maintenance of the disease in nature.^{122,211} Oocysts, which are shed by cats, contaminate the environment and are ingested by herbivorous animals, which subsequently infect carnivorous animals higher in the food chain, such as people. Sporulated oocysts can survive up to 18 months during unfavorable environmental conditions and are resistant to most disinfectants. Even unsporulated oocysts can survive for at least 11 weeks at refrigerated temperatures.²¹² Dogs that eat cat feces may also act as transport vectors for sporulated oocysts as they will shed these sporulated oocysts in their feces for 2 days after ingesting them.²¹⁸

Although oocysts are key in the epidemiology of toxoplasmosis, in most studies, no direct correlation has been found between toxoplasmosis in adults and cat ownership (see [Chapter 99](#)).^{*} Studies showing seroconversion during pregnancy have independently linked the consumption of under cooked meat and soil contact through gardening or eating unwashed vegetables with primary infection.^{185a} In one study, veterinary staff in Canada, which regularly handled cats, did not have a high prevalence of serum IgG reactive to *T. gondii*.³⁰⁴ In another serologic survey, prevalence of serum antibodies to *T. gondii* were 5.2% for children living in rural environments and 1.1% among those in urban areas.²⁶⁹ Seroprevalence increased with age in both groups, and cat ownership was associated with seropositivity in rural but not urban children. Rural children in a household with more cats had a much greater risk of exposure. These differences may relate to the health habits of children and the contrasting defecation habits of rural versus urban cats.

Given that individual cats provide human emotional health benefits and are not a direct risk factor for acquiring toxoplasmosis where good hygiene is practiced, relinquishing them is unnecessary.^{5,340} Most cats become infected from carnivorous behavior soon after weaning and shed oocysts for only short periods (under 3 weeks) thereafter. Cats found to be shedding *T. gondii* oocysts should be hospitalized for this period and treated to eliminate shedding, particularly when a pregnant woman is present in the household. To prevent inadvertent

Infectious Diseases of the Dog and Cat, 3rd Edition

environmental contamination, cat owners, and especially childbearing-aged women, should practice proper hygienic measures on a routine basis. Because infected cats rarely have diarrhea, and they groom themselves regularly, direct fecal exposure from handling infected cats is unlikely. Oocysts were not detected in fur of cats that had shed large numbers of *T. gondii* oocysts.⁸⁰

Litter boxes should be changed daily because at least 24 hours are usually necessary for oocysts to reach the infective stage. Oocyst sporulation depends on environmental temperature (Table 80-4). Unsporulated oocysts are more susceptible to disinfection and environmental destruction; therefore control efforts should be directed at this stage. Litter pans should be disinfected with scalding water. Cat feces should be discarded in the septic system, incinerated, or sealed tightly in a plastic bag before placing in a sanitary landfill. Only organic litters that are biodegradable should be placed in the septic system. High temperature composting to kill oocysts remains to be proved. Under no circumstances should litter boxes be dumped into the environment.

Oocysts survive best in warm, moist soil, a factor that helps explain the high prevalence of disease in temperate and tropical climates. Nonsporulated oocysts kept at 0° to 4° C survive and are viable for sporulation and infecting cats for at least 11 weeks.²¹² They also withstand exposure to constant freezing temperature, drying, and high environmental temperature up to 18 months or more, especially if they are covered and out of direct sunlight. A cat's natural instinct to bury or hide its feces provides the protected environment for oocyst survival. Children's sandboxes should be covered to prevent cats from defecating in them. Mechanical vectors, such as sowbugs, earthworms, and houseflies, have been shown to contain oocysts, and cockroaches and snails are additional mechanical vectors. Control of these invertebrates will help reduce the spread of infection.

Table 80-4 Effects of Temperature on Toxoplasma Oocyst Sporulation

TEMPERATURE	DAYS
23.8° C (75.8° F)	1–3
15° C (59° F)	5–8
11° C (51.8° F)	21

Dogs that commonly roll in foreign feces were examined for their potential to act as mechanical vectors for oocysts. Oocyst sporulation did not occur when cat feces were placed on the skin and fur of dogs kept at 19°C to 22° C (66° F to 71.6° F) and 40% to 100% relative humidity.²¹⁸

Sporulated oocysts resist most disinfectants, and only 10% ammonia is effective when it is in contact with contaminated surfaces for 10 minutes. Because of the time required for chemical disinfection and the fumes produced by ammonia, immersing litter pans in boiling or scalding water is usually the easiest means of disinfection. Steam cleaning can decontaminate hard, impervious surfaces.

Outbreaks of human infections have been reported when oocyst contaminated dust particles were inhaled or ingested.^{7,23,329} Dispersion of oocysts can also occur by earth moving or cultivating equipment, shoes, animal feet, wind, rain, and fomites. Streams can become contaminated via water runoff. Stray and wild cats have been known to contaminate streams. Water from streams or ponds should always be boiled before drinking. Heating utensils to 70° C (158° F) for at least 10 minutes will kill oocysts.

Prevention of human toxoplasmosis involves avoiding exposure of susceptible hosts, which includes the unborn fetus and immunosuppressed adult. Risk of exposure by contact with infected meat can be avoided by cooking all meat to an internal temperature greater than 67° C (152.6° F) (Table 80-5). Microwaving does not kill all *T. gondii* because of uneven heating.²³⁰ Gamma-ray irradiation at doses of 5 centigray has been effective.¹²⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

Freezing of meat in home freezers (−12° C) (152° F) for at least 24 hours is an effective method for killing organisms. Good personal hygiene dictates that hands be thoroughly washed after handling raw meat. Animal care technicians who clean cat cages should wear masks and protective clothing.

* References: 17, 57, 176, 250, 274, 320.

80.2 *T. GONDII*–LIKE INFECTION OF CATS

T. gondii is thought to be a single species despite its widespread host range. An unidentified, structurally different, *Toxoplasma* like parasite has been found in five cats with systemic or neurologic manifestations, or both, that might be confused with toxoplasmosis.^{97,100,120} Fever and multisystemic signs had been present in some cats, and some had predominant signs of cervical spinal cord injury, which are unusual for toxoplasmosis. In one cat with disseminated infection, hyperemic skin nodules were observed.^{225a} Some reactivity was noted to *T. gondii* in serologic testing. In one cat in which CSF was examined, an elevated white blood cell count (117 cells/μl) and protein level (186 mg/μl) were present, and the cells were predominantly lymphocytes. Histologically, nonsuppurative inflammation was observed in many organs, including the CNS. Unlike lesions caused by *T. gondii*, many tissue cysts and free bradyzoites were present; tachyzoites in inflammatory lesions were lacking. The tissue cysts were larger than those of *T. gondii*, they had thinner walls, and, ultrastructurally, they had micronemes arranged in rows. Although not evaluated, treatment would likely be similar to that of toxoplasmosis. The significance of this parasite awaits elucidation of its life cycle and host range.

Table 80-5 Survival of *Toxoplasma*

CONDITIONS	MAXIMAL SURVIVAL TIME
Bradyzoites	
−3° C (26.6° F)	3 weeks
−6° C (21.2° F)	11 days
50° C (122° F)	20 min
58° C (136° F)	10 min
61° C (142° F)	4 min
64° C (147.2° F)	1 min
Oocysts	
<i>Unsporulated</i>	
−21° C (−5.8° F)	1 day
4° C (39° F)	30 days
37° C (98.6° F)	1 day
50° C (122° F)	10 min
<i>Sporulated</i>	
−20° C (−4° F)	28 days
50° C (122° F)	30 min
5% Ammonia	60 min

80.3 *T. GONDII*–LIKE CUTANEOUS INFECTION OF DOGS

A 6-year-old female Great Dane dog from Rio de Janeiro, Brazil, died from chronic illness caused by an *Ehrlichia*–like organism.¹²¹ As a co-infection in this dog, numerous apicomplexan parasites were found in dermal lesions. The protozoan reacted with polyclonal anti-*T. gondii* sera but not with *Neospora caninum* or *Sarcocystis neurona* antibodies. Ultrastructurally, the protozoa had schizont-like structures, with merozoites arranged around a prominent residual body, and the merozoites had several rhoptries with electron-dense contents. In contrast, *T. gondii* tachyzoites are electron lucent, and a residual body is not found in groups of tachyzoites.

Infectious Diseases of the Dog and Cat, 3rd Edition

80.4 NEOSPOROSIS (NEOSPORA CANINUM INFECTION)

80.4.1 Etiology

N. caninum is a protozoan of the phylum Apicomplexa; before 1988, it had been confused with *T. gondii*.^{92,97a,99} Its tachyzoites and tissue cysts resemble those of *T. gondii* under light microscope. The domestic dog or the coyote (*Canis latrans*) is the definitive host and sheds oocysts following ingestion *N. caninum*-infected tissues (Fig. 80-16).^{19,143b,219,241,242} The shedding period appears to be short and oocysts few. However, shedding in some instances has been documented up to 4 months by both visual inspection and PCR methods.²⁴² Detecting oocysts in naturally and experimentally infected wild canids has been unsuccessful.^{3,221} Cats are not definitive hosts because they do not shed oocysts after consuming bradyzoites.²⁴¹ Antibodies to *N. caninum* have been detected in the sera of domestic cats from São Paulo, Brazil,¹¹³ but the significance of this natural exposure is unknown. As with other coccidia, herbivores likely become infected by ingesting oocysts shed by the definitive host or by subclinical congenital infection from transplacental transmission or through ingestion of milk by neonates.⁴ Canids can be experimentally infected by ingesting parasitized tissues from the intermediate herbivore hosts. Deer and cattle, whose carcasses may be preyed upon by dogs and coyotes, appear to be the intermediate hosts for *N. caninum* infection. Larger numbers of oocysts are detected after feeding dogs infected tissues from cattle, the natural intermediate host, as compared with tissues from rodents.^{124a,143} In naturally infected dogs, the predominant route of transmission is considered to be transplacental, and a clinical sign is often an exacerbation of congenitally acquired infection. Tachyzoites are 5 to 7 $\mu\text{m} \times 1$ to 5 μm , depending on the stage of division (Fig. 80-17). They divide into two zoites by endodyogeny. In infected carnivores, tachyzoites are found within macrophages, polymorphonuclear cells, spinal fluid, and neural and other cells of the body. Individual organisms are ovoid, lunate, or globular. They contain one or two nuclei and are arranged singly, in pairs, or in groups of four or more. Cell necrosis occurs after rapid intracellular replication of tachyzoites. Widespread dissemination of tachyzoites to many organs may occur in the acute phases, with subsequent restriction by the host's immune response, to neural and muscular tissues in more chronically affected dogs.¹³

Nonseptate tissue cysts (up to 100 μm in diameter) are found mainly in neural cells (brain, spinal cord, peripheral nerves, and retina) and occasionally in muscles.^{92,124a,270a} (Fig. 80-18). They may be round or elongated. The cyst wall is up to 4 μm thick and encloses slender, periodic acid-Schiff-positive bradyzoites.⁹² Rupture of tissue cysts is associated with a granulomatous inflammatory reaction in the involved tissue.

Unsporulated oocysts (10 to 14 μm in diameter) are shed in dog feces 5 days or later after ingesting tissue cysts. Sporulation occurs after 24 to 72 hours outside the body. Sporulated oocysts contain two sporocysts each with four sporozoites.^{219,241} Unlike the transient shedding associated with *T. gondii* infection in cats, *Neospora*-infected dogs may shed oocysts over an extended period of several months.²⁴² Susceptible hosts can become infected after ingesting food or water contaminated with *N. caninum* oocysts.

80.4.2 Epidemiology

Naturally occurring infections in dogs have been found throughout the world.^{99,101,215,271} Seroprevalence of clinically healthy dogs is usually much less than 20% but much greater than the prevalence of clinical illness,

Infectious Diseases of the Dog and Cat, 3rd Edition

suggesting subclinical infections.^{220,334} Purebred dogs, especially German shorthaired pointers, Labrador retrievers, boxers, golden retrievers, basset hounds, and greyhounds, have been noticeably prevalent in published case reports.^{215,293} Seroprevalence in canids also varies according to geographic location and whether domestic or wild populations are examined.^{11,58} In the same geographic area, feral dogs have a higher prevalence rate of *N. caninum* serum antibody reactivity than do owned dogs.^{9a,141} Dogs being fed raw meat have a much higher prevalence of reactive antibody than do dogs on commercial diets.^{185,242} Serologic prevalence is also greater in farm dogs as compared with urban dogs.^{6,295,298} A strong statistical association has been found between infections in dairy herds and the presence and density of dogs on farms.^{264a} Serologic studies suggest that dogs may acquire their infection mainly via horizontal transmission from ingesting tissues of infected herbivores as evidenced by the increase in seroprevalence with age.^{11,45} Dogs in urban areas, which were free roaming on the street, have greater seroprevalence than do companion pets.⁴⁵ Dogs that have been fed raw bovine meat have a much higher prevalence of serum antibody reactivity to *N. caninum*.¹⁸⁵ Dogs on farms or dairy farms had higher prevalence of reactive antibodies in serum to *N. caninum* than did those in urban areas.^{179,347,341a} In comparative analysis with uninfected dairy farms, those with established infection in cows had dogs consuming vaginal discharges, aborted materials, or milk from cows, and where dogs defecated in the food or feeding alleys.^{72,73} Introduction of a previously infected dog onto a farm may also precipitate infection in a herd.⁷³ Ingestion of infected calf tissues appears to increase the numbers of oocysts shed compared with numbers produced following ingestion of infected mice.¹⁴³ Experimental transmission in dogs has been produced by oral or parenteral administration of *Neospora*, but transplacental transmission is also an important route in natural infections. Suppositions are that the chronically infected bitch develops parasitemia during gestation, which spreads transplacentally to the fetus. Successive litters from the same subclinically infected dam may be born infected, although perhaps at a reduced rate.^{106a} However, transplacental transmission alone will not be able to propagate *N. caninum* infection in nature.¹⁵ The majority of, but not all, puppies in a litter have clinical manifestations.¹⁰⁷ Other pups may carry the infection subclinically with reactivation. In contrast to toxoplasmosis, underlying immunodeficiencies or concurrent illnesses are not always apparent in adult dogs with neosporosis. However, reactivation of infection causing cutaneous, neural, or muscular disease has occurred following immunosuppressive illnesses or administration of modified live virus vaccines, cytotoxic agents, or glucocorticoids.²⁶¹ Glucocorticoids can also increase the shedding period and number of oocysts excreted by dogs.²¹⁹ With new awareness and available serotesting, postnatal infections are being recognized with increasing frequency.²⁴²

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 80-16 Life cycle of *N. caninum*. **A**, Following ingestion of tissue cysts, some bradyzoites transform to tachyzoites with systemic spread resulting in encystment in neural and muscle tissues. In the intestine, enteroepithelial replication also occurs with merogony leading to the development of gamonts and a zygote. **B**, Oocysts are shed unsporulated in the stool. **C**, Once mature and infectious, sporulated oocysts are ingested by a variety of herbivores. Organisms spread from the intestine as tachyzoites and encyst in muscle and nervous tissues. Spread to reproductive tissues often results in abortion. The tissues of the fetus or the infected intermediate host are ingested by a new definitive host and the cycle continues. (Courtesy University of Georgia, Athens, Ga.)

Fig 80-17 Numerous tachyzoites of *N. caninum* in a smear of an ulcer in the skin of a dog. Dividing tachyzoites (arrows) are thicker than nondividing tachyzoites (Giemsa, $\times 750$).

Fig 80-18 Transmission electron micrograph of a tissue cyst of *N. caninum* in the brain of a dog. Note the thick cyst wall (CW) and bradyzoites ($\times 9939$).

Infectious Diseases of the Dog and Cat, 3rd Edition

Infection in the intermediate hosts may also be important in maintenance of the disease in nature. This infection has a major economic impact for the cattle industry worldwide. Herbivores such as cattle ingest oocysts that have been shed transiently in the feces of infected dogs. After ingestion and acute exposure, the organism may spread systemically, cross the placenta, and infect fetuses, resulting in sporadic or epidemic infertility, abortion, or neonatal infection. This circumstance is similar to the concern of toxoplasmosis in pregnant women with oocyst exposure from cats. Point source exposure of neosporosis in a cattle herd has been linked to introduction of a dog.⁷³ Once cattle are infected, *N. caninum* spreads endemically in the herd from the transplacental spread of infection from congenitally infected heifers to their offspring. Calves up to 1 week of age can be experimentally infected by ingesting milk or colostrum containing tachyzoites, but lactogenic transmission is not considered epidemiologically important.^{67,190} By these routes, successive generations of cows in a herd remain infected. Dogs shed oocysts following ingestion of bovine placental tissue from *N. caninum* seropositive cows but not after ingestion of colostrum containing *N. caninum* tachyzoites.⁷⁴

Naturally occurring infections have been reported worldwide in domesticated animals such as dogs, cattle, sheep, goats, horses, water buffalo, and camels. *N. caninum* antibodies or infection have also been found in numerous wild canids (red and grey foxes, dingoes, coyotes) and their prey (deer, rhinoceros). A sylvatic transmission cycle likely exists that has evolved over time and maintains the infection in nature.^{143a,337a} Dogs fed CNS tissues from white tailed deer (*Odocoileus virginianus*) shed oocysts.^{143a} Subsequently, these oocysts were fed to a calf that developed a high antibody titer to *N. caninum*, supporting the existence of such a sylvatic cycle. Isolated dogs from the Amazon River region in Brazil have had antibodies to *Neospora*, indicating its widespread environmental prevalence.⁴⁵

80.4.3 Clinical Findings

Rabbits, gerbils, pigeons, foxes, monkeys, and raccoons develop subclinical infections with experimental infection.^{86,244} Mice, rats, pigs, and domestic cats are also susceptible experimentally and show illness.^{91,110,111} A predominant manifestation in herbivores is abortion. Neonatal death and in utero mortality may result, depending on when infection occurs during pregnancy. Infection has been transmitted from mother to fetus in cattle, sheep, goats, mice, dogs, cats, monkeys, and pigs.⁸⁷ Lactogenic transmission has been experimentally proven in cattle.³³⁵ *N. caninum* or another species of *Neospora*, *N. hughesi*, has also been identified as a less common cause of equine protozoal myelitis than is *Sarcocystis neurona*.^{115,232,233}

770

771

80.4.3.1 Dogs

Likely, many dogs diagnosed with toxoplasmosis before 1988 actually had neosporosis. In general, clinical findings in dogs are similar to those of toxoplasmosis, but neurologic deficits and muscular abnormalities predominate (Table 80-6). Clinical signs may also include those of hepatic, pulmonary, and myocardial involvement, but any tissue can become involved. Both pups and older dogs are clinically affected, and the infections can be transmitted congenitally. Experimental studies suggest that *N. caninum* can cause early fetal death, mummification, resorption, and birth of weak pups.¹¹¹ Although abortion is a major feature of the disease in cattle, no reports of abortion in dogs have been produced.

Infectious Diseases of the Dog and Cat, 3rd Edition

80.4.3.1.1 Puppies Younger Than 6 Months

The most severe (disseminated) and frequent infections have been in young (under 6 months) dogs that showed ascending paralysis of the limbs. In the youngest pups, signs are often noticed beginning at 3 to 9 weeks of age. Features that distinguish neosporosis from other forms of paralysis are gradual muscle atrophy and stiffness, usually as an ascending paralysis; the pelvic limbs are more severely affected than are the thoracic limbs. Paralysis progresses to rigid contracture of muscles of affected limbs (Fig. 80-19). This arthrogryposis is a result of the scar formation in the muscles from lower motor neuron damage and myositis. In some pups, joint deformation and genu recurvatum may develop. Cervical weakness, dysphagia, megaesophagus, and ultimately death occur. In some dogs, the progression may become static. Dogs do not develop severe intracranial manifestations and maintain alert attitudes. They can survive for months with hand feeding and care but remain paralyzed with associated complications.

80.4.3.1.2 Dogs Older Than 6 Months

Older dogs most likely become ill from reactivation of a chronic subclinical infection. They often have signs of multifocal CNS involvement with or without polymyositis; less common manifestations result from myocarditis, dermatitis, pneumonia, or multifocal dissemination. These latter syndromes usually result from more widespread dissemination with spread of tachyzoites. Cutaneous neosporosis has been most common in dogs that become immunosuppressed from concurrent illnesses or drug therapy.^{261,326} Should a dog be examined with concurrent signs of multifocal CNS disease and myositis such as hyperesthesia, muscle swelling or atrophy, and increased creatine kinase activity, then neosporosis should be highly considered. Death from diffuse CNS or muscle inflammation can occur in dogs of any age.

80.4.3.2 Cats

N. caninum can induce a fatal infection in experimentally inoculated cats.¹¹⁴ The infection is most severe in prenatally and neonatally infected kittens. Subclinical disease was found in adult cats. These cases were more severe and acute when the cats were immunosuppressed with glucocorticoids. As in dogs, encephalomyelitis, polymyositis, and hepatitis are the predominant lesions. Natural clinical infections have not been documented, although antibodies to *N. caninum* have been reported in domestic and wild felids.

80.4.4 Diagnosis

Hematologic and biochemical findings have been variable, depending on the organ system of involvement. With muscle disease, creatine kinase and AST activities have been increased. Serum ALT and ALP activities are increased in dogs that develop hepatic inflammation. CSF abnormalities have included mild increases in protein (over 20 but under 150 mg/dl) and nucleated cell (over 10 but under 100 cells/dl) concentrations. Differential leukocyte counts, in decreasing numbers, included lymphocytes, monocytes and macrophages, neutrophils, and eosinophils.^{61,106a,266} CSF results can be within reference limits in some dogs.¹⁵⁶ 771
Electromyographic abnormalities have consisted of spontaneous activity of fibrillation potentials, positive sharp waves, and occasional repetitive discharges. Nerve conduction velocities may be reduced in the most severely affected limbs, especially proximally, but they are often within reference range. Low evoked action potentials may be found with myositis. 772

80.4.4.1 Serologic Testing

Demonstrating serum antibodies to *N. caninum* can help confirm the diagnosis of neosporosis. Assays have included indirect FA, ELISA, and immunoprecipitation.^{106a,245,249,295} For indirect FA assays, serum is reacted with cell cultured *N. caninum*. Serum indirect FA titer results can vary between laboratories; however, in one reference laboratory, values of 1:50 or greater are considered positive, and values are often greater than 1:800.²¹⁶ CSF can be tested, but titers are of lesser magnitude (1:50 to 1:800).¹⁴ Positive titers can exist in previously exposed dogs that may be infected, but they remain nonsymptomatic, with values of 1:800 or greater for years. Indirect FA IgG titers in most species increase 1 to 2 weeks after infection.¹¹²

Infectious Diseases of the Dog and Cat, 3rd Edition

Higher indirect FA results have been found in clinically versus subclinically affected dogs and in those with the longest duration of illness.¹⁴ However, no correlation has been found between the magnitude of titer and clinical signs. Indirect FA titers appear to have high specificity at greater dilutions of sera; occasionally animals with histologically verified infections have low titer results.^{99,103a,106a} Maternal antibodies may be passed from dam to offspring, making false-positive titers; however, these levels were gone in uninfected pups by day 32 of life.^{106a}

Several ELISA methods are available to detect *N. caninum* antibodies. A direct agglutination test measuring IgG was as sensitive and specific as was an indirect FA test, with the advantage of being useful in a variety of host species.²⁸⁹ Antibodies to *T. gondii* do not cross react with *N. caninum* at dilutions of 1:50 or less; therefore serum or CSF antibody titers to *T. gondii* in *Neospora* infected dogs are negative. Slight cross reactivity with sera from dogs infected with *Babesia gibsoni* but not *B. canis* has been observed.³⁴⁹ Some cross reactivity has been observed with ELISA testing when crude extracts are used as antigens.¹¹¹ Some cross-reaction exists among cellular antigens of *T. gondii*, *H. heydorni*, and *N. caninum*.^{213a,249} Western blots show four major antigens (17, 29, 30, and 37 kD) that appear to be specific for *Neospora*.³¹

80.4.4.2

Organism Detection

In canine feces, *N. caninum* oocysts are very similar in morphology to those of *Hammondia heydorni*.³⁰⁰ Critical analysis has indicated that these are different species.¹⁰⁵ Immunologic cross-reactions may exist between other parasites and *N. caninum*. Tachyzoites can be found in aspirates or smears from any parasitized tissue or body fluid. With immunostaining, cross-reactions with *T. gondii* may be found in CSF or tissue aspirates and biopsies of some dogs and may be detected with any material used to stain blood films. Monoclonal antibodies have been developed for immunohistochemical staining that can distinguish between different organisms. Biopsy of affected muscle may yield a definitive diagnosis when organisms are detected.²⁴⁹ Tachyzoites may be visualized in tissues, fluids, or cytopathologic samples. Muscle biopsy should be considered when serologic testing for neosporosis yields negative or inconclusive results but muscle disease is still suspected. *N. caninum* tachyzoites are similar to *T. gondii* tachyzoites by light microscopy (see Fig. 80-17) but can be differentiated by electron microscopy (Fig. 80-20). Tissue cysts of *N. caninum* have thicker walls than those of *T. gondii* (Fig. 80-21). *N. caninum* can be grown in cell culture and in mice. *N. caninum* must be distinguished from *T. gondii* in sections by immunochemical stains.⁵⁵ Structural differences can also be detected with transmission electron microscopy. *T. gondii* has a thinner cyst wall and fewer micronemes and rhoptries. PCR can be used to specifically detect *N. caninum* in biologic specimens and differentiate infection with other protozoa; however, the sensitivity has been lower relative to other diagnostic methods.^{227a,310} PCR has also been used to differentiate *N. caninum* and *H. heydorni* oocysts in canine feces.^{309,310,316,316a} The use of molecular genetics and PCR to distinguish *Neospora* from other related parasites has been reviewed.^{111,316a}

772

773

Infectious Diseases of the Dog and Cat, 3rd Edition

80.4.5 Pathologic Findings

Gross lesions include multifocal streaks of necrosis, fibrosis, and mineralization of striated muscles, especially the diaphragm. Hepatomegaly, pneumonia, and discoloration of brain or spinal cord tissues may be apparent on cut section.

Pups with disseminated infection can have parasitic stages in the thymus, liver, kidney, stomach, adrenal, and skin, among other tissues. With respect to neural and muscular tissues, parasite-containing lesions are found in the muscles, heart, brain, spinal cord, nerve roots, and retina. Nonsuppurative encephalomyelitis, polyradiculoneuritis, ganglionitis, myositis (of all striated muscles), and myofibrosis are the predominant histologic findings (see Fig. 80-13). The radiculoneuritis is a more typical feature of infection in pups. The encephalomyelitis is characterized by inflammation, axonal degeneration, and formation of glial nodules in gray and white matter. Parasites are most consistently found in the cerebrum, regardless of the clinical presentation.¹³ Cerebellar cortical necrosis and inflammation has been a predominant feature in some dogs.^{29,146,172,227} Tissue cysts are present mainly in central or peripheral neural tissues, whereas tachyzoites are present in many tissues. Tissue cysts are often present, even in treated animals.^{99,106a} Muscle lesions can range from focal necrosis to generalized inflammation of all skeletal muscles and esophageal and cardiac muscles. Inflammation and necrosis of other tissues also occur. Finding tachyzoites in lesions is diagnostic of infection. *N. caninum* appears to induce more inflammation compared with *T. gondii* and causes severe phlebitis and dermatitis. Nonsuppurative myocarditis, pneumonia, and hepatitis are commonly present as subclinical lesions. Lesions caused by *N. caninum* are similar to those caused by *T. gondii* or to granulomatous meningoencephalitis. Confirmation therefore requires serologic or immunohistochemical methods. Antibodies to *N. caninum* tachyzoites may offer more specific staining as antisera to bradyzoites may have some cross-reactivity with some antigens, such as BAG1, of *T. gondii*.

80.4.6 Therapy

Information on effective therapy for this disease is limited. However, drugs used in therapy for toxoplasmosis should be tried early in the course of illness. In vitro assays have shown activity of dihydrofolate reductase inhibitors (trimethoprim), ionophore antibiotics (monensin and salinomycin), macrolides (azithromycin, clarithromycin, and erythromycin), tetracyclines (doxycycline and minocycline), and lincosamides (clindamycin).²¹³ Clindamycin, sulfadiazine, and pyrimethamine alone or in combination have been administered to treat canine neosporosis (Table 80-7).^{14,106a,111} In neonates, clinical improvement is not likely in the presence of muscle contracture or rapidly advancing paralysis.^{14,106a,111} To reduce the chance of illness, all dogs in an affected litter should be treated as soon as the diagnosis is made in one littermate. Older (over 16 weeks) puppies and adult dogs respond better to treatment.¹⁴ In adult dogs with acute lower motor neuron paralysis from myositis, dysfunction is often more amenable to early treatment because scar contracture is less common.¹⁴⁷ Dermatitis and myositis have responded to therapy with clindamycin. With neurologic involvement, trimethoprim-sulfonamide or pyrimethamine and sulfonamide should be used because of better penetration of the CNS. No known therapy to prevent a bitch from transmitting infection to her pups is available. Clindamycin is effective in suppressing the replication and dissemination of tachyzoites but does not appear to be effective against encysted bradyzoites.^{106a}

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 80-7 Drug Therapy for Neosporosis^a

DRUG	SPECIES ^a	DOSE (mg/kg) ^b	ROUTE	FREQUENCY (HOURS)	DURATION (WEEKS)
Trimethoprim-sulfonamide	D	15–20	PO	12	4–8
		10–15	PO	8	4–8

- b Dose per administration at specified interval.
- c Also been used in combination with trimethoprim-sulfonamide or pyrimethamine.
- d Can be substituted with trimethoprim-sulfonamide.

80.4.7 Prevention

In dogs, *N. caninum* can be transmitted repeatedly through successive litters and litters of their progeny. This tendency should be considered when planning the breeding of *Neospora* infected bitches.¹⁰⁷ Dogs should not be fed uncooked meat, especially beef. On farms, dogs should not be allowed to feed on offal or aborted materials. They should be prevented, when possible, from defecating in feed troughs, watering sources, pastures, or livestock holding pens where cattle are housed. No vaccine has been developed to combat neosporosis. No drugs are known to prevent transplacental transmission.

80.4.8 Public Health Considerations

The zoonotic potential of *N. caninum* is unknown. Nonhuman primates can be experimentally infected.¹⁶³ There is no direct evidence that the organism can infect people, although serologic evidence suggests that people are exposed to the organism.^{249,332} In examining sera from 76 women with a history of abortions, none had detectable serum antibodies to the parasite.²⁷² Serum samples from human agricultural workers and blood donors in Ireland had no measurable antibody reactivity to *N. caninum*.¹⁴⁵ Additional refinements and antigen purification may be needed in human serologic testing to clarify whether cross-reactivity or actual infection exists.

80.5 NEOSPOROSIS (NEOSPORA HUGHESI INFECTION)

Equine protozoal myeloencephalitis is caused predominantly by *Sarcocystis neurona* (see [Chapter 80](#)). *N. hughesi* has also been described as a cause of this disease.^{232,233} *N. hughesi* is morphologically similar to, but ultrastructurally, antigenically, and genetically distinct from, *N. caninum*. Tissue cysts of *N. hughesi* are smaller compared with *N. caninum*, with thinner cyst walls. *N. caninum* has been described from infections in horses and antibodies to *N. caninum* have been found in horses.^{87,151} Further molecular studies will be needed in future cases to determine which species is infecting the horse. Glucocorticoid-immunosuppressed dogs fed brains from

Infectious Diseases of the Dog and Cat, 3rd Edition

experimentally infected mice that contained *N. hughesi* stages did not shed oocysts.³⁴¹ Dogs are likely not involved in the role of transmission of this infection, and another carnivore definitive host is likely.

81 CHAPTER 81 Enteric Coccidiosis

J.P. Dubey

Craig E. Greene

Coccidia are obligate intracellular parasites normally found in the intestinal tract. They belong to the phylum Apicomplexa, class Sporozoa, order Eucoccidiorida, and depending on the species, family *Eimeriidae*, *Cryptosporidiidae*, or *Sarcocystidae*. Coccidian genera that infect cats and dogs are *Isospora* (also called *Cystoisospora*), *Hammondia*, *Besnoitia*, *Sarcocystis*, *Toxoplasma*, and *Neospora* species (see [Chapter 80](#)), as well as *Cryptosporidium* and *Cyclospora* species (see [Chapter 82](#)).⁵ *Caryospora* infections are also discussed in this chapter. Another coccidian genus, *Eimeria*, found commonly in herbivores, birds, lagomorphs, and rodents, is found only in feces of dogs and cats after they ingest intestinal contents or feces from these animals. The oocysts pass unchanged through the feline or canine intestine. Some coccidians of dogs remain unclassified.

Intestinal coccidia discussed in this chapter are host specific. Infections of definitive or intermediate hosts generally only occur in cycles established by evolution. Some aberrant cycles exist, such as with *Sarcocystis neurona* infections in horses. Human health risks from these parasites are considered minimal to nonexistent, even in immunosuppressed humans.

81.1 INTESTINAL COCCIDIOSIS

All coccidians have an asexual and a sexual cycle. In some genera, such as *Sarcocystis*, the asexual and sexual cycles occur in different hosts, whereas in *Isospora* both cycles may occur in the same host ([Table 81-1](#) and [Fig. 81-1](#)). The oocyst is the environmentally resistant stage in the life cycle of all coccidia and is excreted in feces of the definitive host.

A representative coccidian life cycle is best described as follows. Oocysts are passed unsporulated in feces and contain a single nucleated mass called a *sporont*, which almost fills the oocyst ([Fig. 81-2](#)). After exposure to warm (20° C to 37° C [68° F to 98.6° F]) environmental temperatures and moisture, oocysts sporulate, forming two sporocysts. Within each sporocyst are four sporozoites ([Fig. 81-3](#)). The sporozoites have a banana shape and are the infective stage ([Fig. 81-4](#)). They can survive environmental exposure, protected inside the oocysts for many months. After the ingestion of sporulated oocysts by cats or dogs, sporozoites excyst in the intestinal lumen, and the sporozoites initiate the formation of schizonts or meronts. During schizogony or merogony, the sporozoite nucleus divides into two, three, or more nuclei, depending on the parasite and the stage of the cycle. After nuclear division, each nucleus is surrounded by cytoplasm, forming a merozoite. The number of merozoites within a schizont varies from two to several hundred, depending on the stage of the cycle and the species of coccidia. Merozoites are released from the schizont when the host cell ruptures. The number of schizogonic cycles varies with the parasitic species. First-generation merozoites repeat the asexual cycle and form second-generation schizonts or transform into microgamonts (males) and macrogamonts (females). The microgamont divides into many tiny microgametes. A microgamete fertilizes a macrogamete, and an oocyst wall is formed around the zygote. The life cycle is completed when unsporulated oocysts are excreted in feces.

Infectious Diseases of the Dog and Cat, 3rd Edition

81.1.1 *Isospora* Species

Members of the genus *Isospora*, the most commonly recognized coccidians infecting dogs or cats, are species specific for the definitive host. At least four species—*Isospora canis*, *Isospora ohioensis*, *Isospora burrowsi*, and *Isospora neorivolta*—infect dogs, and two species—*Isospora felis* and *Isospora rivolta*—infect cats.

81.1.1.1 Epidemiology

The life cycle of *Isospora* infecting dogs and cats is similar to the basic coccidian intestinal cycle, except an asexual cycle can also occur in the definitive or intermediate host. On ingestion by definitive or suitable paratenic (intermediate) hosts, oocysts excyst in the presence of bile, and free sporozoites invade the intestine. Some sporozoites penetrate the intestinal wall and enter mesenteric lymph nodes or other extraintestinal tissues, where they form enlarging unicellular cysts (Fig. 81-5). If no replication occurs, the host is called a *paratenic host* rather than an *intermediate host*. Monozoic cysts of *Isospora* may remain in extraintestinal tissues of definitive and paratenic hosts for the life of the host. In dogs and cats, these cysts may serve as a source of intestinal reinfection and relapse of enteric coccidiosis. Ingestion of monozoic cysts in paratenic hosts leads to intestinal infection in the definitive dog and cat host. The life cycle after the ingestion of paratenic host is the same as after the ingestion of sporulated oocysts from feces.

777

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 81-1 Life cycle of *I. felis*, which is typical of the *Isospora* spp. The mode of transmission may be direct, via ingestion of sporulated oocysts from the environment, or indirect via ingestion of cysts in prey animals. **A**, Either sporulated oocysts or monozytic tissue cysts are ingested. **B**, These excyst in the intestine. **C**, They undergo asexual (endodyogeny) and **(D)** sexual (merogony and gametogony) reproduction with the formation of a zygote. **E**, The zygote becomes an **(F)** unsporulated oocyst that is shed in the stool **(G)**. This matures into the infectious sporulated oocyst which can be ingested by the definitive or intermediate host. **H**, In the intermediate host, the excysted sporozoites migrate to tissues and form cysts. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

81.1.1.2

Clinical Findings

Diarrhea with coccidiosis in immunocompetent animals probably represents incidental or concurrent infections with coccidia and other infectious agents because coccidial infection can be present in the absence of clinical illness. Enzootic infections are frequently found in catteries or kennels where animals congregate. Clinical signs are most apparent in neonates. Experimental studies have shown that clinical signs of intestinal disease are uncommon unless large numbers of oocysts are fed to very young (younger than 1 month) or immunosuppressed animals. Clinically, severe diarrhea has been associated with naturally occurring coccidiosis in immunosuppressed dogs and cats. German shepherd dogs may have an increased susceptibility to clinical infection.^{27,41} Diarrhea with weight loss and dehydration and, although rare, hemorrhage is the primary sign attributed to coccidiosis in dogs and cats. Anorexia, vomiting, mental depression, and ultimately death may be seen in severely affected animals. Severely immunosuppressed dogs and cats may have extraintestinal stages in macrophages of the lymphocyte-depleted mesenteric lymph nodes or extraintestinal tissues.

Fig 81-3 Sporulated oocysts of *I. canis* (C), *I. ohioensis* (O), and *H. heydorni* (H) (unstained, ×1700). Compare with Fig. 81-2. (From Dubey JP. 1976. A review of *Sarcocystis* of domestic animals and of other coccidia of cats and dogs, *J Am Vet Med Assoc* 169:1061-1078.)

Intestinal coccidiosis may be manifest clinically when dogs or cats are shipped or weaned or experience a change in ownership. Diarrhea might result from the extraintestinal stages of *Isospora* returning to the intestines. Monozoic cysts do not cause clinical disease in paratenic hosts.

Fig 81-4 *I. canis* sporulated oocyst treated with 5.25% sodium hypochlorite solution to dissolve part of oocyst wall (OW). Two sporocysts occupy most of oocyst. Each sporocyst has a thin sporocyst wall (SW), four banana-shape sporozoites (S), and a sporocystic residual body (SR). SR may be compact or dispersed (unstained, $\times 1600$). (From Kirkpatrick CE, Dubey JP. 1987. Enteric coccidial infections. Isapora, Sarcocystis, Cryptosporidium, Besnoitia, and Hammondia, Vet Clin North Am Small Anim Pract 17:1405-1420.)

Fig 81-5 Tissue cyst of *I. ohioensis* in smear of mesenteric lymph node of an experimentally infected mouse. The sporozoite (S) is surrounded by a thick cyst wall (CW). Vacuole around cyst wall is fixation artifact (PAS stain, $\times 1250$).

777

81.1.1.3

Diagnosis

778

Intestinal coccidial infection in dogs and cats is diagnosed by identification of the oocysts with any of the fecal flotation methods commonly used to diagnose parasitic infections (see Fecal Examination, [Chapter 70](#)). Shedding of oocysts by some animals may be erratic, therefore repeated examinations are recommended. In dogs, only *I. canis* can be identified with certainty by oocyst size and shape (see [Fig. 81-2](#)). The two species of *Isospora* found in cats can be readily distinguished by oocyst size (see [Fig. 80-9](#)). Oocysts of *I. felis* in cats and *I. canis* in dogs are large and easily distinguished from small oocysts, whereas it is almost impossible to distinguish *I. rivolta*, *I. burrowsi*, and *I. ohioensis* morphologically ([Fig. 81-6](#); see also [Fig. 80-9](#)). Although *I. felis*-, *I. rivolta*-, *I. canis*-, and *I. ohioensis*-like oocysts are passed unsporulated in freshly excreted feces, they sporulate partially by the time a fecal examination is made. Partially sporulated oocysts contain two sporocysts without sporozoites. *Isospora* spp. may sporulate within 8 hours of excretion, and these *Isospora* are highly infectious.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 81-6 Unsporulated oocysts of *I. ohioensis* (O) and *H. heydorni* (H) compared with eggs of nematodes *Toxocara canis* (C) and *Ancylostoma caninum* (A) in flotation of canine feces (unstained, $\times 385$). (From Dubey JP. 1976. A review of *Sarcocystis* of domestic animals and of other coccidia of cats and dogs, *J Am Vet Med Assoc* 169:1061-1078.)

81.1.1.4 Therapy

The presence of underlying disease or host immunosuppression should be suspected when coccidial infections persist for extended periods in older animals or when associated with chronic diarrhea. Treatment is often indicated in bitches and their newborn puppies because of the severity of clinical signs at this age. If diarrhea or dehydration is severe, parenteral fluid therapy must be considered as a supportive measure. Blood transfusion may be required when severe intestinal hemorrhage results in anemia.

Specific therapy involves the use of drugs that are coccidiostatic rather than curative (Table 81-2). However, as with many protozoal diseases, the presence of low-level infection may lead to premunition. The drugs shorten the prepatent period and may shorten the course of the disease.

Sulfonamides have long been the drugs of choice for the treatment of coccidiosis. Rapid-acting sulfonamides, such as sulfadimethoxine or sulfaguanidine, can be given alone or in combination with other antifolate drugs such as trimethoprim. Trimethoprim-sulfonamide offers the advantages of being readily available and being less toxic than other drugs. It should be considered a drug of first choice. Nitrofurazone can be administered alone or in combination with sulfonamides. Nitrofurazone is also available as a 4.59% soluble powder that can be added to drinking water (up to 1 g/2 L) for 7 days.

Infectious Diseases of the Dog and Cat, 3rd Edition

Amprolium is considered an effective preventive and treatment for coccidiosis in kenneled puppies. Although it is not currently approved for use in dogs, it can be administered as an undiluted liquid and a paste, but it is unpalatable in these forms (see Drug Formulary, [Appendix 8](#)).

778

779

Table 81-2 Anticoccidial Drugs for Dogs and Cats

DRUG ^a	SPECIES	DOSE (mg/kg) ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Sulfamethoxine ^c	B	50–60	PO	24	5–20
Sulfaguanidine	B	100–200	PO	8	5
Trimethoprim-sulfonamide	D	30–60 ^d	PO, SC	24	5
	B	15–30 ^e	PO, SC	12–24	5

Roxithromycin	H	2.5	PO	12	15

B, Dog and cat; D, dog; C, cat; H, human; PO, by mouth; SC, subcutaneous.

- See [Appendix 8](#), Drug Formulary, for additional information.
- Dose per administration at specified interval.
- Other sulfonamides, such as sulfadimidine and sulfaguanidine, can be used, but sulfaquinoxaline should not be used because it interferes with vitamin K synthesis and may result in hemorrhagic complications.
- Greater than 4kg body weight.
- Less than 4kg body weight.
- 11 mg ormetoprim and 55 mg of sulfadimethoxine.
- When furazolidone is combined with sulfonamides, 50% of this dose is used.
- Total dose per day. Lower dose recommended for puppies, with a maximum of 300 mg total per day (see Drug Formulary, [Appendix 8](#)).
- Total dose per day. Combine 150 mg amprolium and 25 mg sulfadimethoxine per kilogram per day for 14 days (see Drug Formulary, [Appendix 8](#)).
- Total dose per day. Dose on a mg/kg basis is listed in Drug Formulary, [Appendix 8](#).
- Doses of 30 mg/kg have been used for 1 day; however treatment at half that dose for at least 3 days with repeating if needed, has been more effective in treatment of pups and kittens with coccidiosis without relapses.
- Dose extrapolated from use in horses and mice for treatment of *Sarcocystis neurona* infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

Quinacrine, spiramycin, toltrazuril, tetracycline, and roxithromycin have been used on a limited basis to treat canine and feline coccidiosis.⁴ Their use might be considered if more established treatment regimens fail or protozoal resistance develops.

81.1.1.5

Prevention

Coccidiosis tends to be a problem in unsanitary environments. The fecal shedding of large numbers of environmentally resistant oocysts makes infection likely under such conditions. Animals should be housed in a way that does not allow contamination of food and water bowls by oocyst-laden soil or infected feces. Feces should be removed daily and incinerated. Oocysts survive freezing temperatures. Runs, cages, food utensils, and other implements should be disinfected by steam cleaning or immersion in boiling water or by a 10% ammonia solution. Animals should have limited access to intermediate hosts and should not be fed uncooked meat. Insect control is essential in animal quarters and food storage areas because cockroaches and flies may serve as mechanical vectors of oocysts. Coccidiostatic drugs can be given to infected bitches before or soon after whelping to control the spread of infection to puppies.

81.1.2

Hammondia Species

Two species of *Hammondia* exist in domestic animals: *Hammondia hammondi*, with cats as definitive hosts, and *Hammondia heydorni*, with dogs and other canids as definitive hosts.^{5,25} Unlike *Isospora* species, *H. hammondi* and *H. heydorni* have obligatory two-host life cycles (see [Chapter 80](#) and [Table 81-1](#)). Goats and rodents are natural intermediate hosts for *H. hammondi*, and the domestic cat (*Felis catus*) and the European wild cat (*Felis sylvestris*) are the definitive hosts. *H. hammondi* does not invade extraintestinal tissues of the cat, and cats are infected only by eating tissue cysts. Experimentally, many warm-blooded animals, including monkeys, sheep, goats, pigs, rabbits, guinea pigs, and mice, can serve as intermediate hosts. Intermediate hosts become infected by ingesting sporulated oocysts, which resemble those of *T. gondii*. Sporozoites excyst in the intestinal lumen, invade the intestinal wall, and multiply as tachyzoites in the intestines, mesenteric lymph nodes, and other tissues. The parasite eventually encysts principally in muscles ([Fig. 81-7](#)).

H. heydorni's life cycle is not fully known but seems to be similar to that of *H. hammondi*. Dogs and other canids are definitive hosts, and cattle, sheep, goats, buffaloes, camels, moose, and deer serve as intermediate hosts.^{14,26a} The structure of the parasite in the intermediate hosts is not known. *H. hammondi* and *H. heydorni* are nonpathogenic, therefore no treatment is necessary.

81.1.3

Besnoitia Species

Cats, not dogs, are definitive hosts for three species of *Besnoitia*: *Besnoitia wallacei* of rats and mice, *Besnoitia darlingi* of opossums and possibly lizards, and *Besnoitia oryctofelisi* of rabbits.^{18,26}

The life cycle of *Besnoitia* is similar to that of *T. gondii* (see [Table 81-1](#)). Cats become infected by ingesting tissue cysts, and schizonts ([Fig. 81-8](#)) and gamonts are formed in intestinal goblet cells or lamina propria.

779

Schizonts may be found in extraintestinal organs.²⁶ Unsporulated oocysts are shed in feces, and they are difficult to distinguish from those of *T. gondii*. Intermediate hosts become infected by ingesting sporulated oocysts. The parasite develops in connective tissue, and cysts may become macroscopic. *Besnoitia* is considered nonpathogenic in cats, and no treatment is necessary.

780

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 81-8 *B. oryctofelisi* schizonts in the lamina propria of jejunum of an experimentally infected cat (H and E stain, ×750).

Infectious Diseases of the Dog and Cat, 3rd Edition

81.1.4 Intestinal *Sarcocystis* Species

Infections resulting from *Sarcocystis* spp. are ubiquitous in reptiles, birds, and warm-blooded animals.⁵ Virtually all cattle and sheep are infected with this parasite. More than 90 species of *Sarcocystis* have been identified, and they have an obligatory two-host life cycle (see [Table 81-1](#)). Carnivores (predators) are definitive hosts, and herbivores (prey) are intermediate hosts. As the name implies, the parasite forms tissue cysts (sarcocysts) in muscles and neural tissues of these intermediate hosts ([Fig. 81-9](#)). Sarcocysts are thin or thick walled, and the zoites are usually separated from each other by septa. Cats and dogs become infected by ingesting sarcocysts. The life cycle of *Sarcocystis* is distinct from other coccidians of domestic animals in that oocysts sporulate within the definitive host and are excreted in the feces in an infective form ([Fig. 81-10](#)). The intermediate hosts become infected by ingesting sporocysts or oocysts. One to three generations of schizogony occur in blood vessels or hepatocytes (depending on the species of intermediate hosts). Merozoites then invade skeletal muscles and nerve cells, where they form sarcocysts (see [Figs. 81-10](#) and [81-11](#)). Certain species of *Sarcocystis*, transmissible via dogs, are pathogenic in cattle, sheep, goats, pigs, and mule deer, whereas species transmissible via cats are generally nonpathogenic.

Fig 81-9 Esophageal muscle with thick-walled sarcocyst of *Sarcocystis hirsute* (H and E stain, ×630). (From Gardiner CH, Fayer R, Dubey JP. 1988. *An atlas of protozoan parasites in animal tissues*, Beltsville, Md, USDA Agricultural Handbook No 651.)

More than 20 species of *Sarcocystis* infect cats and dogs. It is not possible to differentiate species on the basis of measurement of sporocysts. *Sarcocystis* is excreted in feces fully sporulated, often as free sporocysts when examined microscopically ([Fig. 81-12](#)). They are small and not very dense, so they lie at a different plane of focus than other parasites.

Infectious Diseases of the Dog and Cat, 3rd Edition

Sarcocystis species are not pathogenic for the intestinal tract of dogs or cats, so no treatment is necessary. Infections can be prevented by cooking all meat fed to animals. Occasionally, sarcocysts are found in skeletal muscles of immunosuppressed or wild cats and dogs, but their life cycle is unknown.^{8,12}

81.1.5 Extraintestinal *Sarcocystis* spp.

81.1.5.1 *Sarcocystis canis* Infection

One of the extraintestinal *Sarcocystis*-like parasites (*S. canis*) has been found in Rottweiler dogs in the United States.^{10a,21-23,48a} Only asexual stages (schizonts) were seen in various cells, including neurons, hepatocytes, and dermal cells (Figs. 81-13 and 81-14). Affected dogs ranged from 2 days old to adult dogs and had neurologic and hepatic signs and dermatitis. Schizonts were 5 to 25 × 4 to 20 μm and contained 6 to 40 merozoites. Occasionally, merozoites were arranged around a residual body. The parasite was named *S. canis* because it differed from other species of *Sarcocystis*. Its life cycle is unknown. An unidentified *Sarcocystis* sp. caused granulomatous myositis in a dog.^{2a}

81.1.5.2 *Feline Sarcocystis* Infection

Sarcocysts have been identified in the skeletal and cardiac muscles of 11 free-ranging Florida panthers and cougars,³⁰ 3 domestic cats³² and in hind-limb muscle biopsy specimens of 2 domestic cats.²⁸ The sarcocysts found in these studies were not specifically identified, and the immune status of the host may have been compromised. Some of these infections might have been caused by *Sarcocystis neurona*, which is discussed in the following section.

Infectious Diseases of the Dog and Cat, 3rd Edition

81.1.5.3 Sarcocystis neurona Infection

S. neurona is the principal parasite associated with equine protozoal encephalomyelitis, although a species of *Neospora* has also been incriminated (see [Chapter 80](#)). Opossums (*Didelphis virginiana*) are the definitive hosts for *S. neurona* ([Fig. 81-15](#)). Animals that ingest oocysts from opossums and serve as intermediate hosts by developing muscle sarcocysts are the nine-banded armadillo (*Dasypus novemcinctus*), striped skunk (*Mephitis mephitis*), raccoon (*Procyon lotor*), sea otter (*Enhydra lutris*), and brown-headed cowbird (*Molothrus ater*).^{19,36} Experimentally and naturally, cats have been shown to be intermediate hosts of *S. neurona*, although results have varied with individual isolates.^{1,19,49} Cats experimentally fed sporocysts shed by opossums develop schizonts in their tissues and sarcocysts in their muscles, and infected cats develop high antibody titers (1:4000) as measured by a serum agglutination test.¹⁷ Opossums were shown to shed *S. neurona* sporocysts after ingesting feline tissues containing sarcocysts.¹⁶ Horses are considered incidental or aberrant dead-end hosts because they only develop lesions within the central nervous system, and muscle sarcocysts have not been documented. This organism can cause fatal encephalomyelitis in dogs, raccoons, mink, and cats.

Fig 81-13 *S. canis* schizonts in section of dermal ulcer from dog. Note distended macrophages (arrows) with parasites in inflammatory exudate, mainly neutrophils (H and E stain, ×750).

Fig 81-14 An intact *S. canis* schizont (arrow) and several merozoites (arrowheads) released from ruptured schizont in smear of exudate from dermal ulcer of dog (Giemsa stain, ×750).

Sarcocystis-associated meningoencephalomyelitis was described in a 13-week-old Burmese kitten with lethargy, depression and crying, and progressive upper motor neuron hemiparesis.¹³ Another 12-week-old kitten developed progressive neurologic dysfunction 3 days after a routine castration.⁶ Encephalomyelitis was associated with numerous *S. neurona* schizonts and merozoites in the brain and spinal cord. *S. neurona* infection was also documented in a 13-year-old captive Canadian lynx (*Felis lynx Canadensis*).²⁹ Serum antibodies to *S. neurona* were detected in 13% of 310 farm cats from Ohio⁴⁸ and in 5% of 196 domestic cats from Michigan whose sera were submitted for *T. gondii* antibody testing.⁴³ Diagnosis in horses has involved immunoblot testing for specific antibodies to *S. neurona* in cerebrospinal fluid not contaminated with blood. Use of feline antibody conjugates would be needed to apply this method for use in cats. Treatment of affected cats has not been attempted because diagnosis of clinically affected cats was made after death. Effective treatment of horses has involved the use of ponazuril. (See [Table 81-2](#) and Drug Formulary, [Appendix 8](#), for dosage information that has been extrapolated from dosages used to treat horses and mice.) Other anticoccidial drugs such as clindamycin, tetracyclines, or antifolate inhibitors might also be considered.

784

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 81-15 Life cycle of *S. neurona*. Opossums (*Didelphis virginiana*, *D. albiventris*) are its definitive hosts. They ingest organisms from the tissues of intermediate hosts. **A**, These excyst in the small intestine and enter the gut epithelium. **B**, Gametogony occurs followed by fertilization producing a zygote which eventually forms an oocyst. **C**, Sporulated oocysts shed in the feces are ingested by natural intermediate hosts such as cats, armadillos, raccoons, sea otters, skunks and possibly other mammals. **D**, Ingested sporocysts excyst in the small intestine and **(E)** replicate to a limited extent within the vascular endothelium and leukocytes within viscera and then spread, probably by leukocytes, to other tissues. **F**, There, sarcocysts, composed of bradyzoites, develop in the muscle and neural tissues. Equids are considered aberrant intermediate hosts as development does not occur beyond schizont and merozoite stages. (Courtesy University of Georgia, Athens, Ga.)

Fig 81-16 Section from skin of dog with *Caryospora* dermatitis. Note numerous *Caryospora* stages in dermal cells, including gamonts and schizonts (H and E stain, $\times 750$; bar = 10 μm). (From Dubey JP, Black SS, Sangster LT, et al. 1990a. *Caryospora*-associated dermatitis in dogs, *Parasitol* 76:552-556.)

81.2 VISCERAL AND CUTANEOUS CARYOSPOROSIS

A *Caryospora bigenetica*-like organism was isolated from cutaneous nodules in five dogs ranging in age from 2 to 6 months. The dogs were thought to be concurrently affected with a distemper virus-like infection.⁷ The skin nodules were up to 2 cm in diameter, and some had a central ulcerated area through which serohemorrhagic exudate could be expressed. Microscopically, the dermatitis was characterized by edema and infiltrations by polymorphonuclear cells, eosinophils, and macrophages (Fig. 81-16). Schizonts, male and female gamonts, unsporulated and sporulated oocysts, and caryocysts were seen in macrophages. In one dog, infection had spread to the lymph nodes.

Members of the genus *Caryospora* have an oocyst with one sporocyst that contains eight sporozoites, and they typically parasitize reptiles and raptors. At least two species, *C. bigenetica* and *Caryospora simplex*, parasitize rodents and snakes. *Caryospora* spp. have a complicated life cycle involving asexual and sexual multiplication in the prey (rodent) and the predator (snake). In addition to usual schizonts and gamonts, sporulated oocysts and monozytic cysts (caryocysts) are formed in connective tissue cells of the prey. The caryocysts (unlike sporocysts and oocysts) have a thin cyst wall enclosing the host cell nucleus. Two unusual features of *Caryospora* stages are noted in histologic sections of dog tissue: (1) the small size (less than 15 μm) of all developmental stages and (2) the presence of gamonts, schizonts, and oocysts in a single macrophage.

Infectious Diseases of the Dog and Cat, 3rd Edition

(From Gardiner CH, Fayer R, Dubey JP. 1988. *An atlas of protozoan parasites in animal tissues*, Beltsville, Md, USDA Agricultural Handbook No 651.)

81.3 INTRAHEPATIC BILIARY COCCIDIOSIS IN DOGS

Intrahepatic biliary coccidiosis is a rare condition in dogs.³⁴ Clinical signs associated with hepatic disease include icterus, weight loss, and vomiting. Small and large bile ducts are enlarged because of inflammation and desquamation of epithelial cells. Lesions may extend into hepatic parenchyma. Asexual stages (schizonts) of an unidentified coccidium are found in biliary epithelial cells (Fig. 81-17). These coccidia are different from *Toxoplasma*, *Sarcocystis*, *Hammondia*, and *Cryptosporidium* species and any other known coccidium found in the dog.

81.4 INTRAPULMONARY COCCIDIOSIS IN DOGS

An adult dog with clinical signs of weakness, fever, diarrhea, dehydration, weight loss, and harsh lung sounds was found to have canine distemper complicated by pulmonary infection with coccidia-like organisms.³⁸ Asexual stages of coccidia were observed in cytoplasmic vacuoles of many bronchiolar epithelial cells.

82 CHAPTER 82 Cryptosporidiosis and Cyclosporiasis

Stephen C. Barr

82.1 CRYPTOSPORIDIOSIS

82.1.1 Etiology and Epidemiology

Cryptosporidium is a ubiquitous coccidian genus in the phylum Apicomplexa, suborder Eimeria, family Cryptosporidiidae, that inhabits the epithelium of the respiratory and digestive systems of reptiles, birds, and mammals. Infections of the ileum are most common, but gastric, respiratory, and conjunctival infections have been observed in immunosuppressed hosts. Most species may be relatively host specific. *Cryptosporidium* found in reptiles and birds apparently do not infect mammals. The multiple genospecies of *Cryptosporidium* include *Cryptosporidium felis* and *Cryptosporidium canis*.^{*} Only two morphologically distinct species are recognized mammals based on the very small oocyst size, namely *Cryptosporidium parvum* (4 to 5 μ m in diameter) and *Cryptosporidium* sp. (= *Cryptosporidium muris*; 6 to 8 μ m in diameter). Strains that infect cats and dogs cannot be morphologically differentiated from those that infect people. However, genetic methods can be used to differentiate different isolates of *C. parvum*. New species designations have been made for these distinct isolates (Table 82-1). Many of the newly described genospecies from animals were originally thought to be host specific. However, the host restriction may be less strict given the evidence of a complex circulation of the cryptosporidial species in the environment.¹⁵ Oocysts are often difficult to demonstrate in the feces without special techniques. The biology of *C. muris* is not well known and its host range is limited,⁵ and it will not be considered further. *C. parvum* subtype 1 is the cause of most human infections and is anthroponotic. In contrast, subtype 2 is zoonotic, with cattle being a principal reservoir host. The organism is thought to be by far the most commonly occurring species in mammals and, similar to *Toxoplasma*, has a wide mammalian host range.⁹⁷ *Cryptosporidium* has been reported in rodents, domestic livestock, cats, dogs, people, and numerous wild mammals. Ruminants, especially calves, are considered reservoir hosts for the cattle subtype. Cross infection between various mammalian hosts occurs with this strain.⁹³ Despite their host specificity, experimentally, *C. parvum* from calves can induce respiratory signs in chickens¹⁰³; however most such attempts have failed.⁹⁷ Canada geese (*Branta canadensis*) have been shown to be vectors of *C. parvum* infection and they may cause fecal contamination far from the site of its origin.³⁶ A high prevalence of serum antibodies to cryptosporidia in most species tested, including cats, suggests that exposure to the parasite is common.⁹² Prevalence of serum antibodies to *C. parvum* in cats in various geographic regions in the United States ranges from 1.3% to 14.7%, with older animals in the southeastern states showing the highest exposure rate (15.3%).^{80,81} However, young stray cats are more likely to excrete cysts in their feces. In New York, 3.8% of shelter cats between 1 and 12 months of age were excreting cysts in their feces, while in Colorado, 5.4% of cats were positive.⁴⁷ In the Colorado study, dogs and cats with diarrhea were more likely to shed cysts in their feces compared with clinically normal animals.⁴⁷ In a clinical and postmortem study in metropolitan domestic and feral cats, the prevalence of infection was 5.1% and 12.1%, respectively.⁹⁰ In rural cats from the surrounding area, the prevalence was 12.3%.⁹⁴ Fecal cyst excretion rates in dogs in California and Colorado were 2% and 3.8%, respectively, suggesting that the number of dogs excreting oocysts at any one time may be

Infectious Diseases of the Dog and Cat, 3rd Edition

lower than that in cats.^{24,47} Ranges for prevalence of fecal oocysts in various populations have been 0–38.5% in cats and 0–44.8% in dogs.^{70a}

The life cycle of cryptosporidians differs from most other coccidians (Fig. 82-1). All stages of development (asexual and sexual) of cryptosporidia occur within one host.⁹⁷ After ingestion, oocysts excyst in the gastrointestinal (GI) tract, releasing infective sporozoites, which become enclosed as trophozoites within parasitophorous vacuoles of the microvillous surface of enterocytes rather than in the cytoplasm (Fig. 82-2). The trophozoites proliferate (asexually) by merogony to produce, sequentially, two types of meronts. Within 24 hours, type I meronts (containing eight merozoites) leave the parasitophorous vacuole to invade other epithelial cells where they develop into more type I meronts or type II meronts (containing four merozoites). The type II meronts do not undergo merogony but produce sexual reproductive stages (gamonts). The zygotes formed by sexual reproduction (gametogony between male microgamonts and female macrogamonts) form either thick walled (excreted in the feces) or thin walled (autogenous reinfection) oocysts each containing four sporozoites.

Oocysts of cryptosporidia are highly resistant and spread via the fecal oral route. Fecal contamination of food or drinking water is a common source of infection. Large outbreaks can occur when a community water source becomes contaminated.^{25a} The organism is extremely infective; as few as 100 oocysts are necessary to precipitate disease in people.⁷⁶

* References: 2, 53, 88, 89, 109, 120.

82.1.2 Pathogenesis

Cryptosporidia are either primary pathogens or secondary invaders in a variety of immunosuppressive diseases of animals and people. Crowding and unsanitary practices increase the risk of exposure. Cryptosporidial diarrhea is common among calves in intensive raising units and among children in day care centers.

Cryptosporidiosis may cause malabsorption or secretory diarrhea, but the underlying mechanisms are complex and still not fully understood and have been reviewed elsewhere.³⁴ The organism remains just beneath the luminal cell membrane of the intestinal epithelial mucosa. Functional impairment (glucose stimulated sodium and water absorption) and morphologic changes (villous atrophy, crypt hyperplasia, and inflammatory cell infiltration) have been reported in pigs experimentally infected with *C. parvum*.^{4,86} Although secretory toxins have been implicated in the electrogenic chloride secretory stimulation,³⁹ the mechanism of action is unclear.⁷⁶ Substance P, a neuropeptide in the tachykinin family, is increased in symptomatic as compared with asymptomatic people with cryptosporidiosis related to acquired immunodeficiency syndrome (AIDS).¹¹⁶ Neuropeptides such as SP are known to mediate many inflammatory processes in the intestine. Tumor necrosis factor and prostaglandins, which are released during infection, may also be involved in a disturbance of the epithelial cell function. The net effect of the cellular mediators and villous atrophy is nutrient and electrolyte malabsorption and shifts in water balance in favor of net secretion.³⁴ Lymphocytic duodenitis and intestinal bacterial overgrowth have been documented in a young cat with cryptosporidiosis; however, whether *Cryptosporidium* sp. caused the lesion is unknown.⁴⁶

White, Lilly Research Labs, Greenfield, Ind. From Current WL. 1988. The biology of *Cryptosporidium*, *ASM News* 54:605–612, with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Both humoral and cell mediated immunity (CMI) participate in the host response to infection with *C. parvum*.³⁵ CMI appears to be the major component of the protective response; the role of antibodies is unclear. In affected people, causes of immunodeficiency such as chemotherapy, IgA deficiency or interferon- γ deficiency have been associated with an increased risk infection. Although cryptosporidial cysts are excreted by asymptomatic cats or dogs, most case reports document a potential cause of systemic (feline leukemia virus [FeLV], feline immunodeficiency virus, canine distemper, parvovirus) or local (GI lymphoma, coronavirus, *Campylobacter*, *Isospora* spp., *Toxocara cati*) immunosuppression in infected symptomatic animals.^{19,32,67,113} Concurrent infections with various organisms (*Capillaria* spp., *T. cati*, *Isospora felis*, *Pharyngostomum cordatum*) were detected in normal cats excreting cryptosporidial oocysts in the feces. Cryptosporidiosis was found to be more common among asymptomatic young and newborn kittens as compared with older (6 months or older) cats.⁸³

82.1.3 Clinical Findings

82.1.3.1 Cats

Because experimental inoculations in healthy adult cats or 6 week old kittens with *C. parvum* resulted in asymptomatic infections, whether cryptosporidial infections can cause diarrhea in healthy animals is questionable. Diarrhea can be self limiting or absent in naturally infected immunocompetent cats. Pathogenicity undoubtedly is greater in immunodeficient cats. Intestinal cryptosporidiosis in other FeLV negative or FeLV positive cats has also been associated with chronic anorexia, marked weight loss, and persistent diarrhea.¹¹³ The diarrhea is usually of a small bowel nature, characterized by high volume, low frequency stools with significant weight loss. Tenesmus, fresh blood, swelling, and discomfort may be seen with chronicity. *C. felis* has been identified as a cause of infection in people associated with cats (see Public Health Considerations). Clinical illness, when reported, has been that of diarrhea with occasional blood.⁸⁸ Many cats are possible carriers for this species, and clinical illness may only occur following stress or immunosuppression.

787

788

82.1.3.2 Dogs

In older reports in which the infecting species was unknown, experimental infection of healthy pups resulted in oocyst shedding without accompanying disease.¹¹³ In subsequent reports in which the infecting genospecies has been identified, a majority of dogs infected with *C. canis* have been asymptomatic. However, in two dogs, with concurrent parvovirus infection or immune-mediated thrombocytopenia, the dogs had hemorrhagic diarrhea.^{19,89} In one pup, *C. canis* was found in the stomach mucosae, as a novel finding.⁸² Naturally occurring cryptosporidiosis has been reported in a 1 week old pup that died after an episode of diarrhea and dyspnea,⁹⁷ whereas other pups infected with cryptosporidia did not show clinical signs suggestive of infection.¹¹³ As in cats, signs of diarrhea have been most severe in immunosuppressed dogs. Cryptosporidiosis has been described in immunosuppressed pups with distemper¹¹³ and in dogs with GI lymphoma.⁷ Cryptosporidial infection has been diagnosed in an adult dog with persistent diarrhea, weight loss, and malabsorption syndrome and no obvious cause for immunosuppression.³⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

82.1.3.3 Calves and Other Animals

Although cryptosporidial infection in calves without clinical signs of diarrhea is common, it is an important cause of diarrhea of varying severity (from mild intermittent to profuse watery with dehydration) among calves younger than 3 weeks.⁹⁸ The organism has also been identified in the bronchial epithelium of a calf.⁷⁷ Cryptosporidial diarrhea is also an important disease among young ruminants found in zoos. Less severe infections have been reported in young swine, lambs, and foals. The coccidian is fairly common in birds, infecting the digestive and respiratory tracts and the bursa of Fabricius, and may be a primary pathogen. In captive snakes, cryptosporidia causes gastritis and subsequent vomiting because it parasitizes the stomachs of these reptiles.⁹⁷

82.1.3.4 People

People of all ages can become infected with cryptosporidia, and the severity of disease depends on the immunocompetence of the host. Most people develop transient clinical signs and recover. Cryptosporidiosis is an increasingly common cause of death in people with AIDS.¹²² Individuals with congenital immunodeficiency disease may survive for years with cryptosporidiosis when fed parenterally. Immunocompetent persons may be infected readily with *Cryptosporidium*, as demonstrated when more than 400,000 people in Milwaukee developed diarrhea as a result of contracting the organism via the public water supply.⁷³ Enzootic infections by this means are very common.^{11,31,74} Infection among veterinary students is common after contact with infected calves and has been documented after contact with infected lambs,²⁸ a dog,³⁷ and cats.^{23,60,69} Canine and feline isolates have been found in human immunodeficiency virus (HIV)-infected people, but cat ownership by people with HIV is not associated with an increased risk to cryptosporidiosis.^{30,109} Severe stress or concurrent infection by viruses or bacteria serves to exacerbate the diarrheal syndrome.

In people, a causal connection has been cited between oocysts being shed in the stool and GI signs.⁵⁶ The typical prepatent period is 5 to 7 days. Clinical signs, which may last from 2 to 26 days in immunocompetent people, may include nausea, abdominal cramps, low grade fever, and anorexia. Occasionally, episodes last longer. Diarrhea may be profuse, and dehydration is a common sequela. Asymptomatic infections do occur, especially in recovery phases of the illness. Conversely, symptomatic patients can have intermittently negative stools.⁵⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 82-3 Fecal float with unstained oocysts suspended in water and viewed with bright-field microscopy ($\times 1500$). (From Gardiner CH, Fayer R, Dubey JP. 1988. An atlas of protozoan parasites in animal tissues, USDA Agricultural Handbook No. 651, USDA, Beltsville, Md.)

82.1.4 Diagnosis

82.1.4.1 Fecal Examination

Fecal oocyst excretion directly coincides with the onset and duration of clinical signs. Because cryptosporidial oocysts are directly infective when shed in the feces, caution must be used to avoid accidental infection. To destroy the oocyst, one part 100% formalin (38% formaldehyde) should be mixed with nine parts fluid feces before performing fecal examination procedures. Sodium acetate-acetic acid formalin is another acceptable fixative, but polyvinyl alcohol fixatives are not compatible with most staining procedures. Samples should also be formalinized before shipment to a diagnostic laboratory and should be placed in a nonbreakable container. The outside of the container should be disinfected to avoid accidental infection of laboratory personnel. The laboratory should be notified of suspicion of cryptosporidial infection. Oocysts may be seen microscopically on direct smears of feces, but concentration techniques, such as Sheather's sugar solution, can be used (see Fecal Examination, [Chapter 70](#)). Because oocysts are slightly smaller compared with erythrocytes, and because of transparency, unstained preparations using conventional light microscopy do not permit accurate identification.¹¹³ When searching for cryptosporidial oocysts on unstained preparations, phase contrast microscopy is often recommended; however, bright field microscopy can be used ([Fig. 82-3](#)). A wet preparation in which crystal violet is applied to fluid stools enhances visualization of organisms. Oocysts can readily be seen because they do not stain. Because the small and refractile oocysts cling to the coverslip on Sheather's flotation, focusing immediately beneath the coverslip is imperative. Oocysts appear as circular, sometimes concave, disks that are refractile and pink with bright field microscopy. Dark shadows of sporozoites may be seen within the oocysts.

Infectious Diseases of the Dog and Cat, 3rd Edition

Beagle pups experimentally infected with *C. parvum* of calf origin commenced shedding oocysts 3 to 5 days postinoculation (PI), with a peak shedding at 7 to 9 days PI. Shedding lasted for at least 80 days at a low or intermittent level.

Other procedures, used by diagnostic laboratories to demonstrate cryptosporidial oocysts in fluid stools, include formalin ethyl acetate (FEA) sedimentation technique or examination of direct smears of feces or intestinal contents with positive stains, such as Giemsa (Fig. 82-4), or acid-fast, negative stains, such as

788

Kinyoun's modified carbolfuchsin-malachite green, and crystal violet (Fig. 82-5).^{*} The negative stains give a clear halo around the oocysts. Using the FEA concentration method on watery stool specimens provided

789

100% detection with direct fluorescent antibody (FA) or acid fast staining when 10^4 oocysts/g or more were present.¹³⁶ For formed stools, 5×10^4 oocysts/g or more was needed for direct FA and 5×10^5 oocysts/g or more for acid fast staining. A modification of the acid fast technique using dimethyl sulfoxide has simplified the procedure by staining the internal structure of the organism. Newer but more expensive auramine rhodamine staining techniques are very sensitive.⁷⁵ Staining methods allow for easier detection of the oocysts and their differentiation from yeasts, which stain darker, are oval, appear in clumps, and may show budding, and are slightly smaller than cryptosporidia. Commercial kit staining methods are available.⁹⁷ A direct FA kit for staining cryptosporidial oocysts (and *Giardia* cysts) in feces is commercially available (Merifluor, Meridian Diagnostics, Cincinnati, Ohio). Although few evaluations have been reported in dogs and cats,^{75b} the test is effective for oocyst detection in fecal samples from calves and sheep.¹⁴⁵ Several enzyme-linked immunosorbent assays (ELISA) (ProSpecT and ProSpecTR, *Cryptosporidium* Microtiter Assay, Alexon, Sunnyvale, Calif.; Color Vue *Cryptosporidium*, Seradyn, Indianapolis, Ind.) for the detection of cryptosporidial antigen in feces are also available, but whether these tests will consistently reveal *C. felis* or *C. canis* is unknown. ELISA tests were more sensitive in detecting *Cryptosporidium* oocysts in a single fecal specimen of kittens compared to acid-fast staining and direct FA methods.^{75b} Nested polymerase chain reaction (PCR) has been used to detect *C. parvum* DNA in feces of symptomatic people with 500 oocysts/g of feces, some of whom had negative results with acid fast staining.⁶ Similar high sensitivity has been reported for PCR detection in calf feces.¹³⁶ PCR has been used for the diagnosis and the molecular typing of isolates causing cryptosporidiosis in dogs.^{3,2,121a} A nested multiplex PCR was developed that can simultaneously detect and distinguish between four zoonotic species: *C. parvum* genotypes 1 and 2, *C. canis*, and *C. felis*.⁷⁰ When compared with immunofluorescence, PCR has been shown to be 10 to 100 times more sensitive for the diagnosis of cryptosporidiosis in cats.^{63,121,121a} Flow cytometry has also been used to increase the sensitivity of oocyst detection.¹³³ See Appendix 5 for the laboratories that perform diagnostic tests and Appendix 6 for further information on test kits available for diagnosis of this disease.

* References: 25, 52, 71, 75, 91, 96.

82.1.4.2 Serologic Testing

An ELISA was developed to measure *Cryptosporidium* specific IgG in feline sera.⁶⁵ Positive antibody titers were correlated with exposure but not necessarily active infection or oocyst shedding. This test has been used as an epidemiologic surveillance tool.⁸⁰

82.1.4.3 Animal Inoculation

Oocysts for animal inoculation may be harvested by sugar centrifugation and stored in a refrigerator in 2.5% potassium dichromate for up to 6 months without appreciable loss of viability. Neonatal mice are inoculated per os, and the intestinal tissues are examined microscopically 1 week later.

82.1.4.4 Intestinal Biopsy

Gross lesions consist of enlarged, congested mesenteric lymph nodes, and changes are most severe in the distal ileum. The mucosa is hyperemic and may contain watery, yellow contents. Giemsa and routine hematoxylin and eosin stains are effective given that most parasite stages are basophilic (Fig. 82-6). As a routine method of diagnosis, biopsy is costly, time consuming, and lacks sensitivity because only small amounts of tissue can be examined.

Specimens may be fixed in Bouin's or formalin solutions. Samples must be fixed within hours of biopsy procedure, otherwise cellular death associated with autolysis causes rapid loss of the intestinal surface that contains the organisms. Microscopic lesions vary in degree of villous atrophy, reactive lymphoid tissue, and inflammatory infiltrates in the lamina propria, consisting of neutrophils, macrophages, and lymphocytes. Blunting of the intestinal villi and crypt hyperplasia is apparent. Parasites may be found throughout the intestines but are usually most numerous in the distal small intestine. Electron microscopy (EM) readily identifies organisms by their unique ultrastructural characteristics and location within distinctive parasitiferous vacuoles.⁹⁷ EM shows that the organism is covered by the host cell microvillous membrane and therefore is intracellular but extracytoplasmic in location.

82.1.5 Therapy

Infections in immunocompetent animals or people are usually self limiting, and full recovery soon ensues. To date, few drugs have been used successfully for treating cryptosporidiosis, although more than 100 have been screened.⁵⁸ Spiramycin showed early promise, but subsequent studies did not corroborate its efficacy.¹⁰⁸

Eflornithine,¹¹⁷ oral bovine dialyzable extract,⁷⁹ and hyperimmune bovine colostrum¹¹² have shown clinical benefit. The aminoglycoside antibiotic, paromomycin (Humatin, Parke Davis, Morris Plains, N.J.), is effective in treating acute intestinal cases of cryptosporidiosis in people,¹⁸ calves,²⁶ mice,⁴² and rats.¹³⁵ Clinical signs of disease and oocyst shedding were eliminated in cats and dogs after paromomycin was administered for 5 days (Table 82-2).^{7,8} Paromomycin is not absorbed from the GI tract unless gut epithelium is injured. If injured, a resulting absorption of paromomycin, renal damage, or deafness similar to that caused by other aminoglycosides may occur. Acute renal failure has been described in four cats receiving excessive doses of paromomycin for the treatment of hemorrhagic diarrhea presumably caused by cryptosporidiosis.³⁵

789

790

Infectious Diseases of the Dog and Cat, 3rd Edition

Paromomycin was effective in preventing cryptosporidial enteritis in a controlled study in goats.⁵⁵ See the Drug Formulary, [Appendix 8](#), for further information on this drug. Although paromomycin seems effective against ileal infections, it was ineffective against cecal and biliary tract infections in immunosuppressed rats.¹¹⁵ Tylosin (11 mg/kg, orally, twice daily for 28 days) was helpful in relieving diarrhea in a cat with cryptosporidiosis and lymphocytic duodenitis,^{46,64} which may be related to its antibacterial effects. Neither prior treatment with clindamycin nor metronidazole was effective in treating this cat. Pretreatment with paromomycin was effective in prolonging the prepatent period of infection in a controlled study of calves with experimentally induced infections; however, it did not reduce the severity or occurrence of infection.³⁸ Paromomycin was no more effective than placebo was in treating human patients with advanced AIDS.⁴⁵ Azithromycin, a macrolide antibiotic, was more effective than paromomycin was when used at identical regimens against cryptosporidial infection involving the ileum, cecum, or biliary tract of immunosuppressed rats.¹¹⁵ Azithromycin has been effective in treating an immunocompetent man with cryptosporidiosis acquired from a calf.¹⁰ Azithromycin is being tested in human trials but has not been extensively studied for the treatment of infected dogs or cats. Azithromycin, combined with paromomycin, was highly effective in treating an immunocompromised person with AIDS.¹²⁴ Clarithromycin, a related derivative to azithromycin, was highly effective in preventing development of cryptosporidiosis in human patients with AIDS when it was combined with a rifabutin as prophylaxis for mycobacterial infections.⁵⁰ Nitazoxanide has shown some efficacy in people infected with cryptosporidiosis and has been licensed for treatment.^{118,138} In one study, cats treated with nitazoxanide showed immediate cessation of cyst excretion in their feces, but administration was complicated by vomiting soon after the cats received the oral drug.³⁵ This drug needs further study in cats and dogs. Lasalocid, an ionophorous antibiotic, had in vitro and in vivo activity against cryptosporidia,⁴³ although further studies are needed. For additional information on the above drugs, see [Chapter 34](#), and the Drug Formulary, [Appendix 8](#).

Fig 82-6 *Cryptosporidium* (arrows) in intestine from an infected calf is characteristically located at the microvillous border (H and E stain, ×250). (Courtesy University of Georgia, Athens, Ga.)

- a See Drug Formulary, [Appendix 8](#), for specific information on drugs.
- b Dose per administration at specified interval.
- c Dose for systemic infections; effective level for this disease has not been established.

Parenteral fluid replacement is usually indicated if dehydration is severe. Antibiotic therapy for eliminating secondary bacterial invaders may be necessary. Because absorptive-cell surface epithelium is lost and developing glutamine-dependent epithelium predominates, oral rehydration solutions containing glutamine may be helpful as supportive care.⁴⁰

82.1.6 Public Health Considerations

Cryptosporidial infections in people were not recognized until 1976. Since that time, it has been diagnosed with increasing frequency. Animal handlers, medical personnel, people living or traveling in developing countries, and children in day care facilities have the highest risk of exposure. Infection is not restricted to, but is more severe in, immunocompromised hosts. Between 4% and 7% of human patients admitted to hospitals for gastroenteritis have cryptosporidiosis, and infections are more common during the warm, humid months.

Aquatic transmission via drinking water, the source of infection for more than 400,000 people in Milwaukee in 1993,⁷³ and swimming pools^{74,78} have been major sources of infection. One outbreak in the United States has

also been associated with a recreational lake.⁶² Although major human outbreaks of cryptosporidiosis caused by *C. hominis* and *C. parvum* have been linked to contaminated drinking water, none has incriminated *C. felis* or *C. canis*.^{70a} Reports of food contamination with feces from infected people or animals are less common.⁵⁸

Owning a dog or cat does not increase the risk of humans developing cryptosporidiosis.^{70a} Although epidemiologic data implicating household pets as sources of cryptosporidiosis in people is weak, several reports have been issued of human infection after contact with infected cats⁶⁰ and a dog.³⁷

C. parvum of the cattle genotype has been considered as the predominant zoonotic risk for people. Dogs may also be infected with the cattle genotype, which they may conceivably pass on to people. Dogs are most commonly infected with the host-restricted species *C. canis*. Therefore dogs are not a significant reservoir for human infection. The dog isolate has been identified only in a few reports of human infection.^{*} The people in these reports have generally been immunocompetent and nonsymptomatic. Similarly, human infection with *C. felis* has been an uncommon occurrence; however, clinical illness has been more apparent. Fourteen cases of *C. felis* infection of people have been documented with genetic methods.[†] Clinical illness, characterized by watery diarrhea, was observed in immunocompetent (n = 4) and immunosuppressed (n = 10) people.¹² Reports of human cryptosporidiosis acquired from cats have been published in which the infecting species was unknown.³⁰ A nosocomial outbreak of *C. parvum* infection in animals and people in a veterinary teaching hospital was associated with infection from a hospitalized calf.⁶¹ Numerous reports of transmission from calves to humans

Infectious Diseases of the Dog and Cat, 3rd Edition

have been issued.^{66,68,83} Genetic analyses of human and bovine isolates have shown that two types of *C. parvum* exist.¹⁰⁷ One is involved with calf to human, human to human, human to calf, and other interspecies transmissions. The other is an exclusive anthroponotic cycle, with people being both the reservoir and affected population. Because cryptosporidiosis can be fatal in immunocompromised people, especially those with AIDS, owners of infected animals must be made aware of the zoonotic risks. *C. muris*, predominantly a rodent species that can experimentally infect dogs and cats among other animals, has been isolated from immunocompromised people.¹⁰⁴ Whether dogs can be reservoirs for this species is uncertain.

In immunocompetent people, GI signs, in decreasing frequency, include profuse watery diarrhea, low grade fever, vomiting, and abdominal discomfort. Diarrhea usually lasts 3 to 12 days. Infants, children, and older adults have more chronic persistent diarrhea and dehydration. In immunodeficient individuals, especially those with AIDS, the diarrhea becomes chronic (usually 20 or more weeks), debilitating, and potentially fatal. In addition, respiratory tree, biliary, and pancreatic duct colonization has been reported in immunodeficient people with associated clinical signs.¹⁷

Cryptosporidia are resistant to commercial bleach (5.25% sodium hypochlorite); routine chlorination of drinking water does not affect oocyst viability.¹¹⁴ Of the common disinfectants, only formol saline (10% solution) and ammonia (5% solution) were effective in destroying the viability of cryptosporidial oocysts. However, oocysts had to be in contact with the disinfectants for 18 hours. More concentrated (50%) ammonia solutions have been effective after 30 minutes. Moist heat (steam or pasteurization [over 55° C]), freezing and thawing, or thorough drying are more practical means of disinfection. Swimming pools can be disinfected by using high-chlorine concentrations for long periods (3 mg/L of water for 53 hours or 8 mg/L for 20 hours).⁵⁷ Excellent sanitation and liberal use of boiling water for scalding food and water bowls should minimize contamination in a clinical environment. Chlorination of drinking water is not effective, and because filtration of this small organism is difficult, the organism can enter treated municipal supplies. Even bottled noncarbonated mineral water has been contaminated.⁹⁵

† References: 12, 14, 87, 106, 109, 144.

82.2 CYCLOSPORIASIS

Cyclospora cayetanensis is a member of subclass Coccidia in the phylum Apicomplexa that infects people and animals in warm or tropical climates worldwide. For many years, *C. cayetanensis* was considered a cyanobacterium, a blue green alga, or a large (8 to 10 µm) strain of *Cryptosporidium*. Phylogenetically, the organism is most closely related to *Eimeria*.¹¹⁰ Veterinarians should be aware that this parasite may be mistaken for *Cryptosporidium*, and parasites closely resembling *Cyclospora* have been found in animals. Both *Cyclospora* and other coccidia have similar appearing oocysts in feces and produce similar GI signs.¹⁴³ The morphology and features of *Cyclospora* that distinguish it from other coccidial oocysts are listed in [Table 82-3](#). The life cycle of *Cyclospora* is unknown, but transmission occurs through contaminated water.^{75a} Oocysts are passed in a noninfectious state and must survive long enough to sporulate and to be ingested by a susceptible host. The oocyst dies immediately when desiccated. *Cyclospora* oocysts have only been recovered in limited quantities from water sources because of technological limitations of recovery methods. At least 2 weeks at a temperature range of 25° C to 30° C (77° F to 86° F) are required outside the host for sporulation of oocysts to be infectious.¹²⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

Outside this range, oocyst sporulation does not occur, or the time interval is markedly prolonged. Following ingestion, sporulated oocysts excyst in the small bowel and enter epithelial cells. The upper small intestine is the site of replication in immunocompetent hosts, and more diffuse intestinal involvement occurs in the immunosuppressed hosts.¹⁰⁵ Asexual replication is thought to occur in the small bowel with extruded merozoites penetrating new epithelial cells. Sexual reproduction occurs in the small bowel epithelium as unsporulated oocysts are shed in the stool.¹⁰¹ Malabsorption is caused by inflammation, villous atrophy, and crypt hyperplasia. Cholecystitis has also been reported in people.¹⁴⁸

Outbreaks correspond to the time of the rainy season in endemic countries. Drinking contaminated water or eating unwashed berries (e.g., raspberries) or other plants (e.g., basil, salad leaves) imported from some countries in South America or Southern Europe have been implicated as risk factors in the United States,^{*} where the prevalence in stool specimens submitted to diagnostic laboratories is generally less than 0.5%.^{51,125} Carriage rates of up to 20% of people with diarrhea are found in endemic tropical countries. Animals or insects may act as reservoir hosts maintaining the organism in nature. Although other animals might be infected, this has been currently identified only as a human pathogen. *Cyclospora*-like organisms have been recovered from dogs, chickens, ducks, and primates.¹²⁷ Only in primates has the organisms been confirmed as *Cyclospora*. In other animals, inert passage through the intestinal tract cannot be eliminated. Two cases in dogs in Sao Paulo, Brazil, have been reported.¹⁴⁷ However, when dogs were experimentally inoculated orally with *Cyclospora* cysts, infection did not occur.²² In Mexico, feces of cats were examined to no avail; however, a large number of oocysts morphologically and biologically resembling *C. cayetanensis* was found in poultry feces.²⁹ Fowl feces may be involved in contamination of poultry meat, water supplies, vegetables and fruits, or any combination of these. Animal to human or person to person transmission is not yet documented.

791

792

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 82-3 Comparison of Coccidial Oocysts and Transmission

VARIABLE	CYCLOSPORA	CRYPTOSPORIDIUM	ISOSPORA	TOXOPLASMA
Definitive host	People, possibly animals	People, dog, cat, other animals	People, dog, cat other animals	Cat
Intestinal biopsy				
Intracellular stages	T, S, M	T, S, M, G	T, S, M, G	T, S, M, G
Intracellular location	Deep seated	Intramembranous, extracytoplasmic	Deep seated	Deep seated
Size in tissue (mm)	4–16	2–5	3–15	3–15
Feces				
Oocyst size (mm)	8–10	4–6	10–19 × 20–30 Varies with species	12 × 10
Sporulated oocyst				
Number sporocysts	2	0	2	2
Number sporozoites per 2 sporocyst		4 per oocyst (naked)	4	4
Acid-fast staining	Variable	Yes	Yes	Yes
Ultraviolet autofluorescence, 365-nm filter	Blue-green Circles	None	Yes	None
Auramine fluorescence	Weak	Bright	Variable	Variable
Infectivity in fresh feces (already sporulated)	No	Yes	No	No
Zoonotic transmission	Unknown	Many animals	None, host specific	Cat
Host-to-like-host transmission	Unknown	Yes	Yes	Yes, uncommon via oocyst

Cyclosporiasis produces relapsing watery diarrhea, fatigue, systemic influenza-like manifestations, and weight loss in susceptible people such as those infected with HIV, those receiving organ transplants or immunosuppressants, and those traveling to different geographic areas. Clinical signs usually begin after 1 week following exposure. Clinical signs are infrequent or transient in immunocompetent hosts, who usually recover within several weeks.¹⁰¹

Diagnosis is made by microscopic detection of oocysts in fecal specimens. At present, definitive oocysts have only been identified in human feces. These oocysts can be confused with *Cryptosporidium* and *Isospora*, which also stain acid-fast in stool specimens. However, *Cyclospora* has a variable staining intensity on an individual preparation. The organisms are passed unsporulated in fresh feces and on superficial examination, they may be misidentified as a fungal spore. Although PCR has been used for specific detection of the organism in fecal specimens, cross amplification with other coccidia has not been determined.^{99,111} Organisms can also be detected on jejunal aspiration or biopsy. Unlike cryptosporidiosis, cyclosporiasis in people responds to 7 days of treatment with trimethoprim sulfonamides with rapid cessation of diarrhea and shedding of oocysts.^{49,134} Should a dog or cat be diagnosed with clinical cyclosporiasis or pose a potential risk for human infection, routine dosages of trimethoprim-sulfonamide can be used (see Drug Formulary, [Appendix 8](#)). As with other coccidia, chlorine bleach is not an effective disinfectant for *Cyclospora* spp. oocysts.

Infectious Diseases of the Dog and Cat, 3rd Edition

C. cayetamensis requires a period in the environment to sporulate into the infectious oocysts. Therefore direct animal-to-person or person-to-person spread would be minimal. People tend to acquire their infection from consuming contaminated water or produce. Nevertheless, cyclosporiasis in Peru has been epidemiologically associated with ownership of domestic animals, especially birds, guinea pigs, and rabbits.⁹

83 CHAPTER 83 Rhinosporidiosis

M. Cecilia Castellano

Edward B. Breitschwerdt

83.1 ETIOLOGY

Rhinosporidiosis, a chronic granulomatous disease caused by *Rhinosporidium seeberi*, induces tumorlike growths of epithelial tissues in domestic animals, birds, and people.^{6,13,15}

The taxonomy of *R. seeberi* has long been controversial. Based on its morphologic characteristics, it has been classified in the past few years as a fungus by most microbiologists. Phylogenetic analysis indicates *R. seeberi* to be a member of a newly recognized group of human and animal pathogens that form a branch in the evolutionary tree near the animal-fungal divergence.^{8,10} It has been proposed that this new phylogenetic group be referred to as the class Mesomycetozoea (between fungi and animals) and *R. seeberi* be considered a monotypic genus within this class.^{10,19} Genetic analysis of isolates suggests that host-specific strains of the organism may exist.^{22a} Like other mesomycetozoeans, *R. seeberi* is associated with aquatic environments. Although *R. seeberi* is generally believed to be the causative agent of rhinosporidiosis, a few challenge this accepted premise. In one study, a cyanobacterium *Microcystis aeruginosa* was isolated from water in which human patients with the disease were bathing.^{2,3} The organism was also identified in clinical specimens; however, additional confirmation is needed for this hypothesis. Microscopic findings of lesions indicate that *R. seeberi*, and not a bacterium, is the cause of this disease.

Although a few successful attempts to propagate *R. seeberi* in tissue culture have been described,^{6,14} the results have been questioned.¹⁸ Most microbiologists consider *R. seeberi* to be intractable to culture.^{8,10,19} The infective unit is a small (7- to 15- μ m), round spore that once implanted in tissues progressively develops into large (100- to 450- μ m), spherical bodies known as *sporangia*. Sporangia undergo a maturation process, resulting in the production of 16,000 to 20,000 endospores that are then discharged through an apical pore, and the cycle is reinitiated.⁶

83.2 EPIDEMIOLOGY

Rhinosporidiosis is endemic in India, Sri Lanka, and Argentina and is reported sporadically from other parts of the world. In the United States, canine rhinosporidiosis has been reported only in the southern states; however, occurrence of the disease in a dog native to Ontario and in a cat from a suburb of Washington, DC, suggests the possibility of a more widespread distribution in North America. In Europe, canine rhinosporidiosis has been recognized only in northern Italy.⁷

Feline rhinosporidiosis has been reported in two outdoor cats, both in the United States.^{20,23}

R. seeberi is stimulated to develop mature endospores that are released from its sporangia after exposure to water, thus the disease is associated with wet environments and the host's moist mucous membranes. Most affected animals are exposed to flowing or impounded water. Infection frequently involves the mucous membranes of the

Infectious Diseases of the Dog and Cat, 3rd Edition

nasal cavity, but it may occasionally affect the ear, pharynx, larynx, trachea, esophagus, urogenital mucosae, and skin. Reported cases of canine and feline rhinosporidiosis have involved only the nasal cavity.

The disease is more common in large-breed dogs with a mean age of 5 years (and a range of 1.5 to 13 years) and seems to be more common in males, as it is in people and horses. Behavioral and biologic factors may be responsible for this apparent predisposition. Because of the few reported cases, it is not known whether the same tendencies are found in cats.

83.3 PATHOGENESIS

The pathogenesis of rhinosporidiosis has not been completely characterized because of the difficulties associated with in vitro propagation of the organism.

R. seeberi has not been detected in the environment, and its natural host remains unknown. Reports from endemic areas suggest that infection is acquired by mucosal contact with stagnant water. Mucous membrane trauma may be a predisposing factor. In arid countries, most human infections are ocular, and dust is postulated to be a fomite. In vitro studies suggest that endospore release from mature sporangia is stimulated by mucous secretions.¹⁸ Once implanted in tissues, endospores elicit a severe, focal pyogranulomatous reaction.

Little is known about the immune response to *R. seeberi*. A mucoidlike layer with immunogenic properties has been recognized beneath the sporangium's cell wall.^{11,18} It has been suggested that it may play a role in the immunology of the disease.

83.4 CLINICAL FINDINGS

794

Clinical findings include wheezing, sneezing, unilateral seropurulent nasal discharge, and epistaxis. Polypoid lesions may be visible in the nares (Fig. 83-1) and may also be visualized by rhinoscopy in the rostral nasal cavity (Fig. 83-2). Single or multiple polyps ranging in size from a few millimeters up to 3 cm are pink, red, or pale gray and covered by numerous pinpoint white-yellowish granules (sporangia). Polyps may be sessile or pedunculated, and the superficial surface is irregular, glistening, and possibly ulcerated. Duration of clinical signs in reported canine cases ranges between 2 weeks and 8 months.

83.5 DIAGNOSIS

The organism can be demonstrated by several stains: hematoxylin-eosin, Wright, Gridley's, toluidine blue, periodic acid-Schiff, and Grocott's. Cytologic examination of nasal exudate and of scrape or brush samples obtained from the surface of the polyp usually allows diagnosis through identification of single or clusters of *R. seeberi* spores. Although less common, sporangia may be observed (Fig. 83-3). Sporangia and spores should be easily recognized by histologic examination.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 83-1 Two-year-old male dog of mixed German shepherd breeding from Argentina, with a bright red sessile growth in the right nostril. Rhinosporidiosis was diagnosed after histologic examination.

Fig 83-2 Rostral rhinoscopy in dog with rhinosporidiosis. Polyp is attached to nasal mucosa. (Courtesy University of Georgia, Athens, Ga.)

Fig 83-3 Scrape smear of nasal polyp. **A**, Numerous single endospores of *R. seeberi* dispersed in epithelial-cell background (PAS stain, ×200). **B**, Juvenile sporangium of *R. seeberi*. Note transparent capsules and numerous endospores with internal globular bodies (Wright stain, ×200).

A polymerase chain reaction assay specific for *R. seeberi* has been developed.⁸

83.6 PATHOLOGIC FINDINGS

Microscopic examination reveals that polyps are composed of fibrovascular tissue lined by squamous or columnar epithelium that is frequently ulcerated.⁶ Sporangia at different stages of maturation can be seen (Fig. 83-4) and may be releasing spores through the epithelium to the superficial surface. A superficial exudate most prominent in areas of spore extrusion is composed of spores, neutrophils, epithelia, and erythrocytes. A mixed inflammatory response consisting predominantly of plasma cells and lymphocytes and to a lesser extent, macrophages, is scattered throughout the tissue.

794

795

Infectious Diseases of the Dog and Cat, 3rd Edition

83.7 THERAPY

Surgical excision remains the treatment of choice and may be curative when a single polyp is excised. Because of the frequent rostral location of the polyps, surgical excision through the nares or by anterolateral approach to the nares generally is possible, negating the necessity for the more invasive dorsonasal flap procedure. In four dogs treated with surgery alone, no recurrence was noted after 1 to 2 years.⁷ Recurrence has been reported 2 to 12 months after surgery in dogs with single or multiple lesions. Dapsone has been used to treat human rhinosporidiosis with variable success^{12,6} and might be considered as an adjunct to surgical removal of lesions in dogs or cats. Light and electron microscopic studies have demonstrated that dapsone induces degenerative changes in *R. seeberi* by inhibiting division of the organism.²² Treatment with dapsone (1 mg/kg every 8 hours for 2 weeks, followed by 1 mg/kg every 12 hours for 4 months) likely cured a dog that developed polyps after surgical extirpation.^{6,17} Ketoconazole (8.7 mg/kg every 8 hours for 21 days) eliminated nasal discharge in a dog after 4 days, and visual and cytologic resolution of the polyps occurred after 21 days of therapy.⁶ Although treatment continued for an additional 21 days, the disease recurred 6 months later, necessitating surgical excision of a large polyp. Medical therapy of rhinosporidiosis may be improved by screening antiparasitic drugs that have an effect on other members of the Mesomycetozoea class.

83.8 PUBLIC HEALTH CONSIDERATIONS

Although people are also affected with this disease, no evidence supports the possibility of transmission of *R. seeberi* from animals to people. Dogs and people appear to become infected from common environmental sources.

Andrea Tipold

Marc Vandeveld

Granulomatous meningoencephalitis (GME) has been reported in dogs in the United States,^{16,17,31} Australia,⁴⁷ New Zealand,⁴ Japan,⁷⁴ and several European countries.¹³⁷ It is a relatively common condition and is characterized by disseminated inflammatory lesions in the central nervous system (CNS) with perivascular granuloma formation.¹³⁸

84.1.1 Etiology

GME is thought to be an infectious disease. However, experimental attempts to transmit the agent in dogs using GME-infected brain tissue have been unsuccessful.⁸⁵ Bacteria and fungi can cause granulomatous lesions in the CNS of small animals, but such agents would not likely have escaped detection on light microscopic examination of GME. Possibly, the periodic acid-Schiff-positive and acidophilic inclusions in macrophages in lesions in some cases may be an unidentified infectious agent.³¹ Other investigators have searched unsuccessfully for an infectious organism by electron microscopic (EM) examination of the tissues.³³ Serologic tests for toxoplasmosis have been carried out in a few cases, but the results have been negative.¹⁷ The possibility of rickettsial infection as an underlying cause should also be considered. Certain viral infections such as equine infectious anemia, feline infectious peritonitis, and visna are also associated with granulomatous lesions of the CNS. Canine distemper virus (CDV), which is responsible for a variety of CNS lesions, can be excluded as a cause of GME because systematic immunocytochemical studies in a large number of GME cases failed to find CDV antigen in the lesions.⁵⁹ The presence of anti CDV antibody titers in the CSF of seven dogs with GME can probably be explained by unspecific invasion and amplification of B cells in the inflammatory lesions. Attempts to identify reverse transcriptase activity in the cerebrospinal fluid (CSF) failed. Results have also been negative for rabies virus antigen, fungi, bacteria, and protozoa.⁷² Sophisticated culturing techniques are probably necessary to identify the agent. Some dogs with GME-compatible CSF cytologic abnormalities have had positive serologic test results to *Bartonella vinsonii* subsp. *berkhoffii* (see [Chapter 54](#)).¹⁸ Simultaneous onset of clinical signs in two related Afghan hounds and a certain predisposition for small-breed dogs suggests that the disease may be associated with either common exposure or a genetic predisposition.⁵⁴ Lesions consist of infiltrates of major histocompatibility complex class II antigen positive macrophages and to an equal amount of T and B cells, in contrast to virus-induced encephalitis with a predominance of T cells and bacterial and protozoal infections with a predominance of B cells in perivascular cuffs.¹³³ Other investigators have detected a predominance of T cells.⁷² Before its recognition as a clinicopathologic entity, GME lesions were classified as reticulosis, implying some kind of proliferative disorder. The belief was that granulomatous inflammatory lesions could evolve to neoplasms of the monocytic-microglial lineage. In some instances, differentiating between GME and certain lympho-histiocytic tumors remains difficult. That GME might be a purely proliferative rather than an infectious disease cannot be dismissed.

796

Infectious Diseases of the Dog and Cat, 3rd Edition

84.1.2 Clinical Findings

The disease occurs most often in young to middle aged small purebred females, but dogs of different ages, breeds, and sex can develop the disease. The prevalence for smaller breeds, especially poodles, small terrier breeds, Pekingese, and Maltese, appears to be higher.¹⁶ The disease rarely occurs before the age of 2 years. Clinical signs usually have an acute onset, and the disease is always progressive. Two forms of the disease are described. In the acute form, clinical signs develop rapidly over the course of 1 to 10 days, and without treatment, it is rapidly progressive and fatal. In the chronic form, signs may develop more slowly over a period of 1 to 4 months. The chronic form with long-term survival for several months to years was thought to be associated with the focal form of GME when large tumorlike masses develop. However, clinical signs with slow progression can also be found with diffuse histopathologic lesions. Specific neurologic signs cannot be expected because lesions can occur anywhere in the CNS. Signs are associated with the site of most extensive damage or may reflect a multifocal lesion. Signs consist of disturbances in gait and postural reactions, with ataxia, dysmetria, paresis, and paralysis; changes in mental status, with confusion, lethargy, and coma; and cranial nerve dysfunction. In the acute stage of the disease, more than one half of the animals have fever, and many exhibit paraspinal discomfort¹¹⁹ or cervical pain.^{31,120} In this stage of the disease, central vestibular signs are common (Fig. 84-1); seizures may also be observed. The clinical presentation can also be suggestive of a space occupying mass referring to a single site of involvement, most frequently the posterior fossa, with brain stem and cerebellar signs. Cerebral or spinal signs sometimes predominate. A particular ocular localization of GME, previously called ocular reticulosis, occurs with acute unilateral or bilateral blindness and ophthalmoscopic evidence of optic neuritis.¹⁶

Fig 84-1 Dog showing central vestibular signs.

Infectious Diseases of the Dog and Cat, 3rd Edition

84.1.3 Diagnosis

Typical hematologic and biochemical findings are lacking. Neutrophilia may be present in the acute disease.^{119,120} The CSF is abnormal, with a marked pleocytosis; cell counts of 100 to several thousand leukocytes/ μ l are usual. Mild pleocytosis or even a normal cell count is observed in animals pretreated with glucocorticoids. Mononuclear cells predominate, but a mixed pleocytosis can also be observed with varying numbers of neutrophils.⁷ Cytologic examination of the CSF may reveal large anaplastic mononuclear cells with abundant lacy cytoplasm¹⁶ and up to 20% are macrophages. The acute and the chronic form of the disease cannot be distinguished by differential cell count. Protein concentration is usually increased, with a range from reference values up to 1119 mg/dl and a mean of 163.2 ± 25 mg/dl.⁷ Electrophoretic examination of the CSF may suggest blood brain barrier disruption and intrathecal immunoglobulin synthesis.^{119,120} Such changes are not specific for GME. Electroencephalographic (EEG) patterns studied in some dogs with GME were unspecific. In focal GME, the tumorlike lesions can be detected with computed tomography (CT)¹⁶ after intravenous (IV) inoculation of contrast medium and magnetic resonance imaging (MRI).⁹⁵ With CT, GME lesions are contrast enhanced, however, not to the degree of meningiomas.¹²¹ MRI features can resemble neoplasia in which lesions with T₁-weighted images appear isointense and have hypointense margins, but lesions with T₂-weighted images appear hyperintense.⁸² Inflammatory lesions may have lesions on T₁- and T₂-weighted images that enhance with contrast.⁸² Regardless of ancillary testing, a definitive intra vitam diagnosis still depends on histopathology of brain biopsies. These specimens must be taken by stereotaxic equipment, surgical biopsy, or necropsy. Without these diagnostic modalities, GME can be mistaken for a neoplasm or another focal encephalitis.¹²⁵ Mixed cell patterns and increased proteins in CSF can also occur with inflammatory encephalitis produced by CDV, *Neospora caninum*, *Toxoplasma gondii*, and systemic mycoses.

796

797

84.1.4 Pathologic Findings

Lesions are found in the meninges, brain, and spinal cord, especially in the cervical segments. White matter is generally more severely affected compared with gray matter. Although the lesions are disseminated, the cerebral hemispheres, the midbrain, and the region around the fourth ventricle are most frequently involved. The lesions, which are strictly associated with the vasculature, consist of perivascular cuffing of monocytes, lymphocytes, plasma cells, and sometimes a few neutrophils and mast cells. The formation of eccentrically situated nodular foci of macrophages within these cuffs is a characteristic finding in GME (Fig. 84-2). The cuffs can be distinguished in three degrees of severity: small disseminated perivascular lesions, confluence of several perivascular cuffs into small granulomas, and large focal coalescing granulomas, leading to the formation of tumorlike lesions. Additionally, necrosis of the neuropil, mitosis in the perivascular cuffs, and edema may be observed in both forms of the disease. Tryptase-positive mast cells can be found in perivascular cuffs of the lesions of GME, in the meninges, and in the CNS parenchyma. Dogs with the acute form of the disease have significantly more mast cells compared with dogs with the chronic form, suggesting that this cell population may contribute to the dynamics of the lesion and to the rapid clinical deterioration of dogs with GME.³⁹ Antiastrocyte antibodies are increased in the CSF of dogs with GME and necrotizing meningoencephalitis (NME) but not with other inflammatory conditions of the CNS.⁹³ Autoantibody was also detected in some dogs with brain tumors and may represent only a secondary response to a damaged blood-CNS barrier.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 84-2 Histologic section from a dog with granulomatous meningoencephalitis. **A**, Typical perivascular mononuclear cuffing with eccentrically situated nodular foci of macrophages (*arrows*) (H and E stain, $\times 100$). **B**, Closer view of a perivascular lesion (H and E stain, $\times 250$).

84.1.5 Therapy

No specific therapy for GME exists, although improvement frequently has been observed following administration of glucocorticoids or diverse immunosuppressive drugs (Table 84-1). Because a final intra vitam diagnosis of GME is difficult, treatment studies have been cumbersome. However, all known patients have eventually died of the disease despite glucocorticoid or other treatments. Because glucocorticoid therapy provides only temporary improvement in many cases, other immunosuppressive drugs have been used. The use of procarbazine or cytosine arabinoside, two alternative antineoplastic drugs, may be considered.^{34,99} Procarbazine is a prodrug that forms numerous active cytotoxic metabolites following metabolism. This DNA-alkylating agent is an anticancer drug that has also been used in human transplant cases. It can be used alone or in combination to treat GME.³⁴ Procarbazine is well absorbed orally and may cause neurotoxicity, vomiting, or hepatic dysfunction. The patient should be monitored closely for cytotoxicity, and after 1 month of daily therapy, every-other-day dosing should be used. Cytosine arabinoside, a parenteral drug, is also effective, has few side effects, and is reasonably priced.³⁴ Because of its parenteral route, it is used primarily for induction therapy in the hospital. Both drugs cause myelosuppression and must be monitored for signs of toxicity. Leflunomide is a pyrimidine synthesis inhibitor that suppresses activated T cells. It has been used as an alternative treatment because of the side effects or lack of responsiveness when other drugs are used. Leflunomide can affect cell replication, causing leukopenia, diarrhea, or alopecia in people. Mycophenolate mofetil (MMF) has been used to treat dogs with various immune-mediated diseases such as pemphigus foliaceus and myasthenia gravis. It inhibits an enzyme in purine synthesis, which in turn suppresses lymphocyte function. It causes minimal myelosuppression. MMF is expensive; however, it has a low degree of toxicity,

Infectious Diseases of the Dog and Cat, 3rd Edition

which is usually associated with vomiting or diarrhea. Cyclosporine has shown to be of benefit in treating dogs with localized GME.¹ The response to cyclosporine alone or initially in combination with glucocorticoids achieved remission and halted progression of neurologic signs for up to 1 year of monitoring with continued daily administration of a maintenance dosage. Use of cyclosporine without glucocorticoids avoided many of the undesirable side effects. Nephrotoxicity of cyclosporine was not observed, and blood monitoring showed safe therapeutic blood levels of the drug. Excess shedding of hair, alopecia, and potential worsening of an existing urinary tract infection were the observed side effects.

Table 84-1 Recommended Dosages of Immunosuppressive Drugs for Neurologic Diseases of Unknown Origin

DRUG ^a	SPECIES ^b	DOSE	ROUTE	INTERVAL (HOUR)
Prednisolone	B	2 mg/kg	IV, IM, SC	12–24 ^c
Dexamethasone	B	0.2–0.4 mg/kg	PO, IM, SC	12–24 ^c
Procarbazine	D	25 mg/m ²	PO	30 ^d
Cyclosporine	D	3–6 mg/kg	PO	12 ^e
Leflunomide	D	4 mg/kg	PO	24
Cytosine arabinoside	D	100 mg/m ²	IV, SC	24 ^f
Mycophenolate mofetil	D	10 mg/kg	SC	12

B, Dog and cat; D, dog; IV, intravenous; IM, intramuscular; SC, subcutaneous; PO, by mouth.

- a For more information on all drugs, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c Dose is gradually tapered over 4 months to the lowest that is effective in maintaining remission. Rarely can drug therapy be discontinued.
- d After 30 days, every-other-day dosing is given. With no control, dose is increased to 50 mg/kg every other day and 25 mg/kg on alternate days.
- e Generally, the 3-mg/kg dose is used for induction. Response to treatment and blood levels should be monitored to achieve efficacy and avoid nephrotoxic side effects. Drug levels should be checked 4 to 6 hours after last dose. Dose is usually reduced to every 24 hours for long-term maintenance.¹
- f Use to induce immunosuppression for 4 days in dogs.

Radiation therapy with cobalt or linear accelerator has been used to slow the progression of the disease.⁹⁸ Dogs with focal lesions survive longer than do those with multifocal neurologic signs.⁹⁸ Radiation injury of cranial tissues is an adverse effect; however, this may be an alternative to systemic immunosuppression caused by chemotherapy.

Anticonvulsants may be needed to control seizures associated with inflammatory forebrain lesions in dogs with GME. Oral phenobarbital and potassium bromide are indicated for general use, and IV or rectal diazepam should be used in cases of status epilepticus.

The prognosis of GME is generally guarded given that most dogs develop progressive neurologic signs despite treatment. Dogs with multifocal GME have a rapid and virulent course of illness over several weeks that rarely respond to antiinflammatory or immunosuppressive therapy. Patients with more focal signs can have progressive illness over several months¹¹¹; those with focal forebrain localization have the longest lifespan.⁹⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

84.2 ENCEPHALITIS IN PUG AND MALTESE DOGS

Andrea Tipold

Marc Vandeveld

This disease was initially described only in the Pug dog breed in the United States^{32,36,49} but occurs worldwide.^{11,55,79} The exact prevalence of this disease remains uncertain and seems to be a rare condition. An NME, clinically and pathologically indistinguishable from Pug dog encephalitis, has been reported in five Maltese dogs in the United States¹²² and in one Maltese dog in Europe.¹⁰⁶ The disease may also occur in other toy breeds such as the Pekingese²⁵ and Papillon.¹²⁴

84.2.1 Etiology

The cause of Pug and Maltese dog encephalitis is unknown. The distribution and morphologic characteristics of the lesions are unique for this disease and totally different from the histologic findings in other known CNS infections in small animals. The pathologic findings are, nevertheless, strongly suggestive of an infectious process. Bacterial, fungal, and protozoal organisms may probably be ruled out as potential causes because they would have been detected on histologic examination. The predominantly mononuclear inflammation suggests a viral cause. Viral isolation attempts in two cases, however, were unsuccessful.³⁶ The restriction of this disease to a few breeds is highly unusual for infections of small animals and strongly suggests predisposing genetic factors. Speculatively, these breeds may have a breed specific tissue antigen that might act as a receptor for a hitherto un-known virus or may have a breed specific composition of the immune-response genes, leading to an atypical immunologic reaction toward a known pathogen or perhaps an autoantigen. In this respect, the finding of an autoantibody recognizing glial fibrillary acidic protein can be explained.¹³⁶ The predilection of the cerebral hemispheres for involvement with a necrotic inflammatory process is similar to that with herpesvirus encephalitides of other species.^{32,122}

84.2.2 Clinical Findings

The disease may occur at any age and affects both sexes. The course of the disease is usually 1 to 6 months, but occasionally dogs may die a few days after the onset of signs or survive for more than 1 year. The most consistent sign is the occurrence of focal or generalized seizures. Other signs include decreased consciousness, abnormal behavior, compulsive circling, blindness, hyperesthesia, generalized ataxia and paresis, and deficient postural reactions.^{11,43a} A few animals may exhibit brain stem signs. The disease is always progressive, and many animals die as a result of severe seizures.³⁶

84.2.3 Diagnosis

No typical hematologic and biochemical findings have been determined. CSF analysis is abnormal in most dogs, with a predominantly mononuclear pleocytosis (usually 90 to 600 cells/ μ l) and an increased protein concentration (usually 50 to 200 mg/dl)^{32,67}; however, these are not specific because other encephalitides are associated with similar CSF changes. The massive necrotizing lesions in the cerebrum can be detected with CT or MRI.^{79,122} Lesions appear as multifocal vascularization and hypodense areas with no contrast enhancement.

798

Infectious Diseases of the Dog and Cat, 3rd Edition

Abnormal areas with increased signal intensity of T₂-weighted imaging can be detected with MRI.

799

Irregular-shaped dilation and shifting of the lateral ventricles occurs with progression of the disease as a result of cerebral atrophy from loss of parenchymal tissue.

84.2.4 Pathologic Findings

Necrotizing lesions in the cerebrum may be visible on macroscopic examination. The histologic findings are unusual and highly typical for this disease: disseminated meningitis, choroiditis, and encephalitis, with greatest involvement in the cerebrum. The perivascular and meningeal inflammatory infiltrates consisting of lymphocytes, plasma cells, histiocytes, and macrophages have a strong tendency to invade the parenchyma. Extensive compact subpial and subventricular lesions are present and may extend deep into the underlying brain tissue, with unusually intense microglial proliferation and total destruction of the original tissue elements. In some areas, frank cerebrocortical necrosis occurs. The cerebral white matter also is severely affected, with intense perivascular cuffing and gliosis (Fig. 84-3). In some areas, leukomalacia with liquefaction and cavitation of the tissue is noted.

84.2.5 Therapy

No treatment for this disease has been found. Glucocorticoids do not alter the course of this necrotizing encephalitis in confirmed cases, and antiepileptic drugs are often ineffective in controlling seizures.^{36,55} Animals usually develop persistent seizures and progressive neurologic signs and do not usually live longer than 7 months after the onset of clinical illness.

84.3 ENCEPHALITIS IN YORKSHIRE TERRIERS

Andrea Tipold

Marc Vandeveld

This condition appears to be restricted to Yorkshire terriers. The disease was originally reported in Switzerland¹³¹ but also occurs in other western European countries,¹⁴⁴ North America,^{71,114} and Japan.³⁷ The disease seems to be a relatively new entity because retrospective examination of neuropathologic collections did not reveal cases before 1985. Both clinical and pathologic features of this disease differ considerably from the encephalitis in Pug and Maltese dogs.¹⁴⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 84-3 Histologic section from a case of pug dog encephalitis. Severe perivascular and meningeal inflammation, as well as necrosis of large areas of the cerebral cortex, are evident (H and E stain, $\times 100$).

84.3.1 Etiology

The cause of Yorkshire terrier encephalitis remains unknown. An infectious organism is likely involved. Bacteria, fungi, and parasites can probably be excluded based on microscopic examination of the lesions using appropriate special stains. The appearance of the lesions suggests a viral cause. CDV was excluded by immunocytochemistry and in situ hybridization for CDV antigen and CDV mRNA. Rabies virus and central European tick borne encephalitis virus were excluded using similar techniques.¹⁴⁰ To date, isolation studies have not been attempted.

84.3.2 Clinical Findings

Encephalitis in Yorkshire terriers appears to be predominantly a disease of adult dogs affecting both sexes. Although animals can show acute signs, a clear tendency exists for the disease to become protracted for months or even years.⁸⁰ No extraneural signs occur. Neurologic signs refer to a multifocal-diffuse intracranial disease

Infectious Diseases of the Dog and Cat, 3rd Edition

involving the cerebrum (compulsive pacing, seizures, and visual deficits) and the brain stem (central vestibular signs, severe gait abnormalities with proprioceptive and multiple cranial nerve deficits).⁸³

84.3.3 Diagnosis

No specific diagnostic test exists for this disease. Obviously, neurologic signs are not diagnostic per se. Lesions are quite large and are therefore detectable by imaging techniques.¹¹⁴ In chronic cases, the lesions appear multifocal and cystic. Using CT and MRI, areas of decreased opacity and ventriculomegaly may be seen.^{41,83,114} CSF changes consist of mononuclear pleocytosis, which is marked but not specific for the disease. The differential diagnosis includes chronic distemper encephalitis and GME.

84.3.4 Pathologic Findings

Multifocal, destructive inflammatory lesions are found in the cerebral white matter and in the brain stem. They can be visualized grossly as brownish discoloration on cut section (Fig. 84-4). These lesions have a characteristic appearance consisting of a malacic center surrounded by a rim of extremely intense perivascular infiltration. Older lesions become cystic with intense astrocytic sclerosis.^{83,140}

84.3.5 Therapy

No treatment for this disease has been found. Glucocorticoids do not alter the course of the disease in confirmed cases, and antiepileptic drugs are often ineffective in controlling seizures.

84.4 HYDROCEPHALUS WITH PERIVENTRICULAR ENCEPHALITIS IN DOGS

Andrea Tipold

Marc Vandeveld

Hydrocephalus is probably the most common developmental abnormality of the CNS in dogs and may be the result of congenital or acquired stenosis of the mesencephalic aqueduct, resulting in internal hydrocephalus.⁶³ Acquired hydrocephalus is usually a result of infectious or neoplastic diseases that lead to obstruction of the CSF drainage pathways. A particular form of acquired hydrocephalus in young dogs is associated with severe periventricular inflammation.* In one puppy, inflammation likely closed drainage from the skull, causing external hydrocephalus.⁴¹

799

800

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 84-4 Yorkshire encephalitis. Burnt out cystic lesion in the cerebral white matter (*arrow*).

84.4.1 Etiology

Because of the severe inflammatory changes seen with hydrocephalus, an infectious cause has been suspected. On bacteriologic examination of brain tissue and CSF in two dogs with this disease, three different bacteria were isolated; however, these were thought to be contaminants.^{60,150} Staphylococci were isolated in another case.⁴¹ Possibly, the underlying disease might be caused by a virus, although no infectious agent was found on EM study of the periventricular tissues of two dogs.¹⁵⁰ Canine parainfluenza virus has caused hydrocephalus in dogs after experimental inoculation (see [Chapter 7](#)).^{9,10} However, the clinical and pathologic findings in experimental parainfluenza-induced hydrocephalus are totally different from those of the condition described herein. Serum-neutralizing antibodies against canine parvovirus were absent.¹⁵⁰

* References: 19, 24, 41, 60, 150.

84.4.2 Clinical Findings

The disease occurs in puppies between 2 and 6 months of age. No predilection for miniature breeds exists, as is the case with congenital hydrocephalus. The animals are normal at birth and exhibit normal development for the first 2 months of life. At 2 or 3 months of age, acute neurologic signs occur together with rapidly progressing skull enlargement. Neurologic signs include behavioral changes such as depression, dullness, and hyperactivity. Progressive incoordination occurs in all limbs, and most animals develop central blindness. Less consistent findings are cranial nerve deficits, which may include deafness, and abnormal eye motility, such as strabismus, head tilt, and dysphagia. The course of the disease is usually progressive over several days to a few weeks. In some animals, the clinical condition may stabilize.

Infectious Diseases of the Dog and Cat, 3rd Edition

84.4.3 Diagnosis

No consistent hematologic or biochemical findings are associated with this form of hydrocephalus. CSF abnormalities consist of xanthochromia, increased protein concentration, and pleocytosis, including erythrocytes, mononuclear cells, and macrophages containing erythrocytes. Radiographic examination of the skull reveals abnormalities such as thinning of the cranial vault and homogeneous appearance of the intracranial contents. CT and MRI confirm the enlargement of the ventricles. However, these findings are indicative of hydrocephalus, regardless of its cause.⁶³ The same can be said for the EEG findings indicative for hydrocephalus.⁶³

84.4.4 Pathologic Findings

Massive enlargement of the cerebral ventricles occurs, which are filled with cloudy, hemorrhagic CSF. The internal surface of the ventricles is focally roughened, with a brownish discoloration. A typical finding is the presence of large dissecting cavities, also called false diverticula, in the cerebral mantle (Fig. 84-5, A). These dissecting cavities communicate with the lateral ventricles. Histologically, severe inflammation with necrosis of the ependymal and subependymal tissues can be found.^{24,140} The lesions are always hemorrhagic. Hemosiderin laden macrophages are found in old lesions. Perivascular cuffing with inflammatory cells occurs and, in acute lesions, diffuse infiltration with neutrophils and macrophages (see Fig. 84-5, B, and C). Glial mesenchymal repair tissue is formed later in the course of the disease.

84.4.5 Therapy

By the time the condition becomes evident to the owner, severe damage has already taken place. In most cases, the disease is rapidly progressive, leading to severe neurologic impairment. However, in cases in which the condition stabilizes, conservative therapy with glucocorticoids or surgical treatment may be considered.⁶³ Antibiotics and a ventriculoperitoneal shunt was successful in treating a puppy with external hydrocephalus associated with staphylococcal infection.⁴¹ Prognosis remains cautious given that placed catheters may become obstructed by the inflammatory reaction.

84.5 NONSUPPURATIVE MENINGOENCEPHALITIS IN GREYHOUNDS

Andrea Tipold

Marc Vandeveld

A novel breed-specific meningoencephalitis has been described in young greyhounds from three different kennels in southern Ireland.²³ An infectious origin is suspected, but no inclusion bodies, fungi, or protozoal cysts were seen. Additional tests for common antigens failed to determine the cause of the disease. Neurologic signs occur with acute onset and include central vestibular signs with head tilt, ataxia, and recumbency. Additionally, circling and blindness are common findings. The animals are dull, dehydrated, and have lost weight. Hematologic and biochemical parameters reflect only dehydration. Diffuse encephalitis with perivascular, predominantly mononuclear, cuffing was described.

Infectious Diseases of the Dog and Cat, 3rd Edition

84.6 FELINE POLIOMYELITIS

Andrea Tipold

Marc Vandeveld

Poliomyelitis in domestic cats was first reported in North Africa and Ceylon in the 1950s. Later, additional cases were described in North America and Europe.^{65,77,142} A clinically and pathologically similar condition occurs in large Felidae (lions and tigers) held in captivity.^{45,94}

84.6.1 Etiology

Pathologic findings indicate that poliomyelitis in cats is almost certainly caused by a virus. However, ultrastructural studies to demonstrate a specific causal virus in domestic cats have not yet been performed, and the considerable efforts to identify such a virus in lions and tigers, including tissue culture studies, animal inoculation, and serologic studies for known viruses, have been unsuccessful.⁹⁴ Comparative pathologic studies suggest that several known spontaneously occurring or experimentally induced viral infections of cats are unlikely to cause poliomyelitis; however, the role of togaviruses should be investigated further.⁶⁵ Nonsuppurative encephalitides in cats have been associated with *Borna* virus infection in some European countries such as Austria, Switzerland, and Sweden (see [Chapter 26](#)). Borna disease in cats has been named *staggering disease*. However, Borna disease in cats is morphologically and clinically distinct from feline poliomyelitis. In addition, poliomyelitis also occurs in countries such as the United States where Borna disease is not known.

800

801

Fig 84-5 Gross and histologic specimens from a dog with periventricular encephalitis. **A**, Occipital area at the level of the midbrain showing greatly enlarged ventricles. False diverticulum (*asterisk*) communicates with the lateral ventricle through a defect (*arrow*) in the ventricular wall. **B**, Inflammatory changes (cuffing) in the periventricular tissue (H and E stain, $\times 100$). **C**, Hemorrhage and malacia in periventricular tissue (H and E stain, $\times 100$). (Part **A** from Wouda W, Vandeveld M, Kihm U. 1981. Internal hydrocephalus of suspected infectious origin in young dogs, *Zentralbl Veterinarmed A* 28:481-493, with permission.)

84.6.2 Clinical Findings

Feline poliomyelitis is an insidious disease; its onset is slow, and it progresses over weeks to months. In many instances, the neurologic signs may stabilize, and some animals may recover. Immature and adult cats appear to be susceptible. In cats, the disease is sporadic. However, outbreaks in which several lions and tigers were simultaneously affected have occurred in zoologic gardens.^{45,94} The predominant signs are problems in locomotion, including paresis, ataxia, and depressed postural reactions in the pelvic and thoracic limbs. Lower motor neuron involvement is characterized by muscle atrophy and decreased tendon reflexes. Hyperesthesia in the thoracic and lumbar areas is apparent in some cases. Additional neurologic findings, which occur rarely, include epilepsy, cerebellar signs, and pupillary abnormalities.

Infectious Diseases of the Dog and Cat, 3rd Edition

84.6.3 Pathologic Findings

Disseminated inflammatory lesions are found in the brain and spinal cord (Fig. 84-6). The spinal cord and medulla oblongata are most severely affected. The lesions consist of perivascular mononuclear cuffing, gliosis, and neuronal degeneration, the last being most obvious in the ventral horns of the spinal cord. In chronic cases, little inflammation may be seen, but neuronal loss and intense astrogliosis in the cord are striking. As a result of neuronal damage, marked diffuse wallerian degeneration of the lateral and ventral columns also occurs, resembling a primary degenerative disorder. No consistent lesions in other organ systems are found.

84.6.4 Therapy

No curative treatment has been found for the suspected viral infection. Contact between unaffected cats and those suspected to have the disease should be avoided. The prognosis is not always unfavorable because large Felidae suspected of having the infection have been known to recover.⁴⁵

801

802

84.7 STEROID RESPONSIVE MENINGITIS ARTERITIS

Andrea Tipold

Marc Vandeveld

Infectious Diseases of the Dog and Cat, 3rd Edition

Steroid responsive meningitis arteritis (SRMA) has been described numerous times in veterinary literature in several areas of the world. The name may be somewhat misleading; a positive response to glucocorticoids occurs in a variety of inflammatory conditions caused by infections or their immunopathologic complications. In this chapter, a specific syndrome in dogs is covered in which immune mediated reactions appear to involve primarily arteries and meninges of the CNS. In a certain percentage of the cases, the disease occurs in combination with polyarthritis.¹⁴⁶ A breed predisposition has been noted in Bernese mountain dogs,^{96,107,129} boxers,^{64,105,129} beagles, Toller retrievers, and basset hounds. However, other medium- to large breed dogs, usually young adults,^{64,105} may be affected.

Juvenile polyarteritis, a systemic vasculitis involving medium to small sized muscular arteries, predominantly associated with the coronary and meningeal vessels, has been commonly reported in purpose-bred beagles of 6 to 9 months of age. Beagles kept as companion animals and not derived from inbred colonies are equally affected. Although the *beagle pain syndrome* appears to be of a more systemic nature, it shares many characteristics with SRMA reported in other breeds and has been better characterized.^{44,116}

84.7.1 Etiology and Pathogenesis

The epidemiology of the disease suggests an infectious origin. As in other infectious diseases, the lesions are inflammatory. SRMA, however, displays immunopathologic features especially with respect to the vascular lesions. Although resembling immune complex injury, arteritis of beagles and other breeds has not been associated with immune complex deposits in affected vessels. Nevertheless, immunoglobulin producing plasma cells are associated with the lesions in the meninges. T cells diffusely infiltrate vessel walls.¹³³ In beagles, increased amounts of circulating immune complexes in one dog, increased rheumatoid factors in two dogs, and decreased C3 in one dog have been found.⁵⁶

Further findings suggesting an immunopathologic event are markedly increased IgA levels in CSF and serum, increased B-cell/T-cell ratio in the blood, suppressed blastogenic response to mitogens, inability to generate immunoglobulin-secreting plasma cells following activation, and antineutrophil cytoplasmic antibodies in CSF and serum. However, the last finding is not specific for this disease and can be found in other CNS lesions and even in some healthy dogs.¹³⁰ A large portion of the T cells are activated, suggesting the presence of a superantigen.^{44,134} Immunocytochemically, in SRMA, an overrepresentation of B cells occurred in meningeal lesions, whereas the distribution of lymphocyte subsets was similar to the one in bacterial or protozoal diseases. All attempts to find an infectious agent such as virus isolation, measurement of RT, and cultivation of bacteria failed.¹³⁰ Elevated interleukin (IL) 6 levels in serum have been found in affected beagles, and levels paralleled clinical illness. IL-6 levels decreased following glucocorticoid therapy and remission of clinical signs.⁶⁶ Elevated IL-8 levels and increased chemotactic activity in the CSF were consistent findings in SRMA. IL-8 did not decrease after glucocorticoid administration, which may explain the recurrent nature of the disease.²² The uncontrolled IgA synthesis may be the result of immune dysregulation, perhaps induced by an infectious agent and mediated by enhanced transforming growth factor- β (TGF- β) production. Excessive IgA is likely to play a central role in the pathogenesis of the lesion.

84.7.2 Clinical Findings

The classic clinical presentation is episodic and recurrent and includes cervical pain of acute onset, reluctance to move, stiff gait, resistance to neck manipulation, paraspinal hyperesthesia, and high rectal temperature.

Infectious Diseases of the Dog and Cat, 3rd Edition

Chronically affected animals develop neurologic deficits consistent with a multifocal or spinal cord lesion. In rare cases, spontaneous bleeding in the subarachnoid space may occur and result in tetra- or paraplegia.

84.7.3 Diagnosis

Hematologic findings include a predominantly neutrophilic leukocytosis.⁴⁴ CSF may be turbid, blood tinged, or xanthochromic from hemorrhage occurring in the subarachnoid space. Neutrophilic pleocytosis (up to several thousand cells/ μ l) and erythrophagocytosis are apparent. All dogs synthesize immunoglobulins in high concentrations in the CNS.¹³⁵

High IgA concentrations are found in the CSF, which is synthesized intrathecally.¹²⁹ Simultaneous demonstration of high IgA levels in serum and CSF is highly diagnostic (specificity of approximately 90%). Large numbers of neutrophils are predominant in the CSF in acute cases; in chronic cases, mononuclear cells predominate. Mild-to-moderate hydrocephalus has been documented in some chronic cases with cisternography and neurosonographic techniques. CT reveals hyperdensities in the meningeal spaces after IV injection of contrast medium.

802

803

Fig 84-7 Spinal cord at ventral fissure from dog with steroid-responsive meningitis-arteritis. **A**, Marked infiltration of the vascular wall with inflammatory infiltrate in meninges (H and E stain, $\times 40$). **B**, Closer view of a lesion from an affected dog showing stenosis of spinal meningeal artery from subintimal proliferation with associated periluminal inflammatory cell infiltrate and fibrosis of adjacent arachnoidea (H and E stain, $\times 100$).

84.7.4 Pathologic Findings

At necropsy, subarachnoid hemorrhages extending over the entire length of the meninges of the spinal cord and brain stem have been found in a few cases in which the vascular lesions had led to rupture of major blood vessels. In chronic cases, fibrous thickening of the spinal meninges may be noted. Lesions outside the CNS are relatively rare in affected dogs. Extranuclear arteritis is more frequently noted in affected beagles, particularly in the extramural coronary arteries and myocardium.

Infectious Diseases of the Dog and Cat, 3rd Edition

Histologic changes are found in the meninges of the spinal cord and to a much lesser degree in the brain stem. These changes consist of necrotizing arteritis of medium and small sized arteries and associated leptomeningitis (Fig. 84-7). Chronic lesions include proliferative changes of the vascular intima with stenosis and adventitial fibrosis. The intramedullary arteries and neural parenchyma can be mildly affected in chronic cases. Occasional vessels may be thrombosed. The meningeal infiltrate contains hemosiderin laden macrophages in cases in which hemorrhage had occurred. No evidence of immune complex deposition has been found, but immunoglobulin (IgG, IgM, and IgA) deposits have been found in the vascular walls of some animals¹³⁵ with the chronic stage of the disease.

84.7.5 Therapy

Spontaneous remission has been observed. Response to antibiotics is therefore coincidental because relapses and intermittent episodes occur. In dogs with extremely high body temperatures, fluid therapy and ice packs are useful. In cases with the first episode of pain and mild pleocytosis in the CSF, nonsteroidal antiinflammatory drugs are administered. At the first relapse, if signs worsen, or if massive pleocytosis in the CSF occurs (several thousand cells/ μ l), glucocorticoids are administered. The initial response to this therapy is usually dramatic. Such an immediate and impressive therapeutic response hardly occurs in GME, which usually continues to progress despite treatment. Prednisolone is given as a long-term treatment starting with 4 mg/kg of body weight for 1 to 2 days, a dose that is tapered slowly. Response to treatment and followup examinations determine the treatment protocol. If patients do not respond well to prednisolone or show side effects such as polydipsia or polyuria and polyphagia, immunosuppressive drugs and glucocorticoids are given on alternate days. Several studies have shown that neither glucocorticoids nor immunosuppressive drugs can influence the underlying immunopathologic condition, which appears to abate spontaneously within a certain period (usually several months). However, the described medication is necessary to prevent lasting damage to the CNS related to hemorrhage, bad perfusion, and destructive effects of inflammation. Older dogs with frequent relapses insufficiently treated with glucocorticoids and high IgA levels in the CSF seem to require a longer duration of therapy and have a less favorable prognosis. Long-term treatment studies show a good prognosis in 60% to 80% of treated dogs.²⁸

84.8 PRION DISEASES AND FELINE SPONGIFORM ENCEPHALOPATHY

Marc Vandeveld

Craig E. Greene

84.8.1 Etiology and Pathogenesis

Feline spongiform encephalopathy (FSE) belongs to the transmissible spongiform encephalopathies (TSE), a group of neurodegenerative diseases in humans and animals (Table 84-2) characterized by a very long incubation time and degeneration of the CNS with vacuolation of the neuropil and nerve cells. The infectious agent is small and resistant to inactivation by heat, formalin, glutaraldehyde, alcohol, and radiation. Infectivity is associated with a host-encoded protein, the so-called prion protein (PrP). PrP is widely distributed in the CNS, peripheral nerve, neuroendocrine and lymphatic tissues, and many other organs.³⁰ They are involved in neuronal development and function and prevent cell death. The mechanism of TSE involves a misfolding of the normal prion protein (PrP^C) to a new heat-resistant protein (PrP^{Sc}; PrP^{res}). In its new conformation, the PrP^{Sc} is protease resistant and hence accumulates in the tissue. Misfolding of the PrP can also occur spontaneously and

Infectious Diseases of the Dog and Cat, 3rd Edition

sporadically through genetic mutations in the PrP gene, leading to hereditary SE, which are exceedingly rare in people. Once formed, the modified, abnormal PrP is thought to induce additional copies of itself by interacting with normal PrP. Thus the belief holds that this misfolded protein itself becomes an infectious agent, the prion.³⁰ The prion theory is a revolutionary concept in biology, and many questions remain. Prions are unique because they can be both inherited and infectious.

803

SE, Spongiform encephalopathy		

^a Geographic location in parenthesis when restricted to a specific area.

The PrP^C gene is highly conserved among different animals; however, knockout mice devoid of the protein develop normally with mild neuronal abnormalities. However, the presence of an abnormal PrP in the CNS is devastating. PrP^{Sc} is insoluble and aggregates as amyloid fibrils in infected brain tissue where deposits (amyloid plaques) can be observed in some TSEs. Accumulation of aberrantly folded PrP^{Sc} fibrils is central in the pathogenesis of these diseases.³⁰ Accumulation leads to astrocytic proliferation, microglial cell activation, loss of synapses, and finally to neuronal cell death by apoptosis.

The TSEs are transmissible to other animals, at least under experimental conditions.³⁵ Routes of natural transmission of TSEs involve oral ingestion, skin scarification, or congenital transmission. For example, scrapie has been consistently found in the placenta of ewes.¹⁰⁹ Infection has spread iatrogenically through contaminated biologics²⁶ and likely through other veterinary procedures or feeding practices.¹¹⁸

During the incubation period, PrP^{Sc} accumulates on membranes of follicular dendritic cells (FDC) in local lymphoid tissue.² A crucial phase of neuronal invasion likely occurs at the interface of FDC and nerve endings in secondary lymphoid organs. From the lymphoreticular tissues at the site of inoculation, the prion is thought to gain access to the peripheral nervous system through local nerve endings. From there the prion migrates to the CNS. Knockout mice that lack the chemokine receptor, CXCR5, have altered FDC that are closely related to nerve terminals, and they have accelerated incubation periods. When FDC are depleted from mice

Infectious Diseases of the Dog and Cat, 3rd Edition

experimentally, infection is attenuated. Following ingestion, PrP^{Sc} may enter the gut-associated lymphoid tissue, then enter nerve endings in the intestinal tract, and migrate to the CNS via the vagus nerve. In bovine SE (BSE), the nucleus of the vagus is consistently affected following oral inoculation.⁷⁰

84.8.2 Epidemiology

Scrapie, the classic TSE of small ruminants, has been recognized for approximately 275 years. Since that time, other SEs have been recognized in people and animals. TSEs became notorious in the late 1980s as a result of the BSE outbreak in Great Britain,¹⁴⁷ where scrapie has been endemic for centuries. BSE was spread by animal protein concentrates in cattle feed. The scrapie agent in so called meat and bone meal is believed to be derived from abattoir offal, and fallen livestock, including scrapie infected sheep, was no longer properly inactivated because of changes in the production procedures of the rendering industry. As a result, the scrapie agent probably became adapted to a new host and established BSE in bovines with major epidemic consequences. Animals with BSE were undoubtedly also recycled by the rendering industry until the epidemiology of the disease became understood, thus leading to a considerable enrichment of the agent in meat and bone meal before the protein feeding ban came into effect. By 2004, the outbreak in British cattle involved approximately 180,000 cattle, and millions of animals have been slaughtered to control the outbreak.¹¹⁸ BSE was not restricted to the United Kingdom. Recycling of imported live animals, processed beef, or livestock food supplements from Great Britain in the local rendering industry sparked new small-scale epidemics in many European countries. The United States banned the importation of beef from the United Kingdom since the mid-1980s, and little sheep-derived feed products enter the feed for other animals.⁸⁷ One case of BSE, imported from Canada, has occurred in the United States. Only two cases (of which one was a British import) were found in Canada. Ten cases have been detected in Japan. The incidence of BSE is declining in all European countries as a result of measures taken by the European Union.¹⁴¹

FSE was first recognized during the BSE epidemic in Great Britain.³ Based on strain typing experiments, FSE is undoubtedly caused by the BSE agent.²¹ Cats were probably infected by ingesting BSE contaminated feed.¹⁵² Cats cannot be experimentally infected by the scrapie agent directly as they can by BSE and Creutzfeldt Jakob disease (CJD) agents, which indicates an adaptation to the new hosts.⁵³ The first cases of FSE were diagnosed in the early 1990s,^{81,152} and approximately 90 cases had been reported by the end of 2004. The outbreak was attributed to consumption of beef products contaminated by CNS tissues from infected animals.

In addition to Great Britain, one case of FSE has been described in a domestic cat in Norway that was fed commercial dry cat foods imported from Great Britain.¹⁵ Other single cases of FSE have been reported in North Ireland, Liechtenstein, and Switzerland,³⁸ and more have likely occurred in domestic cats throughout Europe. Captive wild species of Felidae such as lions (*Panthera leo*), tigers (*P. tigris*), cheetahs (*Acinonyx jubatus*), and pumas (*Felis concolor*) that were fed bovine tissues have also been affected with BSE.^{8,73,149} An Asiatic golden cat (*Catopuma temmincki*) imported into Australia from Europe was found to have prion-associated SE.¹⁵³ The number of cats being reported annually with FSE in Great Britain has sharply decreased in the past years. The last case was reported in 2001. This decline is expected because of measures taken to prevent further spread of the bovine disease. TSE has not been documented in the dog.

804

805

Infectious Diseases of the Dog and Cat, 3rd Edition

84.8.3 Clinical Findings

Because of the long incubation time of TSE, the signs of the disease are observed only in adult cats (peak incidence at age 5 years). The neurologic signs develop progressively over several weeks to months and are characterized by behavioral changes such as aggressiveness and fear. Gait abnormalities include ataxia and inaccurate landing while jumping. Affected cats are hypersensitive to tactile stimulation. No focalization of the neurologic signs occurs. The disease is invariably progressive and fatal.

84.8.4 Diagnosis

No typical laboratory findings have been discovered. The suspicion of FSE is based on the age of the animal and the clinical signs. A variety of neurologic conditions have to be considered. Laboratory diagnosis of TSE is based on immunochemical detection of the protease-resistant PrP. Monoclonal and polyclonal antibodies have been generated against PrP,^{115,88} and several commercial kits are on the market. Some species differences can be found in reactions to these commercially available test kits that must be recognized. A commercial test kit (BSE Test Kit®, Bio Rad, Hercules, Calif.) has been developed to detect PrP^{Sc} in the brain of cattle with BSE, and it may be beneficial for testing other tissues and body fluids.⁴⁸ Western immunoblotting methods have also been effective for rapid surveillance of BSE (Prionics-Check®, University of Zuerich-Irchel, Switzerland).¹¹⁵ In living individuals affected by TSE, PrP^{Sc} can be detected in biopsies from lymphatic tissues. In scrapie, the abnormal prion can be demonstrated in lymphoid tissues such as the tonsils or third eyelid.¹⁰⁰ Given that no replication of the BSE agent occurs in lymphatic tissues, laboratory diagnosis is possible only on brain material after slaughter. In cats, extraneural PrP^{Sc} accumulation appears to be inconsistent.¹¹² An insoluble proteinase-resistant PrP isoform is present in urine of people and animals affected with prion disease.¹¹⁷ This isoform can be detected long before clinical evidence of the disease occurs. The value of these methods in testing specimens from various animals requires further study. As a potential premortem test, pathologic PrP was detected by immunoblotting in the dorsal olfactory epithelium of people with sporadic (naturally occurring) CJD.¹⁵⁵ This method might serve as a means of diagnosis of disease in living animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

84.8.5 Pathologic Findings

As in all other TSEs, the pathologic findings in FSE are highly characteristic. The changes consist of vacuolation in the neuropil and neurons in a bilaterally symmetric distribution, especially in the thalamus, basal ganglia, and cerebral cortex (Fig. 84-8, A). Immunocytochemistry for PrP^{Sc} reveals accumulation of PrP in affected areas (see Fig. 84-8, B). Advanced cases reveal neuronal loss and gliosis. Advanced lesions are more commonly observed in human patients because affected animals are often euthanized in early stages of the neurologic disease. No inflammation is present.

84.8.6 Therapy

A large number of potential therapeutic agents have been used to treat TSEs. Polyene antimicrobials have been considered for use in preventing accumulation of PrP^C and treating infection by certain scrapie strains.⁷⁶ Analogs of Congo red, quinacrine, and chlorpromazine and inhibitors of peptide synthesis might also be considered. Active and passive immunization using recombinant PrP^C and antibodies to PrP^C have considerable merit. TSEs are similar to Alzheimer's disease in which neurodegeneration is accompanied by massive deposition of amyloid- β -protein, and some reduction in progression occurs when immunotherapy is used.

84.8.7 Prevention

All TSEs are fatal diseases. Prevention of exposure is the most important control measure. Although transmitting an SE from one species to another orally is generally difficult, 13 other animal species were found to be infected with BSE in Great Britain.²¹ BSE in these other species undoubtedly resulted from oral exposure. Scrapie-infected sheep were processed into meat and bone meal supplements being fed to cattle, and tissue from sick animals were recycled through the animal food supply. Because of the enormous resistance of the infectious agent to physical and chemical inactivation procedures, high titers of infectivity remain, even in extensively processed contaminated feedstuffs. To prevent exposure to other species, including people, the authorities in endemic countries confiscated all tissues (CNS, lymphoid tissues, intestine) in which the infectious agent might be theoretically present from all bovines at the time of slaughter. This measure came into effect in the fourth year of the BSE epidemic and took several years to become completely effective.¹¹⁸ Thus, most likely, the exposure of other species had taken place before that time. Considering an average incubation period of approximately 5 years, the peak of the epidemic in cats has certainly been passed.¹⁴ Further spread in the bovine population in Europe was prevented by banning the feeding of animal proteins to ruminant species and finally to all farm animals. The BSE epidemic is expected to reach its end within a few years.¹¹⁸ FSE should therefore soon disappear. Although BSE will be soon eradicated, scrapie remains a challenge because it is a naturally occurring disease that spreads from animal to animal. Because susceptibility to scrapie is genetically controlled, polymerase chain reaction has been used to detect alleles of scrapie-susceptible sheep to assist selection for breeding of scrapie-resistant animals.¹⁵⁴

805

806

84.8.8 Public Health Considerations

During the outbreak of BSE in Britain, a new variant of CJD (vCJD) occurred in people.⁶⁸ The disease has also been reported in other countries. Approximately 140 cases have been detected, and the epidemic appears to be on the decline. In contrast to classical CJD, the variant disease affected primarily young adults and was

Infectious Diseases of the Dog and Cat, 3rd Edition

suspected as being caused by ingestion of contaminated cattle products. Based on strain typing in mice, the vCJD agent is similar to the BSE agent.⁵² Further evidence for the BSE etiology of vCJD is derived from electrophoretic patterns of the three PrP glycotypes (glycotyping), vCJD, and BSE showing the same type 4 pattern.^{29,50} The prions of BSE, vCJD, and sporadic CJD have been inoculated into transgenic mice.⁶ Although most of the mice produced type 4 prions, a few expressed type 2, which suggests the possibility that some humans with apparently sporadic CJD might be infected with BSE prions.⁶¹ However, this finding can be explained in other ways, and such speculations that are common in the TSE field need more solid scientific evidence. Not all people are equally susceptible to the development of SE. A higher prevalence of disease is associated with homozygosity for a polymorphism at codon 129 of the PrP gene.³⁰

Despite the control of the outbreak through management of livestock feeding, the number of clinically healthy people incubating the disease is still undefined. Transmission of the agent through blood transfusions or organ donation is therefore a major concern. In addition, use of medical and surgical instruments on successive patients is of theoretical concern. The danger of contaminated materials is not with contact but with ingestion or inoculation. The safest method of preventing spread of disease to a new patient is to destroy all instruments used. If this precaution is not possible, then the items should be immersed in 1 M sodium hydroxide (NaOH) and then autoclaved. Work surfaces should be flooded with 2 M NaOH and then allowed to soak for 1 hour. No effective disinfection procedure exists for delicate instruments that cannot withstand autoclave temperatures (134° C) or 1 N NaOH. For delicate equipment, repeated washing with detergent-proteinase solutions and exposing it to 6 M urea or 4 M guanidinium thiocyanate can eliminate the offending prions of TSE.⁹¹

84.9 CONCLUSIONS

In addition to the conditions described in this chapter, other CNS diseases of suspected infectious origin are occasionally encountered in dogs and cats during diagnostic workup. Some will remain a single sporadic observation; others will become recognized as disease entities. The ability to characterize infectious agents in these diseases is limited when formalin fixed tissues are used. Fresh material for culture should be collected when clinical findings are compatible with one of these disorders. In addition to brain tissue taken for isolation procedures, serum and CSF should be collected and screened for antibody activity against a wide variety of known infectious agents. The advent of widely available, extremely powerful molecular biologic techniques also extends the range of etiologic studies considerably. In addition, more systematic ultrastructural studies of appropriately fixed tissues taken from lesions and sites indicated by the clinical examination may be helpful in detecting infectious agents. For a discussion of meningitis of suspected infectious or immune mediated causes, see Bacterial Infections of the Central Nervous System, [Chapter 92](#).

85 CHAPTER 85 Integumentary Infections

85.1 BACTERIAL INFECTIONS OF THE SKIN

Peter J. Ihrke

Pyoderma is defined as a pyogenic or pus-producing bacterial infection of the skin. The diversity of clinical syndromes seen with canine pyoderma is enormous, varying from minor annoyances to disease with life-threatening potential.* Pyoderma may affect the surface, creating inflammation without the invasion of living tissue; be superficial, involving the epidermis and hair follicle units; or invade deeper, compromising structures in the dermis and subjacent fatty tissue. This tremendous diversity and pleomorphism is responsible for diagnostic and management difficulties that may be encountered. Misdiagnosis also may result from the continuum of clinical characteristics and severity of the pyoderma, among various dogs, of different anatomic sites, and between acute and chronic disease. The presence of pus cannot be used as a defining diagnostic criterion because pus may not be visible grossly. The aging and rupture of pustules leads to crusted papules that are much more difficult to use for diagnosis. In addition, accumulations of pus in the mid-dermis in deep pyoderma may not be visually obvious.

Globally, pyoderma remains one of the most common causes of canine skin disease. Pyoderma was second only to flea allergy dermatitis in frequency of diagnosis in a study from North American veterinary colleges.^{67,134} An additional epidemiologic study performed in a relatively flea-free environment in Canada ranked bacterial folliculitis and furunculosis first among all canine skin diseases, comprising more than one quarter of the dermatology caseload.¹³³ Conversely, pyoderma is a relatively uncommon cause of skin disease in cats, other domestic animals, and humans. Bacterial skin disease in the cat is rare, with the exception of subcutaneous bite wound abscesses (see [Chapter 53](#)).

The reasons for the markedly elevated frequency of bacterial skin disease in the dog in comparison with other mammalian species are unknown. Various host factors that may result in enhanced susceptibility include the comparatively thin, compact canine stratum corneum, the relative lack of intercellular lipids in the canine stratum corneum, the lack of a lipid-squamous epithelial plug in the entrance of canine hair follicles, and the relatively high pH of canine skin.^{67,86,98,132}

85.1.1 Etiology and Pathogenesis

85.1.1.1 Normal Microflora of the Skin and Hair

Skin microbial flora is composed of resident and transient bacteria. Resident bacteria are harmless commensals that multiply on the skin surface and in hair follicles and maintain a static, consistent population. Transient bacteria cannot compete long term with the established resident flora and may seed the skin from either mucous membranes, other animals, or the environment. The total number of resident bacteria residing on normal canine skin is not large and may comprise less than 350 organisms per square centimeter.⁶⁷ Studies examining the bacterial flora of normal dogs have documented aerobic organisms, including *Micrococcus* species, β -hemolytic streptococci, and *Acinetobacter* species, and anaerobic organisms, including *Clostridium perfringens* and *Propionibacterium acnes*.*

Infectious Diseases of the Dog and Cat, 3rd Edition

Published data have clarified the role of *Staphylococcus intermedius* in canine pyoderma.[†] This pathogen is probably not a true cutaneous resident but rather a contaminant on normal canine hair and either a contaminant or a transient, restricted, local colonist on normal canine skin. Mucous membranes such as those of the anus and nares probably play an important role as sources of this potential skin pathogen. Normal grooming in all dogs, and excessive licking in pruritic dogs, may repetitively seed the skin with *S. intermedius* from the anus and nares.[‡]

85.1.1.2

Staphylococcus intermedius and Other Canine Cutaneous Pathogens

S. intermedius is the primary canine cutaneous pathogen. This organism is a species separate and distinct from the human pathogen, *Staphylococcus aureus*.^{50,67} Pure cultures of this bacterium are grown from most pustules or draining tracts in dogs with pyoderma. Recently, two subspecies of *Staphylococcus schleiferi* were implicated as causing some cases of recurrent canine pyoderma.^{11,43} It is likely that these subspecies of *S. schleiferi* formerly were misidentified as *S. intermedius*. Limited data indicate that methicillin and fluoroquinolone resistance may be more common in strains of *S. schleiferi*.⁴³ Methicillin resistance also may be increasing slightly within the *S. intermedius* population.⁴⁷

Pathogenicity of staphylococci in humans correlates with virulence factors such as various proteins and toxins. Evidence does not support virulence factors as the cause of differences in canine susceptibility or severity of infection.^{19,25,59,67,68}

When potential virulence factors have been examined comparing *S. intermedius* isolates from normal dogs and dogs with pyoderma, clear differences in toxin profiles, gel electrophoresis of exoproteins, and immunoblotting of concentrated extracellular proteins were not elucidated.* Production of exotoxins does

807

808

not appear to play a role in the pathogenicity of *S. intermedius* for canine skin.¹⁹ The role of various other virulence factors such as protein A, leukocidin, hemolysins, epidermolytic toxin, and other soluble products is less clear in the dog. Data suggest that host factors rather than virulence factors appear to be more important in determining susceptibility, severity, and outcome in canine staphylococcal pyoderma.[†]

Secondary gram-negative invaders such as *Proteus* species, *Pseudomonas* species, or *Escherichia coli* may be isolated in conjunction with *S. intermedius*, usually from deep pyoderma. However, if gram-negative bacteria are isolated from pyoderma without the concomitant isolation of *S. intermedius*, the technique used and the results obtained should be questioned, because canine pyoderma caused by gram-negative bacteria without staphylococcal coinfection is exceedingly rare. Primary infection with *S. intermedius* creates a tissue milieu that is more conducive to secondary invasion by gram-negative bacteria.^{66,67}

* References 1, 3, 19, 49, 50, 67.

† References 1, 3, 50, 19, 25, 67, 132.

Infectious Diseases of the Dog and Cat, 3rd Edition

85.1.1.3 Microbial Alterations with Skin Disease

The factors that promote the proliferation of *S. intermedius* on skin leading to pyoderma are poorly understood. However, it is well established that dogs with other skin diseases are more likely to develop secondary pyoderma. Dogs with defects in cornification exhibit a shift in the balance of bacterial species colonizing the skin such that coagulase-positive staphylococci predominate. Clinically, this correlates with an increased frequency of pyoderma in dogs with cornification abnormalities. A shift in the frequency and intensity of staphylococcal colonization has been noted in dogs with atopic dermatitis and contact dermatitis as well as seborrheic dermatitis.⁶⁷

85.1.1.4 Zoonotic Potential of Skin Pathogens

Because *S. intermedius* is a separate and distinct species from *S. aureus*, this partially explains why humans with a normally functioning immune system are not at great risk for skin or wound infections contaminated with *S. intermedius*. Healthy owners of dogs with staphylococcal pyoderma are generally not at risk for zoonotic bacterial infection. However, subclinical transfer of the organism from dogs to people has been documented.^{51,140} Many of the isolated strains have been antimicrobial resistant strains. These data indicate that a dog with suppurative pyoderma would be of medical concern if an immunocompromised household member were bitten or exposed to suppurative discharges. Dogs harbor this organism in their mouth; up to 21% of dog bite lesions in people may be infected with *S. intermedius*.¹³⁹ Nevertheless, the pathogenicity of other bite-transmitted organisms unassociated with pyoderma is greater. (For additional information on bite transmission of this organism, see Bite Wound Infections, [Chapter 53](#).)

S. schleiferi is a recognized human pathogen, causing nosocomial infections. It has been isolated as a commensal from human skin. Antimicrobial-resistant strains of this organism have been isolated from people, dogs, and cats. In the past, many human and veterinary laboratories have likely confused this organism with *S. aureus* and *S. intermedius*, respectively. Although *S. schleiferi* has been identified in the skin of clinically healthy dogs, the prevalence of carriage has not been determined. Isolations of *S. schleiferi* in dogs have primarily been from those with otitis externa or recurrent pyoderma, and the majority of isolates have been methicillin resistant.⁴³ Because *S. schleiferi* has been both a commensal and pathogen in people, the concern of transferring this potentially drug-resistant pathogen between people and pets is considerable. Additional investigations are needed.

The human pathogen, *S. aureus*, has also been isolated from animals, including dogs and cats that have close association with people.^{63,90} Methicillin-resistant *S. aureus* strains have also been identified in pets, making them potential sources for infection of people. For an additional discussion of this problem, see Staphylococcal Infections, [Chapter 36](#), and Immunocompromised People and Pets, [Chapter 99](#).

85.1.1.5 Susceptibility and Host Response to Infection

S. intermedius does not possess the requisite virulence factors to be a potent pathogen. Consequently, most canine pyodermas probably are associated with underlying disease or other host factors. Diseases such as ectoparasitism, cornification defects (seborrhea), allergies (atopic dermatitis, food allergy, flea allergy dermatitis), hereditary skin diseases (genodermatoses)—especially those affecting hair follicles—and endocrinopathies such as hypothyroidism and Cushing's disease frequently predispose animals to

Infectious Diseases of the Dog and Cat, 3rd Edition

pyoderma.^{35,67,78,131,132} Pyoderma secondary to cornification defects and allergic diseases are best documented. More broadly, pruritus from any underlying disease, cutaneous inflammation from any cause, injudicious use of glucocorticoids (iatrogenic hyperglucocorticoidism), and poor grooming in long-coated dogs all contribute to the likelihood of secondary pyoderma.

Superficial infection of the hair follicle is the most common canine pyoderma. Follicular defects, dysplasia, obstruction, atrophy, inflammation, or degeneration predispose to folliculitis. After pyoderma is initiated, immunologic incompetence, coexisting skin disease, pruritus, inflammation, scar tissue formation, and improper initial therapy are negative prognostic factors.⁶⁷

The initiation of staphylococcal pyoderma requires colonization and invasion of host tissues in addition to evasion of host immunity. Host defense mechanisms mobilized to prevent bacterial invasion include immunologic and nonimmunologic processes. Nonimmunologic mechanisms include the desquamation of the stratum corneum (surface and follicular), the lipid intercellular barrier, epithelial proliferation in response to injury, and the antibacterial effect of inorganic salts found in sebum and sweat. Additionally, competition among resident bacteria is a nonimmunologic, “nonhost” defense mechanism. Immunologic host defense mechanisms of the skin include proteins within the intercellular matrix; immunoglobulins within the basement membrane zone; and immunologically active cells such as Langerhans cells, dermal dendrocytes, lymphocytes, mast cells, and venular endothelial cells present in either the epidermis or dermis.⁶⁷

Host immunologic response may be deleterious as well as beneficial. Some dogs with chronic or recurrent pyoderma exhibit depression of lymphocyte transformation testing. Exceptionally potent bacterial antigens, termed *superantigens*, may explain the troublesome nature of pyoderma secondary to canine atopic dermatitis and the marked inflammation and pruritus seen in some canine pyoderma.⁶⁷

Bacterial hypersensitivity has long been theorized as a complicating factor in recurrent canine pyoderma. The potential importance of bacterial hypersensitivity has been underscored by work indicating that mast cell degranulation can initiate enhanced epidermal permeability to bacterial antigens in atopic dogs.^{67,97} Several studies have verified an association between antistaphylococcal antibodies and various subgroups of canine pyoderma.^{67,105}

85.1.1.6

Classification of Pyoderma

Classification based on depth of bacterial involvement is most useful clinically because it provides information on diagnosis, likelihood of underlying disease, prognosis, required duration of therapy and response to therapy. In general, the deeper the infection, the more likely that underlying triggering causes are present. Deeper infections also require that the clinician be more aggressive diagnostically and therapeutically. Using depth of bacterial infection, canine pyoderma can be described as *surface*, *superficial*, or *deep* (Table 85-1).⁶⁷

808

809

85.1.1.6.1

Surface Pyoderma

Surface pyoderma consist of inflammatory processes in the skin without strong evidence of direct bacterial invasion. Bacterial involvement probably is secondary to various factors that encourage surface bacterial overgrowth. Pyotraumatic dermatitis (acute moist dermatitis, hot spots), intertrigo (skinfold pyoderma), mucocutaneous pyoderma, and surface bacterial overgrowth are classified as surface pyoderma. Pyotraumatic dermatitis usually develops secondary to flea allergy dermatitis. Intertrigo occurs

Infectious Diseases of the Dog and Cat, 3rd Edition

in skinfolds secondary to breed-characteristic anatomic defects and is seen in conjunction with friction, poor drainage, and maceration. In mucocutaneous pyoderma, bacterial involvement may become deeper with chronicity. Mucocutaneous pyoderma is a surface disease of unknown cause that predominantly involves the lips and perioral skin but may involve other mucocutaneous sites such as the anus.^{67,70} Intertrigo and pyotraumatic dermatitis rarely are diagnostic or therapeutic challenges.

Table 85-1 Classification of Canine Pyoderma Based on Depth of Infection

SURFACE PYODERMA

Pyotraumatic dermatitis (acute moist dermatitis, hot spots)

Intertrigo (skinfold pyoderma): lip-fold, facial-fold, vulvar-fold, tail-fold, obesity-fold

Mucocutaneous pyoderma^a

Surface bacterial overgrowth^a

SUPERFICIAL PYODERMA

Impetigo (puppy pyoderma)

Superficial bacterial folliculitis^a

Superficial spreading pyoderma^a (exfoliative pyoderma)

DEEP PYODERMA

Deep bacterial folliculitis and furunculosis

Muzzle folliculitis and furunculosis (canine acne)

Pyotraumatic folliculitis^a

Pedal folliculitis and furunculosis^a

Callus pyoderma (pressure-point pyoderma)

German shepherd dog pyoderma^a

Cellulitis (secondary to demodicosis or immunologic incompetence)

DISEASES FORMERLY CLASSIFIED AS PYODERMA

Juvenile sterile granulomatous dermatitis and lymphadenitis (juvenile cellulitis, puppy strangles, juvenile “pyoderma”)

Hidradenitis suppurativa^b

a Subgroups of pyoderma in which recurrence or recrudescence is more common.

b These diseases were most likely autoimmune subepidermal blistering diseases or were vesicular cutaneous lupus erythematosus of the Shetland sheepdog or collie.

Infectious Diseases of the Dog and Cat, 3rd Edition

In the past, the clinical importance of surface overgrowth by staphylococci and other bacteria has not been recognized in the dog. The author feels that secondary surface bacterial overgrowth triggered by underlying, predisposing skin disease is a prime cause and perpetuator of chronic cutaneous inflammation and pruritus in dogs.

85.1.1.6.2

Superficial Pyoderma

Superficial pyoderma is the most common type of canine bacterial skin disease. Impetigo is characterized by nonfollicular, intraepidermal pustules involving the superficial layers of the epidermis (Fig. 85-1). Superficial folliculitis affects the ostial portion of the hair follicle and is the most common subgrouping of canine pyoderma. Impetigo and superficial folliculitis may be a diagnostic challenge because pustules rupture readily, giving rise to considerably less diagnostic crusted papules. A third clinical subset of superficial pyoderma, termed *superficial spreading pyoderma*, is characterized by centrifugally expanding inflammation with characteristic peripheral epidermal collarettes. Superficial spreading pyoderma may be seen alone or in conjunction with superficial folliculitis.

85.1.1.6.3

Deep Pyoderma

Deep pyoderma is characterized by infection that proceeds deeper in the hair follicle with or without follicular rupture. The factors that allow infection to proceed from superficial to deep folliculitis are not understood. Deep folliculitis can lead to follicular rupture (furunculosis) with a granulomatous foreign body tissue response (Fig. 85-2). Interconnecting furunculosis involving the interstitium between hair follicles, the dermis, and subcutis is termed *cellulitis*. Deep pyoderma is much less common than superficial pyoderma. Diagnosis of deep pyoderma usually is not difficult; however, therapy often is problematic.

85.1.2

Clinical Findings

Dermatology has a singular advantage over most other specialty medical disciplines in that skin lesions are visible for careful inspection and available for precise sampling. Excellent lighting is essential for a proper physical examination. A hand lens is beneficial. Severity, extent, and pattern of clinical findings may be clarified additionally by clipping overlying hair from an affected lesion.

810

85.1.2.1 Primary Skin Lesions

An erythematous papule is the most common primary skin lesion seen in most superficial and milder deep pyoderma. Papules are circumscribed, solid elevations of the skin that usually form in groups. As infection

Infectious Diseases of the Dog and Cat, 3rd Edition

proceeds, pus accumulates in intraepidermal or follicular locations, forming pustules. Small pustules may appear as papules to the unaided eye. Intact pustules often are transient in canine skin. When surface pustules rupture, crusted papules result. In deep pyoderma, more intense inflammation leads to nodule formation. Follicular rupture exacerbates inflammation in the adjacent dermis, resulting in larger nodules with fistulation. Peripheral collarettes, the “footprints” of pyoderma, are composed of detaching stratum corneum at the margins of inflammation. In deep pyoderma, host response is more intense, producing more obvious inflammation and swelling.

85.1.2.2

Secondary Skin Lesions

Pustules either rupture spontaneously or are obliterated by self-trauma, resulting in crusted papules. Clinically, crusted papules are less useful for diagnosis and may be indistinguishable from the papules seen with many other skin diseases. If crusted papules are grouped, crusts composed of dried pus, exudate, and keratin debris may mimic disorders of cornification. Self-traumatic excoriations may obliterate more diagnostic primary lesions, because pruritus is a feature of many pyodermas.

Alopecia commonly is seen secondary to pyoderma as hair fragments are shed from infected follicles. Transient, patchy (moth-eaten) alopecia probably results from premature telogenization and telogen arrest in a normally mosaic, asynchronous hair replacement pattern. Permanent, scarring alopecia secondary to deep folliculitis and furunculosis is uncommon in the dog, in contrast with pyoderma in people. Cellulitis leads to follicular obliteration.

Follicular rupture in deep pyoderma leads to nodule formation and draining fistulous tracts (see [Fig. 85-2](#)). Dermal hemorrhage resulting from follicular rupture with intense inflammation may result in hemorrhagic bullae that appear as dark bluish regions visible in the dermis.

85.1.2.3

Distribution of Lesions

Acute moist dermatitis, usually secondary to flea allergy dermatitis, is seen most commonly in the dorsal lumbosacral region. Intertrigo, or skinfold pyoderma, is observed at the specific site of the anatomic defect (lip-fold, facial-fold, vulvar-fold, tail-fold) according to breed. Mucocutaneous pyoderma occurs predominantly on and around the lips but may affect other mucocutaneous junctions. Surface bacterial overgrowth most commonly initially affects the intertriginous folds, such as those seen in the groin and axillae, but may become a generalized infection.

Uncomplicated superficial pyoderma occurs predominantly in the moist, intertriginous zones of the groin and axilla and to a lesser extent in the interdigital webs. Impetigo occurs primarily in the groin of prepubescent dogs. Superficial folliculitis and superficial spreading pyoderma are most commonly found in the groin and axilla, but lesions may generalize on the thorax. The attendant patchy, partial alopecia is more visually distinctive in short-coated breeds. Improper use of glucocorticoids may contribute to the spread of any superficial pyoderma while paradoxically decreasing visible inflammation. Bullous impetigo in the adult dog is most commonly secondary to iatrogenic hyperglucocorticoidism but can be associated with other underlying immunosuppressive diseases.

Deep pyoderma usually develop as an extension of superficial pyoderma. A characteristic distribution is seen with interdigital, pressure-point and nasal pyoderma, and canine acne. Because most canine cellulitis occurs secondary to generalized demodicosis, the distribution is similar to that of the primary disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

85.1.3 Diagnosis

85.1.3.1 Differential Diagnoses

Many other skin diseases may mimic canine pyoderma. Differential diagnoses are listed in an approximate order of importance in [Table 85-2](#). For additional information, see the Suggested Readings.^{67,131}

Various diagnostic procedures may be helpful in diagnosing pyoderma and determining the presence of underlying diseases or other predisposing factors. Skin scrapings, cytologic examination, and skin biopsy usually are the most useful diagnostic procedures for the evaluation of suspected pyoderma.⁶⁷ Conversely, bacterial culture and identification and antibiotic susceptibility testing are overused procedures, because bacterial species and susceptibility to antimicrobial therapy commonly can be predicted.

85.1.3.1.1 Skin Scrapings

Skin scrapings should be performed in all suspected cases of canine pyoderma, because demodicosis can initiate lesions that mimic uncomplicated pyoderma. It is especially important to scrape any pustular or papular lesion with a follicular orientation. In addition to mimicking pyoderma, demodicosis commonly triggers secondary pyoderma. Pyoderma secondary to demodicosis follows the distribution pattern of demodicosis, aiding diagnosis. Skin scrapings are more likely to yield demodicosis in suspected cases of lip-fold intertrigo, superficial folliculitis, deep folliculitis, furunculosis (canine acne, pedal folliculitis), and cellulitis.

85.1.3.1.2 Cytologic Examination

Cytologic examination is a simple, cost-effective, and frequently beneficial diagnostic test for the documentation of canine pyoderma. Material from either direct smears of pustules or draining tracts often yields as much or more useful information than bacterial cultures and is more rapid and cost effective. Cytologic examinations of inflamed skin lacking primary lesions often demonstrates inappropriate surface bacterial overgrowth. Specimens should be air dried and stained with either a modified Romanovsky-type Wright's stain (Diff-Quik) or new methylene blue. Modified Wright's stain is beneficial both for documenting organisms and identifying inflammatory cells. The identification of cocci indicates the probable presence of *S. intermedius*. The presence of degenerating neutrophils and intracellular cocci supports the diagnosis.

810

812

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 85-2 Differential Diagnosis of Canine Pyoderma

SURFACE

Pyotraumatic dermatitis (acute moist dermatitis, hot spots): Pyotraumatic folliculitis, demodicosis, neoplasia (especially sweat gland adenocarcinoma), cutaneous metastasis, fixed drug eruption, early necrotizing form of idiopathic nodular panniculitis, early localized vasculitis, focal *Malassezia* dermatitis, candidiasis

Intertrigo (skin-fold pyoderma)

Lip-fold intertrigo: Localized demodicosis; fixed drug eruption; superficial necrolytic dermatitis, with or without *Malassezia* dermatitis or candidiasis; zinc-responsive dermatosis; muzzle folliculitis and furunculosis (canine acne); localized pemphigus foliaceus; early pemphigus vulgaris; early autoimmune subepidermal blistering disease

Facial-fold intertrigo: Localized demodicosis, *Malassezia* dermatitis, dermatophytosis

Vulvar-fold intertrigo: Urinary tract infection with self-trauma, vesicular cutaneous lupus erythematosus, ulcerative dermatosis of the Shetland sheepdog and collie, drug eruption, canine familial dermatomyositis, pemphigus vulgaris, early autoimmune subepidermal blistering disease

Tail-fold intertrigo: Flea allergy dermatitis

Obesity-fold intertrigo: *Malassezia* dermatitis

Mucocutaneous pyoderma: Lip-fold intertrigo, localized demodicosis, early discoid lupus erythematosus, zinc-responsive dermatosis, generic dog food dermatosis, muzzle folliculitis and furunculosis (canine acne)

Surface bacterial overgrowth: *Malassezia* dermatitis

SUPERFICIAL

Impetigo (puppy pyoderma): Early flea allergy dermatitis, superficial folliculitis

Superficial bacterial folliculitis: Superficial spreading pyoderma, flea allergy dermatitis, demodicosis, pemphigus foliaceus, sarcoptic acariasis, severe impetigo, drug eruption, erythema multiforme, seborrheic dermatitis, sterile eosinophilic pustulosis

Superficial spreading pyoderma: Superficial bacterial folliculitis, pemphigus foliaceus, erythema multiforme, seborrheic dermatitis

DEEP

Deep folliculitis and furunculosis: Demodicosis, subcutaneous and deep mycoses, opportunistic fungal infections, pythiosis, lagenidiosis, severe maladapted dermatophytosis, sterile granuloma-pyogranuloma, histiocytosis, idiopathic nodular panniculitis, juvenile sterile granulomatous dermatitis and lymphadenitis, vasculitis

Pyotraumatic folliculitis: Pyotraumatic dermatitis, demodicosis, neoplasia (especially sweat gland adenocarcinoma), cutaneous metastasis, fixed drug eruption, early necrotizing form of idiopathic nodular panniculitis, early localized vasculitis, focal *Malassezia* dermatitis, candidiasis

Muzzle folliculitis and furunculosis (canine acne): Localized demodicosis, early juvenile sterile granulomatous dermatitis and lymphadenitis

Pedal folliculitis and furunculosis: Demodicosis, dermatophytosis, subcutaneous and deep mycoses, opportunistic fungal diseases, pythiosis, lagenidiosis, pelodera dermatitis

Infectious Diseases of the Dog and Cat, 3rd Edition

Callus pyoderma (pressure-point pyoderma): Acral lick dermatitis, generic dog food skin disease, focal actinic comedones

German shepherd dog pyoderma: Demodicosis with secondary deep pyoderma, subcutaneous and deep mycosis, opportunistic fungal diseases, pythiosis, lagenidiosis

Cellulitis (with or without demodicosis): Juvenile sterile granulomatous dermatitis and lymphadenitis (juvenile cellulitis), subcutaneous and deep mycosis, German shepherd dog, pyoderma, sterile granuloma-pyogranuloma, idiopathic liquefying panniculitis, opportunistic fungal diseases, pythiosis, lagenidiosis

Modified from Ihrke PJ. 1996. *Bacterial skin disease in the dog: a guide to canine pyoderma*. Veterinary Learning Systems, Princeton, NJ.

85.1.3.1.3

Skin Biopsy

Skin biopsy is an often neglected valuable tool in the diagnosis of canine pyoderma. Increased reliance on skin biopsy has led to the more frequent diagnosis of pyoderma. The benefit of skin biopsy can be maximized if basic principles are followed: timing, lesion selection, method selection, technique, preparation of supportive material, and submission to a dermatopathologist are all important factors.

85.1.3.1.4

Bacterial Culture and Identification and Antibiotic Susceptibility

Bacterial culture is overused in the evaluation and management of canine pyoderma. Bacterial culture and identification and antibiotic susceptibility tests are indicated if mixed infection is suspected (as determined by cytologic examination) or if appropriate empiric antibiotic therapy has not been effective. Cultures of intact pustules, furuncles, and nodules are more likely to yield helpful information. Bacterial cultures from open lesions are less likely to yield meaningful results. Bacterial cultures from the skin surface are not recommended.

85.1.3.2

Evaluation for Immunocompetence

Reliable diagnostic tests to determine immunocompetence in the dog are not available.^{34,67} Gross information can be derived from a complete blood count (CBC) and serum electrophoresis. An absolute neutrophilia with a lymphocyte count of at least 1000 to 1500 cells per milliliter should be observed in normal dogs with ongoing or recurrent pyoderma. A broad-based elevation in the serum electrophoretic pattern in the β and γ ranges should be present.^{66,67} Assays such as in vitro lymphocyte stimulation and bactericidal tests are still primarily research tools because of their expense and lack of availability. The lack of ability to correct any defects that are documented further detracts from the clinical usefulness of these tests.^{35,132} Pyoderma, especially when deep, is associated with a high prevalence of circulating immune complexes (CICs). Dogs with chronic deep pyoderma are more likely to be proteinuric, with a predominance of albuminuria, than dogs with superficial pyoderma.¹⁰ The proteinuria is suspected to be a consequence of CICs depositing in glomerular microcapillaries.

85.1.4

Therapy

Systemic antibiotics usually are not needed to treat surface pyodermic infections such as pyotraumatic dermatitis and intertrigo; topical antibacterial therapy usually is sufficient. However, systemic antibiotics are necessary for the management of mucocutaneous pyoderma and surface bacterial overgrowth. Successful

Infectious Diseases of the Dog and Cat, 3rd Edition

management of most superficial and deep pyoderma requires systemic antibiotic therapy. Topical antibacterial shampoo therapy commonly is applied as an adjunct in the management of mucocutaneous pyoderma, surface bacterial overgrowth, and most superficial and deep pyoderma to speed recovery, improve patient well-being, and potentially prevent recurrence. Immunomodulatory therapy is used less frequently, usually in an attempt to prevent or diminish the frequency of recurrent infection. Extended regimens of antibiotics should be considered a last resort in the management of recurrent pyoderma.

85.1.4.1 Antibiotic Therapy

The basic principles of systemic antibiotic therapy include the selection of an appropriate antibiotic, the establishment of an optimal dosage, and the maintenance of that dosage for enough time to ensure cure rather than transient remission. Although sequestered foci of infection may not be visible, surface lesions in deep pyoderma commonly heal before deeper lesions have resolved, leading to inappropriately early termination of therapy. Antibiotic selection can either be empiric or based on bacterial culture and susceptibility testing. An antibiotic chosen empirically should have a known spectrum of activity directed against *S. intermedius* and ideally should not be inactivated by β -lactamases, although most β -lactamase-resistant antibiotics are more expensive. Antibiotic therapy should be maintained for at least 1 week after the clinical cure for superficial pyoderma and a minimum of 2 weeks after the clinical cure for all types of deep pyoderma.

An ideal empiric antibiotic should have a narrow spectrum of activity, minimal side effects, and reasonable cost and have been shown to be an effective agent in the management of canine pyoderma. Little clinical evidence exists that bactericidal agents are more effective than bacteriostatic agents in the management of uncomplicated superficial pyoderma. Bactericidal antibiotics are recommended if hair follicle defects are present, in most deep pyoderma cases, and when immunosuppression is suspected or confirmed. If culture is performed, pustules or fistulous tracts should be recultured if *S. intermedius* was not isolated as the primary pathogen. If multiple isolates are not sensitive to a single oral antibiotic, an antibiotic effective against *S. intermedius* should be instituted because staphylococci create a tissue milieu favorable to the replication of secondary bacteria invaders. Results of culture and susceptibility studies and detailed information on individual antibiotics are discussed in greater detail in the Drug Formulary, [Appendix 8](#).^{67,131,132}

Antibiotics effective in the management of pyoderma are listed in [Table 85-3](#). Penicillin, ampicillin, amoxicillin, and tetracycline are poor choices for the treatment of canine pyoderma. Previous and regional usage may alter antibiotic susceptibility.* Not surprisingly, resistant *S. intermedius* and gram-negative isolates are seen more commonly in referral practices than in general practice, and resistant bacterial populations are identified most frequently in deep pyoderma.^{64,67,109} Many clinical trials have shown various antibiotics to be effective in managing canine pyoderma. Erythromycin, tylosin, lincomycin, clindamycin, chloramphenicol, trimethoprim and ormetoprim-potentiated sulfonamides, oxacillin, cephalexin, cefadroxil, fluoroquinolones, amoxicillin-clavulanate, and rifampin have been successful in the treatment of various canine pyoderma.†

Previously, it had been predicted that antibiotic-resistant *S. intermedius* would preclude the administration of many antibiotics common in dermatology. An examination of similarities and differences in antibiotic susceptibility patterns published during the past 2 decades indicates remarkably little spp.,⁶⁷ *S. intermedius* strains cultured from canine pyoderma in most locales apparently are no more resistant to commonly used antibiotics than they were 25 years ago. Fortunately, in comparison with *S. aureus* in humans and *Pseudomonas* spp., *S. intermedius* appears to lose resistance profiles rather rapidly when antibiotic pressure is removed. Consequently, many of the antibiotics just mentioned are still effective for the management of canine pyoderma. Preferred narrow-spectrum antibiotics include erythromycin, lincomycin, and oxacillin,

Infectious Diseases of the Dog and Cat, 3rd Edition

and preferred broad-spectrum antibiotics include cephalexin, cefadroxil, ormetoprim-potentiated sulfonamides, enrofloxacin, and marbofloxacin.

Owner compliance using different dosing schedule regimens is not well studied in veterinary medicine.

Perceived differences in efficacy probably correlate with differences in compliance. Compliance is easier with antibiotics given only once or twice daily than with those that need to be given 3 times daily.

812

813

Ormetoprim-potentiated sulfadimethoxine and the fluoroquinolones are the only antibiotics useful in canine pyoderma that can be administered once daily. Cephalexin, cefadroxil, and lincomycin require twice-daily dosing. Most other recommended antibiotics require three daily doses.

Table 85-3 Oral Antibiotics Useful for Treating Canine Pyoderma

DRUG NAME ^a (DOSE)	ADVANTAGES	DISADVANTAGES	ASSESSMENT
Erythromycin (10–15 mg/kg, 3 times daily)	Inexpensive, narrow spectrum	Cross-resistance with lincomycin, vomiting and diarrhea common, multiple daily dosing	Good first empiric choice
Lincomycin (22 mg/kg, 2 times daily)	Less frequent dosing narrow spectrum, few side effects	Cross-resistance with erythromycin, relatively expensive	Good first empiric choice, especially if need twice-daily drug
Clindamycin (10 mg/kg, 2 times daily, or 11 mg/kg, once daily)	Infrequent dosing	Only ~75% effective, development of resistance during therapy	Only a second-choice therapy for a once-daily drug
Ormetoprim-sulfadimethoxine (27.5 mg/kg, once daily) ^b	Less frequent dosing broad spectrum	Relatively expensive	Good first empiric choice, especially if need once-daily drug
Cephalexin or cefadroxil (22–30 mg/kg, 2 times daily)	Less frequent dosing broad spectrum, rare resistance, good tissue penetration	Cefadroxil expensive, generics moderately expensive	Excellent choice refractory-recurrent deep pyoderma, twice-daily drug
Enrofloxacin (5–15 mg/kg, once daily)	Less frequent dosing broad spectrum, rapidly absorbed, excellent tissue penetration	Expensive, cannot use in growing dogs	Excellent choice for refractory-recurrent deep pyoderma, once-daily drug
Marbofloxacin (2.5–5 mg/kg, once daily)	As above	As above	As above
Orbifloxacin (7.5 mg/kg, once daily)	As above	As above	As above
Oxacillin (22 mg/kg, 3 times daily)	Narrow spectrum, rare resistance, side effects rare	Expensive, multiple daily dosing absorption decreased by food	Good choice for refractory-recurrent deep pyoderma
Amoxicillin-clavulanate (12.5–20 mg/kg, 2 or 3 times daily)	Broad spectrum, side effects rare	Expensive, moisture sensitive, in vivo effect may not be as good as would be predicted	Efficacy low, somewhat expensive, for deep pyoderma
Trimethoprim-sulfonamide (22 mg/kg, 2 times daily)	Inexpensive, less frequent dosing broad spectrum	Side effects: keratoconjunctivitis sicca, severe cutaneous drug reactions, hepatic necrosis	Good empiric choice, concern for drug reactions
Modified from Ihrke PJ. 1996. <i>Bacterial skin disease in the dog: a guide to canine pyoderma</i> . Veterinary Learning Systems. Princeton, NJ.			

a For additional information on listed drugs, see Drug Formulary, [Appendix 8](#). Treatment generally lasts for a minimum of 21 days.

b Give dose twice daily on the first day.

Infectious Diseases of the Dog and Cat, 3rd Edition

Various *tiered systems* for antibiotic usage have been popularized in the past.^{35,67,78,131,132} The following recommendations comprise the tiered system recommended by the author. Erythromycin, lincomycin, clindamycin, and ormetoprim-potentiated sulfadimethoxine are useful for the management of uncomplicated, first-occurrence superficial pyoderma. The advantages and disadvantages of these drugs are listed in [Table 85-3](#). Trimethoprim-potentiated sulfonamides are additional possible candidates for uncomplicated, first-occurrence pyoderma. However, the potential side effects of trimethoprim-sulfonamides are of concern.⁷⁷

First-generation cephalosporins (cephalexin and cefadroxil), enrofloxacin, marbofloxacin, and oxacillin are recommended for pyoderma refractory to initial antibiotic therapy or recurrent pyoderma. Some veterinary dermatologists use amoxicillin-clavulanate. Chronic, deep pyoderma requires antibiotics with better penetrating ability because sequestered foci of infection and scarring prevent antibiotic access to the site of infection. Cephalexin, enrofloxacin, and marbofloxacin offer better penetrating ability. In the exceedingly rare circumstances when efficacy is not achieved with these drugs alone, rifampin (in conjunction with cephalexin or oxacillin) may be considered.

Enrofloxacin and marbofloxacin and other fluoroquinolones offer the advantages of once-daily dosing, excellent tissue penetration, activity against *S. intermedius* and gram-negative secondary invaders, and less likely development of resistance.^{39,69,71} Once-daily dosing is recommended because the bactericidal effect is concentration rather than time dependent.^{71,103} Uptake of enrofloxacin by macrophages leads to potent tissue-penetrating abilities.^{39,71}

813

Oxacillin is a β -lactamase-resistant, narrow-spectrum, synthetic penicillin. Advantages include consistent efficacy in pyoderma and few side effects. Price is the primary disadvantage, even as a generic. Oxacillin must be administered 3 times daily and should be administered at least 1 hour before feeding, because food interferes with absorption.

814

† References 13, 67-69, 71, 129, 132.

85.1.4.2

Topical Therapy

Topical therapy is important in the management of pyoderma. Shampoos are the most commonly used delivery system. Antibacterial shampoos may be effective without concurrent antibiotics in some surface pyoderma and are frequently used as adjunctive therapy in the management of superficial and deep pyoderma. Antibacterial shampoos aid in debridement, encourage drainage, and decrease pain and pruritus. Their desired mechanisms of action are to decrease surface bacterial counts and limit recolonizing organisms, thereby diminishing the likelihood of recurrent infections. Improvement in patient attitude and owner encouragement are additional benefits.

Available antibacterial shampoos contain benzoyl peroxide with or without sulfur, chlorhexidine, ethyl lactate, or triclosan. Twice-weekly use of antibacterial shampoos with a minimum of 10 minutes contact time are recommended. Benzoyl peroxide shampoos may decrease recrudescence in susceptible dogs. This compound acts as an antiseborrheic, having antibacterial and degreasing properties.

Dogs with deep pyoderma require more aggressive topical therapy. After clipping, dogs benefit from daily antibacterial shampoos or twice-daily whirlpools or soaks. Chlorhexidine or povidone-iodine are added to

Infectious Diseases of the Dog and Cat, 3rd Edition

warm water in whirlpools or soaks. Whirlpools remain a seldom used but very beneficial modality of topical therapy for deep pyoderma.

Antibacterial gels, creams, and ointments may be applied in the treatment of limited areas of skin. Cost, messiness, and time required for application limit their usefulness. Benzoyl peroxide is available in a gel vehicle. Mupirocin is a potent antibacterial agent with superior penetrating ability formulated for skin but not mucosal surfaces. Mupirocin should not be used when absorption of large amounts of the polyethylene glycol vehicle is likely because of the potential for nephrotoxicity.⁶⁷ Fusidic acid, a topically applied steroid antibiotic, has activity against gram-positive bacteria, such as staphylococci. It is bactericidal at higher concentrations. When applied to canine mucosal sites including the conjunctiva, nostrils, anus, and vulva, populations of *S. intermedius* were reduced on the mucosal and skin sites within 2 to 4 days after treatment was instituted and continued for up to 2 weeks after treatment was discontinued.¹²³

85.1.4.3

Immunomodulatory Therapy

Immunomodulatory therapy remains controversial because of widely varying perceptions of efficacy. If immunomodulation is attempted, it should be an adjunct to antibiotic and topical therapy with the goal of diminishing the frequency or severity of recurrence of infection. Immunomodulatory therapy is most efficacious in dogs with idiopathic recurrent superficial pyoderma that respond completely to appropriate therapy, but recurrence follows within weeks after therapy has been discontinued. Most mentions in the literature referable to immunomodulatory therapy are either highly subjective or anecdotal, because it is often used in conjunction with combined systemic and topical antibacterials. Controlled trials are difficult to perform because immunomodulatory therapy rarely is the sole therapy.

Immunomodulators can be either bacterial or nonbacterial preparations. Commercial products contain either killed *Staphylococcus* or *Propionibacterium* species as the antigen. Nonbacterial immunomodulatory drugs include levamisole and cimetidine (see Immunostimulants, [Chapter 2](#)).

Staphage Lysate (Delmont Laboratories, Swarthmore, Pa.) is the most common commercial bacterin used in North America and contains bacterial antigens of *S. aureus* isolated from humans. Staphage Lysate is the only product for which efficacy has been documented (approximately 40% of cases using 0.5 ml twice weekly³⁷) by double-blinded, placebo-controlled studies. Autogenous bacterins occasionally are made from specific staphylococcal organisms isolated from a dog with pyoderma for use in that dog. Inactivation methodology is crucial because the process must kill the organism without disrupting antigenic determinants.

Nonbacterial immunomodulatory therapy is controversial; most reports are anecdotal. Levamisole, a levo-isomer of tetramisole sold as a vermifuge for large animals, may alter lymphocyte and phagocyte immune function. The recommended dosage of the sheep boluses is 2.2 mg/kg given every other day orally. Cimetidine, an H₂-histamine receptor blocker developed for treating gastric ulcers, theoretically could reduce immunosuppression by down-regulating suppressor T lymphocytes, thereby modulating cytokine production. The suggested dosage is 3 to 4 mg/kg orally given twice daily for at least 10 weeks. Controlled studies of efficacy have not been performed with either product.⁶⁷ Oral recombinant interferon- α 2b has been used to treat idiopathic recurrent superficial pyoderma in dogs.¹⁴² Only transient benefit was noted as compared with placebo.

Infectious Diseases of the Dog and Cat, 3rd Edition

85.1.4.4 Factors Contributing to Therapeutic Failure and Complicating Management

The most common cause of therapeutic failure in second-opinion cases noted in University of California, Davis Teaching Hospital is failure to adhere to the basic principles of systemic antibiotic therapy. The most common errors are the lack of establishment of an optimal therapeutic dosage and the failure to maintain therapy for long enough to achieve clinical cure.

Treatment failure, disease recrudescence, and disease recurrence also commonly are associated with lack of recognition of factors that can complicate management and influence prognosis. The most common complicating factors include inappropriate initial therapy, unidentified coexisting problems, sequestered foci of infection in deep pyoderma, and external environmental factors such as poor compliance that may not be known to the veterinarian.

Most antibiotic dosages for treatment of pyoderma are largely empiric, because little research has been done in this area. In deep pyoderma, sequestered foci of infection impede antibiotic penetration, and keratin debris from ruptured hair follicles encourages foreign body granulomatous response. Antibiotics that require microbial replication for activity, such as penicillins, are less effective when necrotic tissue and obstructed drainage routes create conditions that are no longer favorable for bacterial multiplication. Consequently, higher dosages usually are warranted in the management of chronic, deep pyoderma. Flexible dosage ranges approved for enrofloxacin and marbofloxacin encourage appropriate dosing.

Concomitant problems such as demodicosis, cornification disorders, hair follicle defects, hypothyroidism, and steroid abuse may hinder successful management. Pruritus, associated with either a pyoderma or an underlying pruritic disease, is an additional complicating factor.

85.1.4.5 Assessment of Therapy

All dogs receiving systemic antibiotics for pyoderma should be reevaluated within 10 to 14 days. If substantial improvement is not noted, the clinician should consider other factors that can complicate management. The clinician should consider owner compliance to the appropriate dosage regimen, drug loss through vomiting, drug inactivation by food, or malabsorption. Lack of identification of underlying triggering diseases also must be considered as should initial misdiagnosis since other diseases may closely mimic pyoderma. The alternative of referral to a veterinary dermatologist should be considered each time that clinical failure occurs.

814

815

85.1.4.6 Recurrent Pyoderma

Recurrent pyoderma can be defined as bacterial skin infections that respond completely to appropriate therapy, leaving the dog free of clinical signs of infection between episodes of pyoderma. The relatively small but unknown percentage of cases characterized by frequent recurrences is one of the most frustrating aspects of veterinary dermatology. Recurrent superficial pyoderma is the most common subgroup. Underlying skin disease or undiagnosed internal medical abnormalities are the most common causes of recurrent canine pyoderma.^{35,67,78,131,132} Possible causes of recurrent pyoderma can be subdivided into persistent underlying skin disease, bacterial hypersensitivity, immunodeficiency, resistant strains of *S. intermedius*, and nonstaphylococcal pyoderma.³⁵ Recurrent pyoderma is considered idiopathic only if all appropriate diagnostic procedures have failed to reveal a predisposing cause.

Infectious Diseases of the Dog and Cat, 3rd Edition

Recurrent pyoderma triggered by continuing underlying skin disease may alter the clinical appearance of the predisposing condition, making identification of the predisposing trigger difficult. Diagnosis of the underlying disease may be facilitated by first treating with an appropriate course of antibiotics to unmask the symptomatology of the underlying disease.

Pruritus can be an important discriminating feature in evaluating recurrent pyoderma. If pruritus is totally ameliorated by antibiotic therapy, the pruritus probably was caused by the bacterial infection. If pruritus is still present after complete resolution of the pyoderma, the pruritus is most likely being caused by an as yet undiagnosed underlying disease.

Recurrent pyoderma commonly is a lifelong disease requiring extensive client communication and counseling. An informed client is more likely to make the necessary commitment to treatment. Curing underlying diseases may completely prevent recurrent pyoderma. Hypothyroidism is an example of an underlying disease in which pyoderma may be completely eliminated. In contrast, therapy for underlying flea allergy dermatitis seldom completely eliminates secondary pyoderma and requires constant flea control. Many skin diseases that act as triggers for recurrent pyoderma can be controlled but not cured, requiring continuous management. Canine atopic dermatitis and defects in cornification are examples of skin diseases that rarely respond completely to appropriate therapy and therefore continue to trigger occasional secondary pyoderma.⁶⁷

Choices in the management of recurrent pyoderma in which successful management of an underlying disease is not possible or the pyoderma is idiopathic include long-term topical antibacterial shampoos, immunomodulatory therapy, and extended regimens of systemic antibiotics. Antibacterial shampoo therapy performed once or twice weekly should be attempted initially. If this therapy prevents recurrence, it can be maintained indefinitely. Adjunctive immunomodulatory therapy should be considered as the next option if shampoo therapy alone is unsuccessful.

Extended regimens of antibiotics using subtherapeutic dosage regimens to prevent recurrence are viewed as a last resort in the long-term management of recurrent canine pyoderma and should be used only after the current episode of the pyoderma has been brought under complete control. Antibiotics most useful for extended regimens include cephalexin, enrofloxacin, marbofloxacin, oxacillin, and amoxicillin-clavulanate.

Risks inherent in the extended administration of systemic antibiotics using subtherapeutic dosage regimens include undesirable effects in the patient, induction of antibiotic resistance, and formation and possible dissemination of resistant strains of bacteria in the environment. The relatively high cost is an additional drawback. The author currently prefers 2 or 3 consecutive days per week at the full daily dosage. Other options include every-other-week dosing at therapeutic levels followed by extending the duration of time off antibiotics in gradual increments (2 weeks, 3 weeks).⁶⁷ Long-term therapy must be monitored carefully because of inherent risks.

85.2 OTITIS EXTERNA

Craig E. Greene

Infectious Diseases of the Dog and Cat, 3rd Edition

85.2.1 Etiology

Otitis externa is inflammation of the external ear canal. The following discussion focuses on microbial factors; reviews should be consulted concerning other causes of this condition. (For a discussion of otitis media-interna, see Musculoskeletal Infections, [Chapter 86](#).) Numerous causative agents have been associated with otitis externa ([Table 85-4](#)), and failure to identify and eliminate the underlying cause results in ineffective treatment. Most microbial infections of the external ear canal are secondary to another disease or factor that make it susceptible to colonization by normal or opportunistic microflora. Bacteria, yeasts, parasites, and viruses have all been incriminated as causing otitis externa. In many cases, an underlying disease can be found, and the role of the infectious organism as the primary cause of otitis externa cannot be substantiated. For example, cocker spaniels have ceruminous and sebaceous gland hyperplasia with chronic otitis externa, whereas other breeds develop fibrosis.⁶

The normal ear canal is colonized by various microorganisms that can proliferate with damage or inflammation from the primary factors ([Table 85-5](#)). Microfloral overgrowth can exacerbate or perpetuate inflammatory reactions. Higher concentrations of bacterial and yeast organisms have been found in the ear secretions of dogs with otitis externa than in clinically healthy dogs.¹⁵² Coagulase-positive *S. intermedius* is the most common isolate in normal ears and in acute otitis externa, in which it is even more prevalent. β -Hemolytic streptococci are found with equal frequency in normal and diseased ears, so their pathogenic status is uncertain. Other common organisms rarely found in clinically healthy ears and isolated predominantly in cases of chronic otitis externa are *Pseudomonas* species and *Proteus mirabilis*.¹⁵² *Pseudomonas* species have been associated with a severe, virulent form of otitis externa. These organisms are isolated from the ear canal of fewer than 1% of clinically healthy dogs and up to 20% of those with chronic otitis externa. *Pseudomonas* organisms isolated from the ear canals of dogs are often highly resistant to antibacterial drugs. In one report, *Pseudomonas aeruginosa* isolated from canine ear cultures were 32% resistant to gentamicin and 100% resistant to ampicillin, cephalothin, trimethoprim-sulfonamide, and tetracycline.¹¹⁷ Because of the multidrug resistance pattern of *Pseudomonas*, empirical therapy is not advised. Mixed infections usually are composed of *S. intermedius* in conjunction with a gram-negative rod. In cats, *Pasteurella multocida* may also be isolated.

Bacteria or the broad-based budding yeast *Malassezia pachydermatis* may proliferate in an ear canal of an animal predisposed to infection because of other underlying diseases or prolonged antibacterial therapy. 815

Microsporum canis is considered to be a secondary invader contributing to or perpetuating and exacerbating inflammation in an already diseased ear canal. In cats the relative importance of *M. pachydermatis* in disease is less certain because it is found with equal frequency in clinically healthy cats and those with otitis externa. (For additional discussion of *M. pachydermatis* infections in dogs and cats, see [Chapter 58](#).) 816

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 85-4 Predisposing Factors for Otitis Externa

HOST	
Anatomic	
Breed	German shepherd
Conformation	Long droopy ears (cocker, bassett), stenotic canals (English bulldog, Shar pei, chow chow), hair in canals (poodle, schnauzer, bichon, Airedale, wirehaired, and fox terriers), ceruminous gland hyperplasia (cocker spaniel)
Otitis media-interna	Causing self-inflicted trauma or act as nidus
Masses	Polyps, squamous cell carcinoma, ceruminous gland tumors, papilloma, sebaceous adenoma, ceruminous adenoma, fibroma squamous cell carcinoma, basal cell carcinoma, fibrosarcoma
Hyperkeratosis	Seborrheic diseases (German and Belgian shepherds), sebaceous gland infection (standard poodles, Akitas, Samoyeds), inflammatory polyp (cats)
Immunologic Conditions	
Hypersensitivities	Atopic dermatitis, juvenile cellulitis (puppy stranglers, golden and Labrador retrievers, dachshunds, pointers, Lhasa apso), contact allergies (propylene glycol), food allergy, drug eruption
Immunodeficiency	Debilitation
Autoimmune	Systemic lupus erythematosus, pemphigus foliaceus
Endocrinopathic Conditions	
	Male-feminizing syndrome, hypothyroidism, Sertoli cell tumor, ovarian imbalance
ENVIRONMENT	
Moisture	Swimming (Labrador retrievers), high environmental temperature and humidity
Foreign material	Plant material, excessive otic medicants, soil, exudates, dried wax
Medicants	Yeast infections due to chronic antibiotic and glucocorticoid therapy
Astringents	Alcohol, cleansing agents
Trauma	Iatrogenic or self-induced, lacerations of aural mucosal, excessive cleaning or medicants, cotton swabs
AGENT	
Parasites	<i>Otodectes cynotis</i> (ear mite), biting flies, chiggers, ticks, <i>Demodex canis</i> , <i>Sarcoptes</i> , <i>Notoedres</i> , flea allergy
Bacteria	<i>Staphylococcus intermedius</i> , β -hemolytic streptococci, <i>Proteus</i> , <i>Pseudomonas</i>
Fungi	<i>Malassezia canis</i> , <i>Microsporum canis</i> , <i>Candida</i>

The ear mite *Otodectes cynotis* is believed to be responsible for a majority of feline cases of otitis externa; dogs have a much lower prevalence of infection. Most animals develop a hypersensitivity reaction to the mite that causes the inflammation seen clinically; however, some are nonsymptomatic carriers. In others, the inflammation may lead to a secondary bacterial or yeast infection that can eventually result in the destruction of the mites.

85.2.2 Clinical Findings

A complete history, with special attention to the animal's environment and exposure to vegetation and water, is helpful. Pruritus, a major problem with otitis externa, is manifest by head shaking, scratching, or rubbing the ears along the floor or other objects. On physical examination, pinna or caudal auricular alopecia, matted hair, broken hairs, excoriations, and occasional areas of acute moist dermatitis are apparent. The external auditory meatus may be erythematous and swollen. In many uncomplicated cases of otitis externa, the clinical findings are limited to erythema and possibly a slight increase in ear wax (ceruminous otitis) (Fig. 85-3). When otitis externa is complicated by secondary bacterial or yeast infections, the character and amount of discharge may become more purulent and moist and may have a foul odor (suppurative otitis). Inflammation may be severe,

Infectious Diseases of the Dog and Cat, 3rd Edition

the ear canals may become painful, and self-inflicted trauma may be apparent. Some animals become head shy; others show evidence of pain only when the canal is palpated. Chronic otitis is characterized by epidermal hyperplasia with thickening of the pinna and narrowing or calcification of the ear canal or both. Fibrosis is observed in most breeds with chronic otitis, although cocker spaniels have the most significant degree of ceruminous and sebaceous gland hyperplasia (Fig. 85-4).⁶ A thorough examination of the ear with an otoscope is needed to determine the presence of secondary changes and the extent of the inflammation and discharge as well as the condition of the tympanic membrane. If the canal is very swollen and stenotic, treatment should proceed with a broad-spectrum topical preparation for up to 1 week before performing the otoscopic examination.

Pseudomonas ear infections are highly virulent and characterized by unilateral or bilateral aural pruritus, head shaking, scratching, and rubbing of the ears. A foul-smelling, greenish-yellow discharge is typically found.

816

817

Table 85-5 Organisms Isolated from External and Middle Ear Canal of Dogs and Cats

		FREQUENCY OF ISOLATION (PERCENTAGE) ^a			
ORGANISM	HOST	CLINICALLY HEALTHY	OTITIS EXTERNA	OTITIS MEDIA	PHYSICAL DESCRIPTION
GRAM-POSITIVE BACTERIA					
Staphylococci (coagulase positive), includes <i>Staphylococcus intermedius</i>	Dog	9–20	22–40	18	Light brown or pale yellow exudates
Streptococci (β-hemolytic)	Dog	16	10	9	Light yellow to light brown exudates
GRAM-NEGATIVE BACTERIA					
<i>Pseudomonas</i> species	Dog	0.4	20	26	Painful, copious light yellow to green exudates, often ulcerated epithelium
<i>Proteus</i> species	Dog	0	11	6.5	Light yellow exudates, ulcerated with chronicity
<i>Escherichia coli</i>	Dog	0	14	2.6	Light yellow exudates
FUNGI					
<i>Malassezia</i> species	Dog	15–49	50–83	17	Light brown to dark (chocolate) brown exudates
	Cat	23	19		
METAZOANS					
<i>Otodectes cynotis</i>	Dog	0	5–10	0	Dark brown exudates
	Cat	0	50		

^a Data on animals with otitis media are from Cole LK, Kwochka KW, Kowalski JJ, et al. 1998. Microbial flora and antimicrobial susceptibility patterns of isolated pathogens from the horizontal ear canal and middle ear in dogs with otitis externa, *J Am Vet Med Assoc* 212:534–538. Data on clinically healthy animals and those with otitis externa are from references cited in the text.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 85-4 Chronic proliferative epidermal hyperplasia of ear canal of cocker spaniel dog with otitis externa. (Courtesy University of Georgia, Athens, Ga.)

817

After a complete history and physical otoscopic examination, smears of the ear canal contents should be made. To prevent cross-contamination, a separate, clean otoscope cone must be used for each ear. Sterilized cones should be used if bacterial or fungal culture specimens are taken. The canal should be examined for its diameter, amount and type of exudate, foreign bodies, neoplasms, parasites, condition of the tympanic membrane, and integrity of the epithelium. As described by others,²⁸ ears can be thoroughly cleaned by placing ceruminolytic ear cleaners within the ear for 10 minutes to emulsify wax and debris. Ears are then flushed with warm sterile isotonic 0.9% saline using a bulb syringe to remove any loosened debris. Some ceruminolytic agents can be irritating and damage the structures of the middle and inner ear if the tympanic membrane is perforated.⁹² Because the integrity of the tympanic membrane is not known before cleaning, only mild agents should be used for this purpose.

Additional examination can be done with general anesthesia or sedation. Hand-held or videoendoscopes are used to examine the horizontal canal and deeper structures. Further drying of the cleaned canal may be accomplished using swabs so that the entire canal can be visualized. Deeper irrigation of the canal is accomplished with a syringe attached to an 8 French polypropylene urinary catheter cut to approximately 9 cm, blunted using a flame, and attached to a 12-ml syringe.²⁸ Swabs should be inserted into the horizontal canal of each ear through a sterilized otoscope cone to recover material for microscopic examination and culture. One swab should be placed in a drop of mineral oil on a slide and examined for ear or *Demodex* mites. Another swab should be rolled onto microscope slides, and a fast stain based on Giemsa's or Wright's methods is often used. Before staining, the slide should be heat fixed by passing it over an open flame 2 or 3 times. Heat fixing melts some wax and debris, which causes them to adhere better to the glass slide. Without heat fixing, much of the wax, lipid, and associated yeasts may wash away in the staining process. More than 10 yeasts per high-power field are suggestive of their overgrowth.

Cytologic examination of exudate is needed to evaluate the type of inflammatory response and potential underlying cause. Numbers and morphology of leukocytes, neoplastic cells, and bacteria or fungi should be recorded. In one report, mean *Malassezia* counts per high-dry power (40×) field equal to or greater than 5 in the dog and equal to or greater than 12 in the cat and mean bacterial counts of ≥ 25 in the dog or equal to or greater than 15 in the cat were considered indicative of external ear canal infection.⁴⁵ Because commensals are cultured from normal ears, cytologic enumeration of bacteria provides a means of determining their overgrowth and a hint about their type before culture results become available. When secondary bacterial infections are contributing to the disease, leukocytes and phagocytized bacteria are usually present. When primarily wax and keratin are present, the bacteria observed are most likely incidental but can still contribute to the odor and inflammation by their lipolytic action on waxy debris.

Occasionally, *O. cynotis* or *Demodex* can be identified during examination of a smear. Failure to find mites, especially if secondary infection is present, does not rule out their existence.

Bacterial culture and susceptibility testing offer little additional information compared with good basic cytologic evaluation and are costly. Antimicrobial susceptibility can usually be determined on the basis of organism morphology (Table 85-6). Furthermore, the levels achieved by topical application are much higher than the serum levels of sensitivity disks. Bacterial isolation is of more benefit if the tympanic membrane is ruptured with otitis media or interna and the clinician is contemplating systemic antibiotic therapy. Culture and susceptibility testing also are indicated in chronic otitis externa when primarily bacterial rods are found on a smear or when microorganisms persist in spite of apparent appropriate topical medication. *Malassezia* is better

Infectious Diseases of the Dog and Cat, 3rd Edition

identified by cytology than by culture (see [Fig. 56-4](#)). Repeating cytologic examination on subsequent visits helps evaluate drug resistance or owner compliance. Persistent inflammation in the absence of abundant microorganisms suggests an allergic or ceruminous otitis.

In a prospective study of 23 dogs with chronic bilateral otitis externa, infection was identified in at least one tympanic bulla in 22 dogs.²⁸ Infection of the middle ear could not be determined by the presence or absence of an intact tympanic membrane. Myringotomy was used to detect infection within the tympanic bulla. Furthermore, organisms isolated from the horizontal ear canal and middle ear were only identical in 10.5% of the ears. Therefore for definitive evaluation, specimens for cultures should be taken from the horizontal ear canal and in the bulla via myringotomy during examination under general anesthesia. Myringotomy is accomplished by passing a sterile culture swab or rubber or polypropylene catheter through a sterilized otoscope cone into the caudoventral portion of the tympanic membrane. Use of a catheter allows for lavage of the bulla should exudate be found on penetration. Duplicate specimens should be taken and submitted for cytologic and cultural examination.

Radiologic imaging should be considered with chronic or recurrent otitis when signs of vestibular dysfunction or other neurologic signs of dysfunction or cranial hyperesthesia are observed. Skull radiography allows for visualizing the tympanic bulla; however, computed tomography and magnetic resonance imaging with contrast enhancement are able to detect meningeal or intracranial involvement.

85.2.4 Therapy

Effective treatment and management of otitis externa are best achieved by combining several principles. If possible, predisposing causes should be identified and eliminated or prophylactically treated. Topical therapy is especially beneficial because drugs attain their highest concentrations with the fewest systemic effects. To obtain owner compliance, the treatment should be specific and simple. Systemic antibacterial or antifungal therapy may be needed if the external canal is occluded or otitis media is present. Systemic therapy can be selected on the basis of culture and susceptibility results. For empiric systemic bacterial therapy, drugs used to treat staphylococcal pyoderma such as erythromycin, first-generation cephalosporins, lincomycin, clindamycin, amoxicillin-clavulanate, ormetoprim- or trimethoprim-sulfonamides, or fluoroquinolones are most effective. For *Pseudomonas* species, effective drugs have included extended-spectrum penicillins (piperacillin, ticarcillin, carbenicillin), third-generation cephalosporins (ceftazidime, cefoperazone), aminoglycosides, and quinolones. *P. aeruginosa* is more likely than other organisms to develop resistance to any of these drugs during treatment. For example, isolates of *Pseudomonas* and *Enterococcus* species from dogs with otitis externa or urinary tract infection have been shown to develop resistance to enrofloxacin, whereas *Klebsiella*, *Proteus*, and *Streptococcus* species were less likely to develop resistance.¹⁵ In one report, *Pseudomonas* organisms isolated from chronic canine otitis externa were more susceptible to tobramycin, marbofloxacin, and ceftazidime than to enrofloxacin, presumably from more extensive use of the latter drug.⁹⁴ Regardless of which antimicrobial therapy is instituted, treatment usually lasts a minimum of 3 to 4 weeks (see [Table 85-6](#)).

85.2.4.1 Cleaning

Depending on the animal's temperament, sedation or anesthesia may be needed for cleaning the ears, which should be dried before initiating therapy. Initial cleaning and drying of the ear canals are essential to complete the otoscopic examination, determine the integrity of the tympanic membrane, and facilitate the penetration of topically administered drugs. Thorough cleansing of the ear canals removes small secondary foreign bodies as well as degenerated inflammatory cells, free fatty acids, bacterial toxins, wax, and debris.

818

819

Infectious Diseases of the Dog and Cat, 3rd Edition

Ear cleaning with physical flushing of the canal may be repeated as needed, but it should not be performed more than 2 times weekly because it produces mucosal ulceration. Ear-cleaning solutions may be applied more frequently by the owner, who can instill a few drops just before an otic antimicrobial drug is given. The animal should be allowed to shake its head to disperse the solution, and the excess removed before instilling the desired medication. Cleaning and flushing solutions are generally disinfectants and are listed in [Table 85-7](#). They are used for initial removal of debris or as ceruminolytics. Ceruminolytics are selected when excessive waxy accumulation is present. In most cases, ceruminolytic agents, such as carbamide peroxide and dioctyl sodium sulfosuccinate, are most effective in emulsifying and facilitating the cleaning procedures and are water soluble. Carbamide peroxide has a foaming action that breaks down debris. Ceruminolytic oils such as squalene, lanolin, and mineral oil are more difficult to clean up. Many combination ceruminolytic and drying products contain organic acids with a ceruminolytic agent or alcohol added. They are easier to clean up and can be used as a one-step procedure. These products must be applied with great caution if the tympanum is ruptured. In a study of several ceruminolytic agents, only a solution containing squalene and isopropyl myristate with liquid petrolatum base (Cerumene, Evsco Pharmaceutical, Buena, N.J.) was nonirritating to the middle ear in the presence of a ruptured tympanum.⁹² If ceruminolytics are used before the discovery of a ruptured membrane, thorough rinsing with pure water or saline is preferred. Other rinse solutions should not contain detergents or disinfectants because they are ototoxic and contraindicated with a ruptured tympanic membrane.

819

820

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 85-6 Antimicrobial Selection for Otitis Externa^a

ACUTE OTITIS

Cytologic exam: gram-positive cocci; culture; staphylococci, streptococci

Topical

Neomycin (Panolog, Tritop, Quadritop, Tresaderm, Neopredef)

Povidone-iodine (Betadine) dilute 1 : 50 (intact tympanum); 1 : 100 (perforated tympanum)

Chlorhexidine (Nolvasan) dilute 1 : 40 in water

Acetic acid (white vinegar 5%) dilute 1 : 3 in water; concentrations of 2%-5% are irritating (many formulations)

Cytologic exam: gram-negative bacilli; culture; *Proteus* species, *Escherichia coli*

Topical

Neomycin (Panolog), polymyxins (Surolan), gentamicin (Gentocin otic)

Acetic acid (white vinegar 5%) dilute 1 : 3 in water (many)

Povidone-iodine (Betadine) dilute 1 : 50 (intact tympanum); 1 : 100 (perforated tympanum)

Cytologic exam: yeasts

Topical

Nystatin (Panolog), thiabendazole (Tresaderm), miconazole (Surolam, Conofite), clotrimazole (Otomax, Genotic B-C, MalOtic Ointment, Otibiotic, Otosoothe, Tri-Otic, Mometamax Otic)

CHRONIC OR RESISTANT OTITIS

Yeasts

Topical

Clotrimazole (Otomax, many formulations), miconazole (Surolam, Conofite), clotrimazole (many), Silvadene

Systemic

Ketoconazole 5 mg/kg twice daily for 2-4 weeks, itraconazole 5-10 mg/kg once daily for 2-4 weeks

Gram-negative species, usually *Pseudomonas*

Topical

Gentamicin (Gentocin otic, otomax), polymyxin B, colistin or polymyxin E (Coly-Mycin), polymyxin B (Cortisporin)

Polyhydroxidine iodine (Xenodyne, Solvay) diluted 1 : 3 to 1 : 5 in water and apply twice daily

Systemic

Ormetoprim-sulfadimethoxine, trimethoprim-sulfonamide, first-generation cephalosporin

Infectious Diseases of the Dog and Cat, 3rd Edition

Culture *Pseudomonas* species

Topical

Ticarcillin (Ticar suspension), add 4 g to 4-oz bottle of Oti-clens

Tobramycin (Tobrex ophthalmic)

Enrofloxacin (Baytril injectable) diluted 50% in water, 3-5 drops twice daily

Amikacin sulfate (Amiglyde-V injectable) undiluted (50 mg/ml) 5-6 drops twice daily

Silver sulfadiazine (Silvadene) diluted 1 : 1 in water, 4-12 drops twice daily

TRIS-edetic acid-gentamicin solution (Wooley's solution) (see [Chapter 34, Table 34-12](#))

Systemic

Enrofloxacin, marbofloxacin, orbofloxacin, gentamicin

a Trade names appear in parentheses.

Table 85-7 Solutions for Management of Otitis Externa

CLASSES AND INDICATIONS	INGREDIENTS	PRODUCTS
Flushing Solutions		
Primary cleaning of canal, have weak antibacterial activity	Cleaning and disinfecting solutions containing dilute acids and disinfectants	Betadine, povidone-iodine 10% (dilute 1:10 to 1:50); Xenodyne, polyhydroxide iodine 0.5% (dilute 1:1 to 1:15); Nolvasan chlorhexidine 2% (dilute 1:40); vinegar, acetic acid 5% (dilute 1:3); lactic acid 2.5%; salicylic acid 0.1%
Ceruminolytics		
Permeate and solubilize waxy debris	Squalenes, surfactants, carbamide peroxide, chlorhexidine, dioctyl sodium sulfosuccinate, propylene glycol	Cerumene, Clear X, Veterinary Surfactant, Sebo-o-sol, Otic Chlor-7, Otic Clear, Nolvasan Otic, Adams Pan Otic
Ceruminolytic and Drying Agent		
When combined, dissolve wax and dry out canal	Same as ceruminolytic ingredients, but also includes alcohols and acids such as lactic, salicylic, malic, benzoic, and acetic	Cerbin-otic, Oti-clens, Epi-otic, Chlorhexiderm Otic, Adams Ear Dessicant, Fresh Ear, VPL Otic Cleanser, Chlor-otic-L, Otic-clear
Drying Agents		
Have mild antibacterial activity, dry ear canal, act as astringents on exuding lesions	Organic acids, alcohols, silicone dioxide (as listed for previous combinations)	Dermal Dry, Otic Domeboro, Panodry, Otic Calm, acetic acid 5% and isopropyl alcohol in a 3:1 ratio

Rubber bulb ear syringes are a very efficient way to flush the ear. After the initial flushing, loops can be used to remove any remaining material. Cotton swabs should be avoided because they pack exudate and debris down in the ear and may injure the tympanum or epithelial lining. In other cases, especially in animals with a ruptured tympanum, a feeding tube attached to a 12-ml syringe may be used for the final flushing as well as for cleaning out the bulla. In addition, by applying negative pressure, it is a rapid, atraumatic way of removing residual water. Head tilt, ataxia, or both may develop after cleaning as a result of otitis media or interna.

Infectious Diseases of the Dog and Cat, 3rd Edition

85.2.4.2 Topical Therapy

Once the ears are clean and dried, topical therapy can be effective in the treatment plan. In general, most ear products contain various combinations of glucocorticoids and antibacterial, antiyeast, and parasitocidal agents in aqueous solution or oil vehicles ([Table 85-8](#)). The most appropriate topical drug can be prescribed on the basis of clinical findings, cytology, and diagnosis. Cleaning solutions and disinfectants (antiseptics) are the first preparations that can be used to help remove debris and control overgrowth of microorganisms. Oil vehicles are best applied when the ears are dry, because they tend to moisturize the skin. In moist, exudative ears, water-soluble vehicles are preferred because they are less occlusive. Water-soluble aqueous preparations are most desirable when the tympanic membrane is ruptured. Besides selecting the most appropriate vehicle, the clinician must decide which active ingredients are most appropriate for each case. No single perfect topical ear product exists.

Topical glucocorticoids are most effective when an animal has early, acute inflammation, and high-potency fluocinolone, betamethasone, and dexamethasone are recommended. Although they are generally contraindicated in infectious processes, they do reduce the inflammation in the ear canal, which controls pruritus, swelling, exudation, wax build-up, and tissue proliferation and hyperplasia. It is difficult to find a commercial otic medication that is not formulated with glucocorticoids. Because they may predispose the patient to secondary yeast infections and hyperadrenocorticism, the lowest required potency (e.g., hydrocortisone) and frequency are recommended for long-term (greater than 3 months) treatment. Otic preparations with dexamethasone and triamcinolone have systemic effects and result in signs of hyperadrenalism with iatrogenic pituitary-adrenal suppression. With severely painful or inflamed ears or stenotic canals, systemic prednisone is recommended at a dose of 0.25 to 0.5 mg/kg twice daily for 1 to 2 weeks in dogs and twice this dose for cats.

Bacterial infections should be treated with topical antibiotics or disinfectants. In general, the aminoglycosides (neomycin, polymyxin, gentamicin) and chloramphenicol are frequently effective.

820

822

Although the aminoglycosides are potentially ototoxic, especially when topically applied to an ear with a ruptured eardrum, this has not been shown to be a problem (see Aminoglycoside Toxicity, [Chapter 34](#)). Optimally, drugs that may later be needed for systemic therapy should not be used topically in acute cases because resistance may develop. Disinfectants are an effective alternative to antibiotics. Iodine and chlorhexidine are good choices for treating bacteria and yeasts, respectively, but are ototoxic when put into the middle ear. Acetic acid at 2% is generally effective against *Pseudomonas* species and at 5% is effective against most bacterial pathogens involved in otitis externa. Other acids that are effective are 2% boric acid, 2.5% lactic acid, and 0.1% salicylic acid.²⁹ For more resistant *Pseudomonas* infections, otic or ophthalmic medicants containing gentamicin, tobramycin, or polymyxins can be applied, and as a last resort, compounded formulations of ticarcillin or amikacin solutions can be prepared and instilled twice daily. Silver sulfadiazine, a compounded mixture of two antibacterial agents, is highly effective against *Pseudomonas* and other bacteria and yeasts in canine otitis externa.¹¹⁰ Silver sulfadiazine ear solution (0.1%) is prepared by mixing 0.1 g of chemical-grade powder into 100 ml distilled water. Alternatively, 1.5 ml of cream is mixed with 13.5 ml distilled water; however, this mixture is more viscous and requires warming above ambient temperature to ease its topical application. TRIS-ethylenediaminetetraacetic acid (EDTA) preparations are also effective against *Pseudomonas* and other resistant gram-negative bacteria (see Buffered EDTA Solution, [Chapter 34](#), and [Table 34-15](#)). *Pseudomonas* infections may be susceptible to quinolones that have been compounded into topical preparations for treatment of chronic otitis externa. (For specific information on compounding topical enrofloxacin and ticarcillin preparations for treating *Pseudomonas* described above, see Drug Formulary, [Appendix 8](#).)

Secondary yeast infection may occur when systemic or topical antibacterial therapy is prolonged. Cytologic examination should be performed at repeat visits to check for this complication.

Enterococci	>10 ⁵	>10 ⁵	>10 ⁵

From Vogel et al. 1999. *J Am Vet Med Assoc* 214:1642-1643.

- a Subcutaneous tissue immediately after skin incision.
- b Excised epithelium from the bulla ossea.
- c Subcutaneous tissue just before skin closure.

When *Malassezia* organisms are present, the topically applied antiyeast agents such as nystatin and thiabendazole contained in many ear medicants are frequently effective. Thiabendazole can be a contact irritant in some dogs. In more difficult cases, 1% miconazole or clotrimazole lotions usually work. A mixture of 2% boric acid and 2% acetic acid instilled in the ear once daily for 7 weeks was reported to be effective in treating *Malassezia* otitis.⁴⁸ If a *Malassezia* otitis media is diagnosed, then the systemic antifungal ketoconazole given 5 mg/kg every 12 hours or itraconazole given 5 mg/kg every 24 hours for 4 to 6 weeks is the preferred treatment (see [Chapter 58](#) for further information on *Malassezia* infections).

O. cynotis is relatively sensitive to most insecticides, including pyrethrins, rotenone, and thiabendazole. In addition to treating the ears, the entire body and other in-contact animals should be treated. Ivermectin at 250 mg/kg, given orally once weekly for 3 to 4 weeks or subcutaneously once every 10 days for two treatments, is effective against *Otodectes* mites. It also eliminates mites from other areas. However, ivermectin is not approved for use in cats or dogs at this dosage. It is absolutely contraindicated in collies.

Surgical treatment of refractory otitis externa and media is total ear canal ablation and lateral bulla osteotomy. In one study, various bacteria were isolated from the subcutaneous tissues at the time of the initial skin incision, the tympanic bulla, and the tissues at the time of closure of the incision¹⁴⁷ ([Table 85-9](#)). In this study, susceptibility of isolates for each drug were as follows: gentamicin (50%), ampicillin (54%),

Infectious Diseases of the Dog and Cat, 3rd Edition

amikacin (62.5%), cefazolin (70%), trimethoprim-sulfonamide (87.5%), and greater than 90% showing susceptibility to amoxicillin-clavulanate, ticarcillin, ticarcillin-clavulanate, or ciprofloxacin. Dehiscence from infection is common after this procedure and may also relate to numerous factors, including difficulty of decontaminating the recesses of the ear canal and bulla during surgical preparation and bacterial resistance to surgical preparation solutions such as chlorhexidine that are in many ear remedies. Therefore care should be taken to reduce bacterial contamination before and during otic surgeries, and bacterial culture with antimicrobial susceptibility testing is indicated at the incision site before closure.

85.2.4.3

Prognosis

The prognosis is generally good in acute (less than 4 weeks' duration) cases of otitis externa when the tympanic membrane is intact. Early control of the disease is important in preventing secondary changes. A guarded to good prognosis is indicated in chronic cases unless surgical intervention is advised. Whenever the tympanic membrane is ruptured, otitis media is diagnosed, and the prognosis for complete recovery becomes guarded with medical therapy alone. When secondary changes have progressed to marked fibrosis with narrowing of the ear canal or osteomyelitis of the bulla, surgical intervention may be required. In animals with calcified ear canals, surgery is also necessary to achieve good results. Lateral (horizontal) ear resection is indicated to facilitate drainage and administer medicants, but it is usually only palliative because diseased tissue often remains. Total (vertical) canal ablation is needed with tissue proliferation and calcification of the ear canal. When clinical signs of middle or inner ear disease occur and fluid density is apparent within the bulla or thickening of the bulla is seen radiographically, bulla osteotomy is the treatment of choice (see also Otitis Media/Interna, [Chapter 86](#)).¹⁴³ Total canal ablation and lateral bulla osteotomy can be done simultaneously.⁷⁶ Although these procedures may cure the otitis externa and media, postoperative complications include hearing impairment, Horner's syndrome, facial nerve paralysis, and vestibular dysfunction.

86 CHAPTER 86 Musculoskeletal Infections

Craig E. Greene

Steven C. Budsberg

Musculoskeletal infections involve bones, joints, and muscles. Osteomyelitis is classically defined as inflammation of the cortical bone, medullary cavity, and periosteum.^{17,46} Most cases involve infectious agents, including bacteria, fungi, and viruses. Other potential causes include irritants, such as radiation therapy, or surgical implants; however, these causes are much less common.^{17,46,62} Bone infections can be divided into skeletal (including the skull and pelvis) and vertebral (including intervertebral disks and vertebral bodies). Diskospondylitis with secondary osteomyelitis developing in the opposing vertebrae is more common in dogs and cats compared with people. In humans, vertebral osteomyelitis often occurs without disk space infection. In animals, vertebral osteomyelitis usually arises from penetrating injuries (see Actinomycosis, [Chapter 49](#)) rather than from blood-borne infections that cause diskospondylitis (see Diskospondylitis and Vertebral Osteomyelitis later in this chapter).

To understand osteomyelitis, the disease process is best divided into hematogenous and posttraumatic causes. Posttraumatic osteomyelitis can be either acute or chronic.^{17,46,62} Because of differences in causes, clinical findings, and treatments, skeletal osteomyelitis and diskospondylitis are discussed separately ([Table 86-1](#)). Additionally, otitis media is covered in this chapter because the bony structures of the middle and inner ear are involved. Joint and muscle infections that concern soft tissues adjacent to bone are each covered separately. [Table 86-2](#) lists microorganisms commonly associated with musculoskeletal infections.

86.1 OSTEOMYELITIS

86.1.1 Etiology

Bacterial infections cause most cases of osteomyelitis in clinical practice. In some studies, gram-positive organisms such as *Staphylococcus* accounted for 50% to 60% of cases,^{46,69} and *Staphylococcus intermedius* is the primary organism. Other gram-positive organisms found less frequently include *Streptococcus* and *Enterococcus*. In other reports, both gram-positive and gram-negative organisms have been approximately equal in their recovery rate.²⁹ Gram-negative organisms have included *Pasteurella*, *Escherichia coli*, *Pseudomonas*, *Proteus*, *Serratia*, and *Klebsiella*. Anaerobic bacteria include *Peptostreptococcus*, *Bacteroides*, *Fusobacterium*, *Actinomyces*, *Nocardia*, and *Clostridium*.⁸⁵ Anaerobic bacteria have been isolated with greater

Infectious Diseases of the Dog and Cat, 3rd Edition

frequency as sample collection, transportation, and incubation techniques have improved.^{69,85} Anaerobic bacteria are rarely isolated alone, and other anaerobes and microaerophilic or aerobic bacteria usually make the environment conducive for anaerobic growth. Polymicrobial infections are becoming more common, presumably because of overuse of antimicrobial agents, which enables resistant bacterial populations to flourish, or because of better bacterial collection and detection methods. In human medicine, a poorer prognosis is found in cases of osteomyelitis when more than one organism is isolated.

A variety of fungi has been identified in osteomyelitis from regions where the organisms are endemic. In the United States, the most common isolates are *Blastomyces*, *Coccidioides*, *Histoplasma*, and *Cryptococcus*.^{62,133} Other organisms reported include *Aspergillus* and *Phialoconidium*. German shepherd dogs have the highest prevalence rate for hematogenous fungal osteomyelitis, making a hereditary immune deficiency a likely contributing factor (see also Disseminated Aspergillosis, [Chapter 64](#)).

Although viral agents have been incriminated as causing inflammatory bone diseases, factual data have been limited. However, virulent and vaccine-strain canine distemper virus (CDV) has been suspected as a cause of hypertrophic osteodystrophy (HOD) and juvenile cellulitis in dogs (see [Chapters 3](#) and [100](#)).^{71,78,130}

86.1.2 Pathogenesis

86.1.2.1 Hematogenous Spread

Spread of infection via the bloodstream from a distant site is rare in dogs and cats. When infection occurs, immature animals are usually affected.^{53,62} The animal's predisposition of the metaphyseal region to hematogenous embolization is likely a result, in part, of the microvascular architecture of the region in growing bone. Capillaries that extend into the growth plate have both variable continuous and discontinuous epithelia.^{44,53} Terminally growing capillary buds lack a basement membrane and have discontinuous endothelium.^{44,53} Discontinuities allow circulating microorganisms to escape into the extravascular tissue space during a bacteremic phase. Blood flow through these capillary beds is slow, creating an ideal environment for bacterial lodgment and proliferation. Furthermore, in contrast to secondary spongiosa, leukocytes appear to be absent around primary spongiosa.⁴⁴ Bacterial invasion in the region of developing bone may be opposed by only tissue-based macrophages. Unrestricted infection in the metaphyses may spread to the epiphyses, periosteum, soft tissues, and adjacent joints. In dogs and cats, unlike other species, transphyseal vessels are absent at birth; thus infection is usually restricted to the metaphyseal side of the growth plate.³³

86.1.2.2 Posttraumatic Injuries

Normal bone is resistant to infection. Osteomyelitis is unlikely to develop in the absence of complicating factors that include tissue ischemia, bacterial contamination, bone necrosis and sequestration, fracture instability, foreign material implantation, and systemic or local alteration in immune response or tissue metabolism.^{17,46,56,62} Tissue trauma and subsequent vascular compromise are important factors when discussing posttraumatic osteomyelitis. Soft tissues provide the first blood supply to the ischemic bone during the initial phases of healing. Inoculation of bacteria can occur from direct penetration of a missile or other foreign body, a bite wound, an exposure of the bone via an open fracture, or a surgical intervention. Avascular bone fragments provide an ideal ecologic niche for bacteria to colonize and proliferate. Fracture instability perpetuates the persistence of infection in the bone. Instability may occur when initial stabilization

Infectious Diseases of the Dog and Cat, 3rd Edition

is inadequate or when initial fixation fails. In either case, disruption of the blood supply is caused by damage to proliferating capillaries, promoting tissue and bone necroses and bacterial colonization and growth.

824

Myositis	

86.1.2.3

Biofilm

Implantation of foreign material has been associated with increased infection rates.^{39,100,112} Staphylococci are the predominant bacterial contaminants in these infections. The primary mechanism in biomaterial-centered sepsis is microbial colonization of these materials and adjacent damaged tissues.⁵⁶ Tissue necrosis and inflammation along the biomaterial's surface, associated with failure of implant integration into host tissues, serve as a glycoprotein-conditioned substratum for which bacteria have specific receptors.⁵⁶ Adherent bacteria produce a matrix of condensed exopolysaccharides known as a glycocalyx.⁷⁷ The biofilm is composed of a cluster of microorganisms and glycocalyx on an inanimate surface. Embedded in the biofilm mixture of glycocalyx, host-derived serum proteins, and cellular debris, bacteria often form

Infectious Diseases of the Dog and Cat, 3rd Edition

into microcolonies (Fig. 86-1). Within biofilms, bacteria are protected from antibodies, phagocytes, and even antibiotics.^{56,62,77} Bacteria within biofilms have been shown to intercommunicate via cytokines,²⁸ and this appears to assist them in adapting as a colony within their biologic environment and avoiding host defense mechanisms. The glycocalyx retards the penetration of drugs, organisms become dormant within the biofilm, and the microenvironment within adversely affects antimicrobial activity.³⁴ Furthermore, several different types of bacteria can both coexist and replicate in glycocalyx-enclosed microcolonies in the interstitial spaces of connective tissue associated with dead bone sequestra, causing mixed infections.

86.1.3 Clinical Findings

Clinical signs of osteomyelitis vary with the type and duration of disease. Acute osteomyelitis, either hematogenous or posttraumatic in origin, produces localized pain, erythema, and soft-tissue swelling. The animal is usually febrile. Elevated leukocyte counts are common. Various signs of systemic illness include lethargy and inappetence.^{17,46,62} Chronic posttraumatic osteomyelitis is a localized disease with rare systemic manifestations; the most common of these is a history of trauma or surgery with a subsequent draining tract and lameness. Nonhealing wounds that continue to drain should always be evaluated by radiography for underlying osteomyelitis.

86.1.3.1 Metaphyseal Osteomyelitis

In young animals, hematogenous osteomyelitis often results in fever, lameness, and swelling of the metaphyseal region of long bones. Dogs and cats have both been affected by this condition.¹⁴ This area is likely predisposed to colonization in the young animal because of its high blood supply and anatomic features, as described under Pathogenesis of Hematogenous infections previously mentioned. Gram-positive bacteria such as *Staphylococcus* are often isolated. Swelling and lameness in a young animal can be confused with HOD in the dog. Radiographically, the features of the two diseases are distinct (Fig. 86-2). In HOD, epiphyseal lines show radiolucent banding with metaphyseal periostitis. In metaphyseal osteomyelitis, either increased or decreased density is observed within the metaphyseal region resulting from osteoproliferation or osteolysis, depending on the type and stage of infection. If multiple animals in a litter develop this condition, then an underlying immunodeficiency or congenital or early neonatal infection should be considered.¹²⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 86-1 Schematic drawing showing osteomyelitis involving the femur and associated surgical implant. Bacteria produce glycocalyx, which, combined with host-derived and implant-derived materials, forms a biofilm. This biofilm protects bacteria from host defenses.

Fig 86-2 Thoracic limb radiography of dogs with (A) hypertrophic osteodystrophy with increased lucency and irregularity of the epiphyseal lines. B, Metaphyseal osteomyelitis with increased density in the metaphyseal region resulting from osteoproliferation as a result of bacterial infection. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

86.1.4 Diagnosis

History, physical examination, and radiography will localize the site of the lesion. Nonspecific laboratory findings may include variable leukocytosis and increased serum concentrations of calcium and phosphorus or high alkaline phosphatase activity. Radiography will localize and determine the type of lesion. In an acute case, the only finding may be soft-tissue swelling. As the infection progresses, radiographic changes include, but are not limited to, periosteal bone proliferation, bone resorption, and increased medullary density. In chronic cases, radiography can demonstrate the presence of loose or broken implants or nonviable bone (sequestra). 826

Unfortunately, radiography reportedly has a sensitivity of 62.5% and specificity of 57% in the detection of osteomyelitis.¹³ More accurate detection can be achieved with the use of nuclear scintigraphy. 827

Technetium-99 m-methylene diphosphonate (MDP), indium-111 leukocyte, and IgG scintigraphy are radionuclide imaging techniques that can provide additional diagnostic information if radiographic findings are equivocal.⁶⁷ However, these tests are used sparingly in veterinary medicine and require the specialized equipment of referral centers.

Cytologic evaluation of exudates is informative, whereas microbiologic culture of an infectious agent is definitive. Specimens from a sterile aspirate of the lesion through intact skin or from sequestra, local necrotic tissue, or implant at the time of Débridement provide the most valuable material for culture. For aspiration for cytologic or culture specimens, the site is aseptically prepared at intact, unaffected skin over the suspected lesion. A 20-gauge needle is then inserted to the level of the bone, followed by aspiration into a 12-ml syringe. Organisms isolated from discharges of draining tracts may be contaminants. Proper collection and transport of both aerobic and anaerobic samples is also imperative (see [Chapter 33](#)). In cases of hematogenous osteomyelitis, blood should be cultured, as well as the secondary site of infection.

Anaerobic infections should be suspected when affected tissue is characterized by a foul odor, sequestra, or the presence of multiple bacterial species suggested by impression smears or histologic specimens (see [Chapter 41](#)).⁸⁵ Further suspicion of an anaerobic infection should be raised if no organism is cultured from material in which cytologic findings indicate infection. Multifocal sterile pyogranulomatous osteomyelitis has been reported in dogs²² but probably is caused by immune dysregulation rather than infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 86-3 **A**, Pelvic limb radiograph of 4-month-old Doberman with lameness and painful stifle swelling of 10 days' duration. Acute hematogenous osteomyelitis with metaphyseal lysis and extensive bony production within the distal diaphysis are evident. **B**, One month after surgical biopsy and culture of *Staphylococcus intermedius* and institution of systemic antibiotic treatment. Remodeling of the femoral metaphysis with reduced sclerosis and periosteal proliferation occurs.

86.1.5 Therapy

The infective agent, local tissue environment, and blood supply should always be considered in any therapeutic strategy. Although treatment is customized to each patient, certain principles must be followed. Mere use of antimicrobial drugs will not eradicate the infection associated with chronic osteomyelitis. The local environment must be improved by Débridement, drainage, fracture stabilization, dead-space obliteration, and antimicrobial therapy. Regardless of the situation, every effort should be made to obtain a culture and susceptibility testing for both aerobic and anaerobic bacteria. Followup evaluation involves serial clinical and radiographic evaluation and repeated culturing of the infected area.

86.1.5.1 Hematogenous Osteomyelitis

Animals with hematogenous osteomyelitis are often septic. The infections, which can occur in any skeletal site, frequently involve the metaphyseal region of the bone and do not extend into the adjacent joint ([Fig. 86-3, A](#)). However, synoviocentesis and radiography are strongly recommended to make this determination. Blood culture results may also be informative. If joints are affected, aggressive management should be

Infectious Diseases of the Dog and Cat, 3rd Edition

undertaken as described later for monoarthropathies. If no joint involvement can be demonstrated, any fluctuant, warm, or painful area around the affected bone can be aspirated for culture and susceptibility testing. If an obvious fluctuant area is present, attempts should be made to open and copiously lavage the region with a sterile isotonic solution and to perform Débridement. Systemic intravenous (IV) antibiotics should be given for a minimum of 3 to 5 days before switching to the oral route. Oral administration should continue for a minimum of 21 days. Bactericidal agents that are active against β -lactamase-producing *Staphylococcus* should be used (Tables 86-3 and 86-4). Systemic treatment for sepsis should be addressed if necessary (see Chapters 38 and 87). Radiographs taken 2 to 3 weeks after treatment can help evaluate progression and response to therapy (see Fig. 86-3, B). Systemic manifestations and presence of joint involvement are indicators of poorer prognoses.⁵³

<i>Toxoplasma</i> (80)	M	Clindamycin, pyrimethamine and sulfonamides, azithromycin

A, Arthritis; D, diskospondylitis; I, otitis media/interna; O, osteomyelitis; M, myositis.

- a Drugs are listed in order of most desirable choice first. See Chapter 34 and Appendix 8, Drug Formulary.
- b Use minocycline or doxycycline.
- c Substitute amoxicillin, first-generation cephalosporin, or erythromycin.
- d Substitute any first-generation cephalosporin.
- e Substitute any β -lactam-resistant penicillin.
- f Substitute gentamicin or amikacin.

Infectious Diseases of the Dog and Cat, 3rd Edition

86.1.5.2 Acute Posttraumatic Osteomyelitis

The prevalence of osteomyelitis is increased in open fractures when bacteria have the ability to invade the wound directly from the environment. However, most cases of posttraumatic osteomyelitis are acquired in the hospital environment and involve staphylococci or enteric gram-negative organisms such as *Pseudomonas*. The condition is likely a result of the adherent biofilms formed by these organisms. Osteomyelitis developing within 2 to 5 days after an insult may be difficult to differentiate from a soft-tissue wound infection. However, most wound complications are restricted to soft tissues. Regardless, treatment is similar, and absolute differentiation is not always necessary. Treatment should be aggressive in an effort to prevent these infections from developing into chronic processes. Modalities include drainage and Débridement, systemic antimicrobial agents, rigid stabilization, direct bone culture, and delayed wound closure (Fig. 86-4, A).^{17,46,62}

Meticulous drainage and Débridement of all necrotic tissues or bones, hematomas, and abscesses should be done first and is an essential component of treatment. Culture and biopsy samples are obtained at this time, followed by copious lavage of the area with lactated Ringer's solution or saline. Drainage by closed suction units and open-wound management with daily flushing are options to be considered. Initial antimicrobial therapy is similar to that of hematogenous osteomyelitis; the most common bacterium is β -lactamase-producing *Staphylococcus* (see Tables 86-3 and 86-4). Drugs should be given parenterally (preferably IV) for the first 3 to 5 days followed by oral therapy for a minimum of 4 weeks; many cases require 8 weeks. Therapeutic agents may be adjusted as culture results become available. Patient monitoring must be intense and regular. In all cases, radiographs should be taken 2 to 3 weeks after intervention and then sequentially as needed (see Fig. 86-4, B).

86.1.5.3 Chronic Posttraumatic Osteomyelitis

Chronic posttraumatic osteomyelitis is the most common type of osteomyelitis seen in veterinary practice. Because of devitalized tissues, therapy with antibiotics alone is usually not successful. Drugs cannot enter the tissue in which they are most needed. Without improving the ischemic, necrotic environment, success in bacterial eradication is minimal. Treatment is based on the same fundamental objectives of Débridement of necrotic tissue, bony sequestra, and all foreign material, including old implants. Attempted bacterial isolation, obliteration of dead space, establishment of drainage, and rigid stabilization of bone should be done. Bone will actually heal in the presence of infection if it can be stabilized.

Débridement and sequestra removal are essential to management. During and after the surgical procedure, copious lavage is performed. Fracture stability should be evaluated intraoperatively; implants must be removed if they are loose. Rigid fixation of fractures is imperative for healing and eradication of infection. Removal of all implants, if the fracture is healed, or of implants that are not adding to the stabilization eliminates sites for biofilm formation. Eradication of dead space and removal of unnecessary foreign material, including sutures, should be performed. Establishment of drainage can be accomplished using many different techniques. Closed suction units, saucerization, and treating an open wound without suturing the skin to the soft tissues are all viable methods. Placement of vascularized muscle flaps over the defect after infection has been controlled can also be considered.

828

Table 86-4 Drug Dosages for Treatment of Musculoskeletal Infections

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)
Amikacin	B	7.5 mg/kg	IV, IM, SC	12
Ampicillin	B	22 mg/kg	IV, IM, SC, PO	6–8
Amoxicillin	B	22–30 mg/kg	IV, IM, SC, PO	6–8
Amoxicillin-clavulanate	B	22 mg/kg	PO	8
Cefazolin	B	22 mg/kg	IV, IM, SC	6–8
Cefotetan	B	30 mg/kg	IV, IM, SC	12
Cefoxitin	B	30 mg/kg	IV, IM, SC	8
Cephalexin	B	22–30 mg/kg	PO	8
Cephadrine	B	22–30 mg/kg	PO	8
Chloramphenicol	D	25–50 mg/kg	IV, PO	8
	C	25–50 mg/kg	IV, PO	12
Ciprofloxacin	B	11 mg/kg	IV, PO	12
Clindamycin	B	11 mg/kg	IV, IM, PO	8–12
Cloxacillin	B	10–15 mg/kg	IV, IM, PO	6–8
Doxycycline	B	12.5–15 mg/kg	PO	12
Enrofloxacin	D	5–15 mg/kg	SC, PO	24
Enrofloxacin	C	5 mg/kg	PO	24
Gentamicin	B	5–6 mg/kg	IV, IM, SC	24
Metronidazole	B	10 mg/kg	PO, IV	8
Minocycline	B	10 mg/kg	PO	12
Oxacillin	B	22–30 mg/kg	IV, IM, SC, PO	6–8
Penicillin G (aqueous)	B	20,000–40,000 U/kg	IV	6
Penicillin G (procaine)	B	40,000–50,000 U/kg	PO, SC	6
Penicillin-V	B	40 mg/kg	PO	6
Streptomycin	B	20 mg/kg	IM	12
Tetracycline	B	22 mg/kg	PO	8
Ketoconazole	D	10 mg/kg	PO	12
Itraconazole	D	5 mg/kg	PO	12
Itraconazole	C	50 mg total	PO	24
Fluconazole	D	5 mg/kg	PO	12–24
Amphotericin B	B	0.25 mg/kg	IV	48

B, Dog and cat; D, dog; C, cat; IV, intravenous; IM, intramuscular; SC, subcutaneous; PO, by mouth.

- Duration of therapy depends on the tissue, site, and duration of infection; see text for guidelines. For additional information and dosages on drugs listed below, refer to Drug Formulary, [Appendix 8](#).
- Dose per administration at specified intervals. Dose until a total of 8–12 mg/kg (dog) or 4–8 mg/kg (cat) is reached.

Fig 86-4 **A**, Radiograph of a 4-year-old dog with open segmental fracture of tibia in which an intramuscular pin was placed 3 months previously. Osteomyelitis with a nonunion and large sequestrum of bone is present in the mid tibia. **B**, Radiograph 2 years later after surgical removal of implant and bony sequestrum, obtaining tissue for culture and susceptibility, débridement, lavage, stabilization with a bone plate, cancellous bone graft, open wound management, and systemic antimicrobial therapy. (Courtesy Dennis Aron, University of Georgia, Athens, Ga.)

Antimicrobial therapy must be based on culture and susceptibility results; however, correlation of clinical response and in vitro susceptibility of some microorganisms is often lacking. These failures can be attributed in part to the inability of antibiotics to achieve sufficient concentrations in affected tissue. With this limitation, the best chance to reach and maintain levels at consistent concentrations would be IV infusions over a minimum treatment period of 4 to 6 weeks. Unfortunately, in practice, financial constraints usually limit treatment to short parenteral regimens followed by orally administered antimicrobials. Antibiotics that can be used orally for long-term treatment that are effective against β -lactamase-producing *Staphylococcus* should be considered (see [Tables 86-3](#) and [86-4](#)). Placement of local infusion drug delivery systems is currently receiving a great deal of research interest. Use of implants impregnated with antibiotics is common in human medicine and less frequent in veterinary medicine. Carriers are usually either a form of bone cement or a biodegradable polymer.^{19,123,129} Polymethylmethacrylate (PMMA) is an implant material that has been used successfully with numerous antibacterials, including vancomycin, clindamycin, tobramycin, and gentamicin. Unfortunately, the slow release of low levels of antimicrobials, such as aminoglycosides that are often employed, may lead to colonization by antimicrobial-resistant microbial strains. After 2 to 4 weeks, elution of the antibacterials is complete, and bacterial biofilms can successfully colonize the foreign material. Treatment of severe orthopedic infections in humans and animals has used antimicrobial-impregnated beads at the site of infection. Slow release in the wound site allows for high concentrations of antimicrobials in the

Infectious Diseases of the Dog and Cat, 3rd Edition

tissue for prolonged periods. Levels of up to 200 times that following systemic administration can be achieved for as long as 80 days after implantation.¹³² Aminoglycosides have been the most commonly used antibacterials impregnated into beads. Despite the high concentrations at the wound site, serum and urine concentrations of antibiotics do not reach toxic levels. In an experimental study in dogs evaluating the effect of PMMA bead implantation on osteomyelitis, implantation had radiographic, bacteriologic, and pathologic evidence of clearing infection compared with control dogs when evaluation was performed after 6 months following implantation.¹²⁷ PMMA is less than ideal in that it is not degraded and can result in eventual inflammatory reactions. Once the antimicrobial efficacy has been lost, it may support bacterial growth, which can result in bone resorption. Use of newer biodegradable polymers has shown fewer side effects. In evaluating other polymers, polyglycolic beads containing gentamicin, staphylococcal osteomyelitis was effectively controlled in dogs.⁵⁰ Such polymers have also been used to coat metallic implants. Other polymers such as bioerodible polyanhydrides or more natural substances such as hydroxyapatite or collagen have been impregnated with antibacterials with some early success.

Management of open wounds or suction systems dictates initial postoperative management. Once this early phase is complete, weekly checks and radiographs at 3-week intervals are advised. Antibiotics must be continued for *at least* 6 to 8 weeks, regardless of any early positive response. Owners should be advised that the animal's chronic osteomyelitis can remain quiescent for weeks, months, or years with potential for relapse or reinfection.

86.1.6 Prevention

Prophylactic antimicrobial therapy is accepted management for dogs and cats undergoing prolonged surgical procedures or those associated with the greatest risk of postoperative infection. For orthopedic procedures, decreases in infection rates have been observed. Dogs undergoing elective orthopedic surgery had a reduced rate of infection compared with saline-treated control dogs when treatment with penicillin G or cefazolin was used.¹³¹ The choice of antimicrobial therapy should be based on the type and location of the surgical procedure and the most likely organisms to be involved in secondary contamination. Antimicrobials are administered only 30 minutes before or during the operative period at an interval of every 90 minutes and not continued beyond the operative period. For further information, see also prophylactic antibacterial therapy in [Chapter 34](#), Nosocomial Infections in [Chapter 94](#), and Bacteremia and Dental Disease in [Chapter 89](#).

86.2 DISKOSPONDYLITIS AND VERTEBRAL OSTEOMYELITIS

Diskospondylitis is defined as inflammation of an intervertebral disk and adjacent vertebral end plates and bodies. In comparison, infections located in the vertebral body usually caused by penetrating wounds, paravertebral infection, or foreign bodies are termed *vertebral osteomyelitis* and are less frequent in dogs than they are in cats. In addition to or in lieu of infection of the disk space, vertebral osteomyelitis often involves the adjacent soft tissues and vertebral bodies and meninges. The most common cause of these processes is bacterial infection; however, fungal infections have also been reported (see [Table 86-2](#)).⁸² Any vertebral space can be affected; the thoracic and lumbar sites are the most commonly involved.

Infectious Diseases of the Dog and Cat, 3rd Edition

86.2.1 Etiology

86.2.1.1 Dog

S. intermedius is the most common causative bacterium identified in the dog.^{63,64,82} Other frequently documented bacterial pathogens include *Streptococcus*, *Brucella canis*, and *E. coli*.^{63,64,82} Less common isolates have been *Pasteurella* spp., *Proteus* spp., *Corynebacterium* spp., *Actinomyces*, *Nocardia* spp., *Bacteroides* spp., *Mycobacterium* spp., *Pseudomonas aeruginosa*, *Enterococcus faecalis*, and *Staphylococcus epidermidis*.^{1,11} The wide variety of other bacterial species underscores the need to attempt to obtain bacterial isolation and susceptibility testing in each case. Fungi are involved in some infections, and most common genera have included *Aspergillus*, *Fusarium*, and *Paecilomyces*.^{20,45,63,82} In addition to hematogenous exposure, migrating foreign bodies have produced spinal infections with vertebral body osteomyelitis (see Actinomycosis, [Chapter 49](#)). Plant materials have been the most widely associated foreign bodies, and geographic regional differences influence the specific causative agent.⁸² Postprocedural diskospondylitis may be caused by direct inoculation during a diagnostic or operative procedure on the spinal column or by spread from other infectious foci to the intervertebral site. Injury to intervertebral endplates, operative trauma to small vessels causing tissue necrosis or hematoma formation, provides growth media for bacteria.⁶¹ Epidural abscess and diskospondylitis can develop after epidural injections.¹⁰⁵ Spinal column and disk infection has also been sequelae of spinal surgery or disk fenestration.

86.2.1.2 Cat

Few reports of diskospondylitis in the veterinary literature have been published.^{4,72,86,128} In all of these cases, soft-tissue injury from trauma or fighting has been the underlying cause. As spreading infections from adjacent soft tissues, most of these infections can more appropriately be termed primary vertebral osteomyelitis with secondary disk involvement. Compared with disk infection in dogs, associated meningomyelitis has also been more commonly associated with these infections in cats. *E. coli* was isolated from the cerebral spinal fluid (CSF) of one cat.⁴ One author of this chapter (CEG) has also documented diskospondylitis in a 6-month-old purebred cat caused by group G streptococcal bacteremia, presumably acquired as a neonate (see [Chapter 35](#)). In this cat, the intervertebral disk space was affected and the lesion progressed to marked involvement of the opposing vertebral bodies ([Fig. 86-5](#)).

830

831

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 86-5 Radiograph of the thoracic spine from a cat with diskospondylitis caused by hematogenous *Streptococcus canis* infection. **A**, At the time of diagnosis. **B**, Five months later after antibacterial therapy. (Courtesy University of Georgia, Athens, Ga.)

86.2.2 Pathogenesis

Diskospondylitis is thought to arise from hematogenous spread of the organism into the disk space and subsequently into the adjacent vertebrae. The most commonly incriminated sources include urogenital tract and skin infections, dental disease, and valvular endocarditis. However, in many cases, no other site of infection is detected. Preferential hematogenous localization in the disk space probably occurs as a result of retrograde blood flow into vertebral sinuses or as a result of subchondral vascular loops in the vertebral epiphysis that slow blood flow.^{63,64,82} Predisposing factors have included immunosuppression and previous trauma, including surgical intervention (see [Table 86-1](#)).^{63,64}

Clinical Findings

86.2.2.1 Dog

Clinical presentation can vary; however, in general, signs progress slowly. Although any dog or cat is susceptible to this disease, the most common signalment is that of a young to middle-aged male large-breed dog.^{63,64} Signs can vary from those of systemic infection (depression, anorexia, fever, weight loss) to musculoskeletal dysfunction. Signs of paraspinal hyperesthesia are the most characteristic of this disease and include abnormal gait and reluctance to rise or ambulate. Neurologic signs, which often develop subsequent to hyperesthesia, are those of extradural compression, resulting in paresis and ataxia, or paralysis ([Fig. 86-6](#)). The neurologic deficits depend on the site and severity of the vertebral lesion. Paraspinal hyperesthesia is often noticed earliest, although some dogs are stoic and do not show overt signs of discomfort. Neurologic dysfunction, demonstrated by paresis, can develop gradually with osteoproliferation. Sudden onset of paraplegia can occur with intervertebral disk rupture from weakened ligaments. The most commonly reported sites of infection are L7-S1, caudal cervical area, and midthoracic spine.^{63,64} Monoparesis or

Infectious Diseases of the Dog and Cat, 3rd Edition

monoparalysis can result from nerve-root involvement in patients with infection, causing chronic asymmetric osteoproliferation.

Fig 86-6 Dog with lumbar diskospondylitis showing complete paraplegia from sudden disk rupture. (Courtesy University of Georgia, Athens, Ga.)

86.2.2.2 Cat

Fever, anorexia, and paraspinal hyperesthesia have been the predominant signs in affected cats. Because of the usual association with adjacent soft-tissue infection, signs have been gradual and progressive from fever, lethargy, progressive gait dysfunction, and eventual paresis and paralysis.

86.2.3 Diagnosis

A tentative diagnosis is made from the patient history and the physical and neurologic examinations. Hyperglobulinemia, associated with the chronic antigenic stimulation from chronic bacterial infection, may be found with evaluation of serum proteins. Definitive diagnosis is made with spinal radiographs. Changes include concentric lysis of adjacent vertebral endplates early, with later vertebral body osteolysis or proliferative sclerosis, vertebral body shortening, narrowing of disk spaces, and ventral osseous bridging (Fig. 86-7, A). This situation must be differentiated from other vertebral lesions, including vertebral osteomyelitis (see Fig. 86-7, B), spondylosis deformans (see Fig. 86-7, C), and neoplasia (see Fig. 86-7, D). Extensive vertebral body infection may result in vertebral body collapse or subluxation.¹⁶ Radiographic changes associated with diskospondylitis can take 2 to 4 weeks to develop after the initiation of the infection.⁶⁴ Thus sequential radiographs may be needed to confirm the diagnosis in an animal with initial signs of hyperesthesia. Clinical signs and radiographic severity of lesions do not always correlate. Computed tomography (CT) and magnetic resonance imaging (MRI) have added a new dimension to detection of infectious lesions of the spine. These measures are always indicated when spinal radiography is inconclusive because radiography may not detect lesions until up to 2 to 6 weeks after infection. CT can also be used to guide fine-needle aspiration and

831

832

Infectious Diseases of the Dog and Cat, 3rd Edition

tissue-core biopsy.¹²⁵ With MRI, early changes are decreased intensity and definition on T1-weighted images and increased intensity of the disk and endplate on T2-weighted images. Later, destruction of the vertebral endplate occurs. With T1-weighted scans after gadolinium–diethylenetriamine pentetic acid, enhancement occurs between the disk and endplate. Bone scans may show increased uptake of radiopharmaceuticals at the affected disk space and endplates. Unfortunately, changes are not detected unless radiographic abnormalities are already visible. In people and dogs, tissue-core biopsy has been superior to fine-needle aspiration for obtaining positive culture results.¹²⁵ For aspiration, which is often done with fluoroscopy, 0.5 ml of sterile saline is injected in the disk space and immediately aspirated to retrieve a specimen.

Fig 86-7 Lateral radiograph of the thoracolumbar spine from dogs with **(A)** diskospondylitis at the L2-L3 interspace from bacteremia, with indistinct endplates and new production of bone ventrally. **B**, Lumbar osteomyelitis from a migrating foreign body, involving L2-L3 (*arrows*) with ventral periosteal proliferation. **C**, Spondylosis deformans at the L3-4 and L4-5 interspaces. **D**, Vertebral neoplasia with focal lucencies in the L3 lumbar vertebrae; the process does not involve the interspace. (Courtesy University of Georgia, Athens, Ga.)

When hyperesthesia and neurologic dysfunction are absent, diskospondylitis may be overlooked. Spinal radiography should be considered as an initial screening test for animals with chronic, recurrent urinary tract infection or fever of unknown origin. Dogs with confirmed diskospondylitis should always be immediately screened serologically for *B. canis* (see [Chapter 40](#)). Should serologic test results be negative, disk-space culture provides the most consistent recovery of the offending organism. However, culturing the disk is often

Infectious Diseases of the Dog and Cat, 3rd Edition

impractical because of the inaccessibility of the lesion unless decompressive surgery is performed. If the lesion is caudal to the thoracolumbar junction and fluoroscopy is available, guided direct aspiration of the disk can be attempted.⁴³ Blood and urine cultures should be performed therefore in an attempt to recover the organism before instituting therapy. Positive blood culture results range from 45% to 75% and should be considered in all cases. This approach is especially warranted in dogs with increased rectal temperatures or animals with signs of sepsis in hematologic parameters.⁶⁴ Organisms may be cultured from urine approximately 40% of the time.⁶⁴ Other sources of infection from which possible dissemination has occurred may be investigated. If infection is detected in urine and blood, the entire urinary tract and the heart valves, respectively, may be evaluated by radiologic or ultrasonographic testing.

Other imaging techniques may aid in the diagnosis of early radiographically undetectable diskospondylitis. CT, MRI, and radionuclide scans, including MDP, gallium-67, and indium-111-labeled leukocytes, may become more routine in veterinary referral centers to augment the diagnosis of occult diskospondylitis. Gross pathologic findings include lysis of the vertebral endplates with purulent material in the disk interspace (Fig. 86-8).

Fig 86-8 Lateral view of transected vertebral column from a 6-year-old female Great Dane with tetraparesis and depression of 6 weeks' duration. The C6-C7 interspace is at the center of the picture. The caudal aspect of the vertebral body of C6 and the cranial aspect of the vertebral body of C7 are irregular in appearance, suggesting vertebral lysis. Fibrous tissue and new bone present dorsal to the disk space compress the spinal cord ventrally. The intervertebral disk at C6-C7 is absent. Considerable new bone occurs ventral to the C6-C7 disk space and sclerosis of the caudal aspect of the vertebral body of C6 and the cranial aspect of the vertebral body of C7. A diagnosis of diskospondylitis was made. (From Kornegay JN. 1979. Canine diskospondylitis, *Compend Cont Educ Pract Vet* 1:931. Used with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

86.2.4 Therapy

Ideally, antimicrobial treatment should be based on culture results from blood, urine, or optimally affected bone. Initial empiric treatment is recommended while culture results are still pending. The initial assumption should be that the offending bacterium is a *Staphylococcus*-producing β -lactamase, rendering penicillin, amoxicillin, and ampicillin ineffective. Use of a bactericidal, β -lactamase-resistant drug that is effective primarily against gram-positive bacteria is preferred. Several drugs fit these criteria (see [Table 86-3](#)). First-generation cephalosporins have been clinically most effective in this regard. [Table 86-4](#) lists dosages of recommended drugs.

The next decision is route of administration, which is dictated by clinical presentation and disease progression. Treatment in patients with minimal to no neurologic dysfunction should begin with the appropriate oral antimicrobial drug. Parenteral therapy should be the initial step in dogs with moderate neurologic dysfunction, including ataxia and paresis. In rare instances, initial therapy may include relieving extradural cord compression with surgical decompression. Analgesics may be needed in dogs with intense hyperesthesia early in the course of treatment. For instance, with acute and rapidly progressive severe neurologic dysfunction, regardless of length of onset, IV administration of antibiotics is needed for 5 to 7 days, followed by a course of oral administration. In more slowly progressive situations, a single loading dose of parenterally administered antibiotics may be followed by oral treatment. The minimal length of oral treatment is 6 to 8 weeks, regardless of favorable patient response in the early period. If *B. canis* titers come back positive, switching to a combined regimen of tetracyclines and aminoglycosides is advisable (see [Chapter 40](#)). *Brucella* test-positive dogs should always be neutered before treatment.

In all cases of bacterial diskospondylitis, improvement should begin within 3 to 5 days after initiation of therapy. If no response is noted and results of cultures of blood and urine are negative, the class of antimicrobial may be switched. In addition, attempts at surgical curettage of the lesion may be considered to obtain a direct bone culture.

The patient should be closely monitored over the first few days after institution of antimicrobial therapy and then evaluated at 2-week intervals once improvement is noted. Followup radiography for monitoring patient progress is controversial. Radiographs have been recommended as frequently as every 2 weeks, but subtle changes are difficult to interpret. A more pragmatic evaluation routine is to obtain radiographs 1 month after initiation of treatment and once again after cessation of therapy.¹⁷ Therapy usually continues at least 2 to 4 months. Resolution of clinical signs occurs well before radiographic improvement. Resolving lesions are characterized by decreased osteolysis and osteoproliferation and new bone formation with intervertebral bridging. Radiographs are usually more of a benefit to document cases of aggressive, spreading infections that are not responsive to treatment.

In animals with complete paralysis, intensive, aggressive, parenteral antibiotic therapy must be instituted. If signs do not improve dramatically in 24 to 72 hours, changing of the antimicrobial agents or possible decompressing of the spinal cord and stabilizing of the vertebral column may be necessary. If vertebral fracture or dislocation occurs, surgical intervention is mandatory, and the prognosis is guarded. If a single disk is affected, based on neurologic and myelographic findings, and paralysis is severe, surgery might be recommended. However, if multiple lesions are causing compression, surgical intervention, including decompression, may not be feasible or advisable *unless* the goal of surgery is biopsy for microbiologic culture and susceptibility testing.¹⁷ Cases of fungal diskospondylitis usually involve *Aspergillus terreus* infections in

Infectious Diseases of the Dog and Cat, 3rd Edition

German shepherd dogs (see [Chapter 64](#)). The dogs usually have complicating signs of systemic infection and respond poorly to treatment.

86.3 OTITIS MEDIA AND OTITIS INTERNA

Clinical signs of otitis media and otitis interna usually reflect neurologic rather than musculoskeletal disease.⁶⁴ However, these conditions are discussed with musculoskeletal infection because the infection is a form of osteomyelitis in bone of the middle ear and the bony labyrinth of the inner ear. Therapeutic considerations are based on principles for treating osteomyelitis. In contrast, otitis externa is considered as an integumentary infection (see [Chapter 85](#)).

86.3.1 Anatomy

Knowledge of the anatomic interrelations of the compartments of the ear is important in understanding the pathogenesis of otitis media and interna and its treatment ([Fig. 86-9](#)). Both middle and inner ears are housed in the petrous temporal bone. The middle ear is separated from the horizontal portion of the external ear canal by the tympanic membrane. Together with the incus and stapes, the malleus connects the tympanic membrane to the oval window of the inner ear. The auditory ossicles are situated in a small dorsal concavity of the middle ear, the epitympanic recess. The larger, air-filled tympanic bulla forms the remainder of the middle ear and contains the round foramen and the aural opening of the auditory tube. The osseous bulla is a major site of localization of infection and a concern for therapeutic intervention. The aural opening is covered by the secondary tympanic membrane and communicates with the cochlea of the inner ear. The cochlea contains the peripheral sense organs of hearing. In addition to the auditory cochlea, the inner ear consists of semicircular canals and the utricle and saccule of the vestibule. These structures are involved with balance.⁶⁴

833

834

Fig 86-9 Diagram of the middle and inner ear of the dog with clinically relevant structures. The middle ear behind the tympanic membrane contains the semicircular canals and auditory structures involved in sound conduction. The inner ear contains the sensor organs of hearing (the cochlea) and balance (the utricle and saccule). (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

86.3.2 Etiology and Pathogenesis

Otitis media and otitis interna in dogs and cats are usually caused by extension of otitis externa. Accordingly, *S. intermedius*, *P. aeruginosa*, *Proteus*, and *Streptococcus* are the most common bacterial pathogens, and fungi such as *Malassezia* and *Candida* may occasionally be isolated (see [Chapter 85](#)). Less frequently, otitis media and interna result from ascension of bacteria from the oral cavity through the auditory tube. Conversely, infections originating in the middle ear may reach the oral cavity through this same route. Rarely, hematogenous spread of blood-borne bacteria or fungi to the middle and inner ears has been observed. *Cryptococcus neoformans*, which often causes upper respiratory tract granulomas, has been associated with otitis media and interna in cats⁷; however, it can also cause vestibular dysfunction as a result of meningoencephalitis. Cavalier King Charles spaniels have a primary secretory otitis that may predispose them to develop otitis media.^{107,114} Cats may have otitis externa as the nidus of otitis media and interna; however, cats also develop inflammatory polyps within the middle ear.^{66,84} These polyps are often associated with bacterial infections; yet the order of occurrence or the association between these findings is not understood.⁴⁰ Polyps of cats did not contain feline calicivirus or herpesvirus-1 with polymerase chain reaction (PCR) evaluation.¹²⁴ Inflammatory polyps of the middle ear also occur in dogs, and they may be a cause of otitis externa or interna.⁹⁹ As with people, congenital palatine defects have also been associated with a higher prevalence of otitis media in dogs in cats.⁵⁵

86.3.3 Clinical Findings

Clinical signs of simple otitis media are similar to those of otitis externa. Aural hyperesthesia is exhibited by head shaking or cocking, pawing of the involved ear, and discomfort on manipulation of the animal's pinna, auditory canal, or face. With unilateral involvement, sound localization may be impaired; and with bilateral disease, deafness is usually apparent. If the infection ascends via the eustachian tube, which is usually the case with chronic upper respiratory tract infections or congenital palatine defects, signs of external ear disease are usually absent. When the infection has followed otitis externa, the external ear canal is inflamed and usually contains debris. On otoscopic examination, the tympanic membrane may be absent or obscured by debris. When visible and intact, the membrane is usually discolored and often bulges outward. Occasionally, a fluid line is observed, indicating the presence of serum or exudate in the middle ear. Some animals may subsequently have evidence of facial nerve paralysis and Horner's syndrome because of the involvement of the facial nerve and ocular branch of the sympathetic trunk, respectively, as they pass through the middle ear.⁶⁴ Horner's syndrome can also be seen in cats with middle ear polyps.⁴⁰ Cats with middle ear polyps also show signs of obstruction of the nasopharynx in addition to vestibular manifestations. Signs of nasopharyngeal irritation include hypersalivation, coughing, and difficulty swallowing. Cavalier King Charles spaniels with otitis media show signs of cervical or cranial hyperesthesia or, eventually, vestibular dysfunction.¹¹⁴

With chronicity, the likelihood that the causative organism of otitis media will spread to the inner ear is increased. In these cases, evidence of peripheral vestibular disease occurs ([Fig. 86-10](#)). Clinical signs include head tilt toward the affected side, horizontal nystagmus with the fast component in a direction opposite the involved side, and asymmetric ataxia demonstrated variably by falling, rolling, and circling in the direction of the lesion. Most affected animals also have clinical evidence of otitis, both media and externa. When concomitant external ear disease is absent in either dogs or cats and only vestibular peripheral nerve dysfunction is noted, idiopathic peripheral vestibular disease or ascending infection from the oropharynx should be considered. If evidence exists of central vestibular disease (postural reaction involvement, vertical or

Infectious Diseases of the Dog and Cat, 3rd Edition

variable direction nystagmus, involvement of cranial nerves other than facial, or mental depression), extension	834
to the brain stem or subarachnoid space may have occurred or meningitis is the primary problem with	835
involvement of the eighth cranial nerve.	

Nystagmus and ataxia usually resolve despite the occasional irreversible destruction of the peripheral vestibular sense organs or nerves. Reasons why these signs resolve are not clear. However, affected animals probably compensate through accommodation of the vestibular system and reliance on other sensory modalities such as vision and conscious proprioception. Head tilt may remain, but this is usually a cosmetic rather than a functional handicap.⁶⁴ In the dark, and after anesthesia or various other stress factors, the head tilt or imbalance may be noticeably worse.

86.3.4 Diagnosis

Animals with clinical evidence of otitis media and interna should be anesthetized so that an otoscopic examination can be completed and radiographs taken. If the tympanic membrane is obscured by debris, the external ear canal should be gently flushed with a sterile saline or lactated Ringer's solution. Although dilute chlorhexidine or aqueous povidone-iodine solutions have been advocated, these should be used with caution because they can be detrimental to deeper tissues if the tympanic membrane is ruptured (see Otitis Externa, [Chapter 85](#)). The external canal is then suctioned and dried. Although the external ear canal should be examined by conventional otoscopy, video otoscopy provides the best views of the tympanic membrane because of enhanced illumination and magnification. Cleaning and removal of debris can be done with more accuracy. If observed changes suggest middle ear disease, both open-mouth and lateral radiographs of the tympanic bullae should be taken. Radiographically, fluid accumulation will be reflected by increased density within the affected bullae. Radiographic examination of the tympanic bulla has low sensitivity because of difficulties in accurate positioning and the extent of bony involvement that must occur to be visible ([Figs. 86-11](#) and [86-12](#)). Cats with nasopharyngeal polyps often have chronic changes in the osseous bulla visible with radiographs. Radiography is more insensitive in early disease when inflammation or some effusion can be present without notable changes. In advanced cases, radiographic evidence exists of osteomyelitis of the bulla and, on rare instances, the adjacent temporomandibular joint. If available, CT offers a more definitive means of identifying these changes.¹² Even though changes found with CT may not be specific for the type of process involved, neoplastic versus inflammatory processes can usually be determined.¹² CT can be used to assess whether middle or inner ear involvement is present and whether the process involves intracranial or adjacent structures. Otolithiasis has also been detected using CT in dogs with chronic otitis.¹³⁴ MRI is more sensitive than CT is in detecting lesions early in the course of disease because most dogs and cats with clinical evidence of central vestibular disease have visible lesions with this modality.* With MRI, meningeal enhancement can be visualized in dogs and cats when a peripheral otitis media spreads into the central nervous system.^{79,113} Reports indicate that ultrasonography is accurate in detecting fluid within the tympanic bulla of cadavers,³⁰ and although it was not as accurate as CT but more so than radiography, it is more available and less expensive.

86.3.5 Therapy

Choice of treatment for otitis media and interna depends on the stage of the disease. In acute cases, and if concurrent chronic otitis externa is not present, systemic administration of a broad-spectrum antibiotic, such as a first-generation cephalosporin or amoxicillin-clavulanate, has been recommended for a minimum of 14 days.¹⁸ However, courses of 5 days have been found to be equally effective in human patients with acute otitis media⁶⁵ and might be considered for treating dogs and cats. In acute cases, antihistamines may be beneficial to help relieve the swelling within the bony labyrinth, and low antiinflammatory doses of glucocorticoids might be considered for a single administration. Chronic otitis media is difficult to resolve with antibacterial therapy

835

836

Infectious Diseases of the Dog and Cat, 3rd Edition

alone, given that resistant bacteria are often involved, and the bullae may become impacted with necrotic debris. Most dogs and cats with otitis media and interna usually also have chronic otitis externa and will benefit from myringotomy or ventral bulla osteotomy. Alternatively, in very chronic cases, total ear canal ablation with a concurrent bulla osteotomy may be necessary. If the tympanic membrane is intact, myringotomy should be accomplished using anesthesia at the time of otoscopic examination and radiography. Either a blunted 17-gauge needle or myringotomy knife is used for the procedure ([Fig. 86-13](#)). The needle allows simultaneous collection of fluid for culture and flushing. The needle is passed along the ventral horizontal ear canal so that it penetrates the ventral aspect of the pars tensa. Performing the procedure in this manner helps prevent iatrogenic damage to the auditory ossicles. After fluid has been withdrawn for bacterial culture and cytologic evaluation, the middle ear is repeatedly but gently flushed until the fluid recovered by suction is clear of debris and blood, and an antibiotic is then instilled. Selection of the antibiotic is based on prior culture results of the external ear. The antibiotic should be changed if followup culture results of middle ear fluid indicate unresponsiveness. When culture and susceptibility results are unavailable, a broad-spectrum antibiotic should be chosen (see [Tables 86-3](#) and [86-4](#)). Aminoglycosides might be avoided because they potentially impair auditory or cochlear nerve function, if these have not already been lost (see Aminoglycosides, [Chapter 34](#)). Cats treated by instillation of 3- or 30-mg/ml gentamicin solution into the middle ear developed vestibular dysfunction after a median time of 19 or 5 days, respectively.⁹² Antibiotics should be applied topically for 10 to 14 days.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 86-13 Myringotomy procedure on a cat performed through an otoscope.
(Courtesy University of Georgia, Athens, Ga.)

Fig 86-14 Myringotomy can be performed through an otoscope. Once the horizontal canal is entered, proper placement of an otoscope is needed for a myringotomy using a sharp probe. If a catheter is used, then the middle ear cavity can be gently flushed to dislodge inspissated debris as seen in the arrow in [Fig 86-12](#). (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Animals with cytologic or cultural evidence of yeast infection should receive a topical antifungal agent for a similar period (see Otitis Externa, [Chapter 85](#)). Systemic antibiotics or antifungal agents are not usually indicated unless the disease is recurrent or establishment of drainage through the external ear is impossible. Animals with nystagmus and vertigo from acute otitis interna also may benefit from antihistamines or benzodiazepines.

Many dogs and cats with otitis media respond to a single session of middle-ear irrigation together with daily cleaning and topical antibiotic application. This approach is particularly effective in animals with recent onset because the inner ear often is either unaffected or only minimally affected. Care should be taken during irrigation because excessive trauma during cleaning can cause complete damage to middle and inner ear structures. Aminoglycoside-containing solutions should be used judiciously when the tympanic membrane is damaged because repeated flushing of dilute gentamicin-containing solutions in the middle ear of cats resulted in vestibular dysfunction.⁹² Some animals with clinical evidence of otitis interna may respond rapidly after myringotomy, suggesting that the clinical signs are associated with either increased pressure within the bony labyrinth or reversible inflammation of the sensory end organs. Animals that fail to respond or have a chronic repetitive history and radiographic evidence of osteomyelitis are candidates for bulla osteotomy. This procedure allows for removal of proliferative tissue and more complete drainage. Operative techniques for this procedure can be found elsewhere.⁴⁰ Ventral bulla osteotomy is the treatment of choice for cats with inflammatory polyps.

836

837

Canine inflammatory polyps should also be treated by surgical removal.⁹⁹ Lateral bulla osteotomy is often used with total ear canal ablation. Postoperative wound contamination is frequent during this procedure, and prophylactic antimicrobial therapy is indicated.¹²⁶

The greatest danger of otitis media and interna is extension of the infection to the meninges and central nervous system along the cranial nerves. The danger is usually avoided if proper treatment is initiated early. Collection and evaluation of CSF should be done when the animal is anesthetized for the myringotomy procedure if neurologic signs suggest intracranial involvement.

86.4 JOINT INFECTIONS

Inflammatory joint disorders are defined as and characterized by inflammation in the synovial membrane and fluid. Systemic signs are variable and may include lethargy, fever, and leukocytosis. The causes of inflammatory joint diseases in dogs and cats are diverse and include both infectious and noninfectious disorders. This section focuses only on infectious arthropathies.

86.4.1 Etiology

Infectious inflammatory arthritis may be caused by bacteria, mycoplasmas, rickettsiae, spirochetes, fungi, and viral agents (see [Table 86-2](#)). Bacteria are the most common infective agents. Bacterial contamination occurs by either direct inoculation (surgery, penetrating wound, or extension from surrounding tissues) or hematogenous seeding of a distant infective nidus. Postoperative infection has been especially common following surgery of the stifle joint of dogs.⁷⁵ Dogs with preexisting chronic osteoarthritis that have joint surgery are more likely to develop complications of postoperative infection.⁷⁵ With direct inoculation by penetrating or surgical wounds, *Staphylococcus* and *Streptococcus* are the most common isolated agents.¹⁰ Direct inoculation induces a monoarticular septic arthritis. If polyarthropathy is diagnosed, hematogenous spread of bacteria directly or immune-mediated disease secondary to a chronic distant infection should be considered. Hematogenously spread bacterial arthritis is uncommon in the dog and cat and is usually limited to

Infectious Diseases of the Dog and Cat, 3rd Edition

neonates or debilitated patients. Young puppies and kittens may develop suppurative bacterial polyarthritis as a result of congenital or neonatal exposure. *Streptococcus canis* has been most commonly incriminated (see [Chapter 35](#)). Immunodeficient shar peis or Akitas may develop chronic polyarthritis (see [Chapters 95](#) and [100](#)). The most common distant sites of infection include skin, heart, lungs, prostate, anal sacs, umbilicus, and digestive tract.^{9,10} Polyarthropathies of an infectious nature, other than bacterial, are being recognized more and more with the overall improvement of diagnostic abilities. Diseases such as ehrlichiosis, Rocky Mountain spotted fever, and Lyme borreliosis have been associated with polyarthropathies.^{25,106,116,117}

Mycoplasma-induced polyarthritis occurs in cats.²⁴ Fungal, viral, and protozoal (leishmaniasis) arthritis are rare and are usually signs of systemic disorders.⁸ Reactive arthritis is a term used in human medicine to describe idiopathic progressive inflammatory arthritis, which may follow mucosal or other systemic infections; however, no organisms can be detected by conventional culture methods. PCR has been used to detect *Chlamydia trachomatis* and *Borrelia burgdorferi* DNA sequences in some of these patients, few of which have measurable antibody titers to the organism.¹¹⁰ Similar testing is in animals to determine if any of such relationships exist. See the respective chapters for specifics on diagnosis and treatment of each infection.

86.4.2 Pathogenesis

Polyarthritis secondary to infectious diseases can result either from systemic spread of organisms to the joints, with subsequent inflammatory reactions, or from development of immune complexes that circulate systemically, eventually depositing in joint tissues with resultant immune complex–mediated injury. If the organisms involved in the primary disease cannot be recovered from the joints, this failure suggests an immune complex–mediated cause for the polyarthritis rather than a direct spread of microorganisms. Canine idiopathic erosive polyarthritis (CIEP) is a chronic symmetric erosive disease affecting the distal joints of the limbs¹⁰⁴ that is similar to rheumatoid arthritis in people and is thought to be noninfectious. Antibacterial therapy has little effect on the course of disease, and immunosuppressive and antiinflammatory therapy is only temporarily effective in controlling progression of the disease. This condition should be differentiated from bacterial polyarthritis, which generally takes a more rapidly advancing course and tends to be nonerosive in the early stages of illness. CDV has been incriminated as a cause of CIEP because increased levels of CDV antibodies have been found in the synovial fluid of affected dogs.⁷⁶ See [Chapter 3](#) for a further discussion of Canine Distemper in this disease.

After direct bacterial invasion, an acute inflammatory response occurs within the joint. A complex set of interactions occurs between host defenses and various bacterial components, including enzymes, exotoxins, and endotoxins. Synovial fluid levels increase, causing higher intraarticular pressure, ischemia, and release or activation of cartilage matrix–damaging enzymes. Cartilage damage occurs quickly and is irreversible. Glycosaminoglycan depletion occurs within the first 5 days followed by cartilage softening and fissuring. This sequence of events leads to the mechanical weakening of the subchondral bone, as well as the cascade of changes within the synovial fluid, articular cartilage, and cartilage matrix.

Arthritis can develop in infectious diseases in the absence of detectable organisms in synovial tissues. Immune complex deposition in joints usually occurs in more chronic, persistent infections. Circulating antibody levels increase, resulting in formation of soluble antigen–antibody complexes that circulate from the site of infection and deposit in joints. Furthermore, after recovery from infections, when organisms enter synovial tissues by local spread or hematogenous means, persistent inactivated antigens or bacterial fragments may perpetuate the inflammatory process. Antibacterial therapy may also produce cell wall–free bacteria (L forms) that are difficult to detect and that can persist, causing continued inflammation (see [Chapter 32](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

86.4.3 Clinical Findings

Monoarthropathies cause an acute limb lameness and have been most common in medium- and large-breed male dogs.¹⁰ The affected joint is usually swollen, warm, and often painful. Systemic signs, including fever, anorexia, and lethargy, are uncommon or variable. Most signs follow some type of insult to the affected joint. In cases of polyarthropathies, secondary to hematogenous spread, systemic signs along with joint abnormalities often occur. Onset of illness may be the classic acute form or the more chronic, local, and low grade. Lameness may vary from mild to severe; however, swelling is usually visible in the joints distal to the shoulder and hip (Fig. 86-15).

86.4.4 Diagnosis

In most cases, clinical signs allow a presumptive diagnosis. However, the definitive diagnosis is based on evaluation of synovial fluid obtained via arthrocentesis (Fig. 86-16 and Table 86-5). The synovial fluid will have increased turbidity and a poor mucin clot and may have an abnormal color (Fig. 86-17). Both numbers and types of leukocytes should be determined with respect to the number of erythrocytes, which usually suggest iatrogenic blood contamination. Cytologic examination will reveal increased total white blood cell counts with a shift in the cell population to polymorphonuclear leukocytes (Table 86-6). Estimates of synovial leukocyte counts have been made by comparing the number of leukocytes on a smear of fluid with the number of leukocytes in a corresponding blood smear with a known count.¹³⁵ Unfortunately, leukocyte estimates from synovial smears are inaccurate by generally overestimating counts. Hemocytometer or electronic particle counters should be employed wherever available and when sufficient volumes of fluid are obtained for counting methods.⁵¹ Bacteria may be visualized; however, in many septic joints, no organisms are detected. Suppurative inflammation can indicate either infectious or immune-mediated disease given that neutrophils are often not degenerate in septic arthritis.^{51,75} Direct synovial fluid culture samples should be taken, before antibacterial administration, to help determine if infection is present. These cultures do not always yield bacterial growth, even when bacteria are seen microscopically. Thus inoculation of blood culture media with the synovial fluid sample should also be done to improve the chances for bacterial growth. These blood culture media samples should be allowed to incubate for 24 hours at 37° C before they are placed on culture media.⁸¹ Blood cultures are indicated when suppurative joint infections are found because the offending organism may have originated from bacteremia or may have spread to the blood after establishing infection in the joint. In cats, L-form- and feline syncytium-forming viral-associated arthritis cause erosive lesions, whereas mycoplasma-, caliciviral-, feline infectious peritonitis viral-, and borrelial-associated arthritis cause nonerosive lesions.²⁴ Negative culture results from a joint with changes typical of infective arthritis may be caused by an anaerobe that is difficult to culture. Controversy exists as to whether culture of joint capsule is more sensitive in detecting infection compared with synovial fluid culture. When synovial fluid or joint capsule biopsy material is directly inoculated onto blood agar plates, the tissue sample yields the highest rate of cultivation.¹⁰ Culture of joint fluid was more productive than that of synovial biopsy when specimens were first inoculated into blood culture medium.⁸¹ Therefore if arthrotomy is not indicated as part of the clinical management, then joint fluid should be inoculated directly into blood culture medium at the time of collection. For handling specimens for anaerobic culture, see Chapters 33 and 41. Culture of biopsied synovial tissue may be more sensitive than that of synovial fluid.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 86-5 Procedure for Arthrocentesis

Materials

1-1.5 inch, 22-gauge needles

3-ml syringe

Sterile tube with EDTA anticoagulant

Sterile gloves

Clippers and 70% alcohol solution

Blood culture bottles

Glass slides

Cytologic stain: Wright's, Giemsa, or Dif-Quik

Method

Sedate or anesthetized the animal for immobility.

Palpate the joint space using flexion and extension.

Clip atraumatically over the intended area.

Prepare the area with alcohol.

Using gloved hands, palpate the site of penetration.

Insert the needle slowly, with the syringe attached.

Apply slight negative pressure when advancing or still.

Release pressure when withdrawing.

Specimen Handling

Infectious Diseases of the Dog and Cat, 3rd Edition

Clean the top of culture bottles or tubes with alcohol.

Change needles and inoculate fluid directly into sterile EDTA.

Put another aliquot in blood culture bottle for culture enrichment.

Save a third aliquot or the balance in EDTA for cytology.

EDTA, Ethylenediaminetetraacetic acid.

Table 86-6 Synovial Fluid Composition in Infectious Arthritis

PARAMETER	REFERENCE VALUES	BACTERIAL POLYARTHRITIS
Consistency	Clear, ropy strand 2.5–5.0 cm long, dripped from syringe	Cloudy, white or tan, less viscosity and more watery
Total protein	<3 g/dl	
pH	7–7.8	
Glucose	Same as blood	Reduced from blood
Cell count	<3000 cells/ μ l	>5000 cells/ μ l
Cell type	Mononuclear (PMN < 10%)	PMN > 30%

PMN, Polymorphonuclear neutrophils.

Hematologic and biochemical abnormalities may indicate systemic inflammatory or infectious diseases associated with arthritis. Inflammatory leukograms may be associated with systemic infections or may be seen secondary to the inflammation of an infected joint. Thrombocytopenia may be observed in animals with bloodstream infections or rickettsial diseases. Biochemical features of bacteremia may include increased serum alkaline phosphatase activity, hypoalbuminemia, and hypoglycemia. Proteinuria can be associated with glomerular diseases that may result from the same diseases causing immune complex or embolic polyarthritis.

Radiographs can also be of some use; however, early signs are usually too nonspecific to allow a diagnosis. By the time substantive radiographic signs appear, severe loss of bone mineral, intraarticular cartilage erosion, and cartilage matrix breakdown occur. Early signs include joint effusion and associated periarticular soft-tissue swelling. Later signs include joint surface pitting or irregularities and subchondral bony lysis. Nuclear scintigraphy can provide supportive data earlier than conventional radiography can; however, it is impractical in most practice settings.

86.4.5 Therapy

Goals of treatment are eradication of the causative agent and preservation of the articular cartilage. Regardless of the cause, infectious arthritis warrants aggressive early treatment. In animals with monoarthropathy, treatment should include the adequate drainage of suppurative material, Débridement of the accessible necrotic tissue, removal of any foreign implants including suture material, and copious lavage of the joint. A further benefit of drainage in the immature patient is decompression of the joint to avoid further vascular embarrassment of the epiphysis. Initial antimicrobial therapy centers on parenteral bactericidal antibiotics.

Adequate drainage and Débridement of the joint are best accomplished by arthrotomy. Needle aspirations are difficult and do not provide for adequate Débridement, drainage, or extensive lavage. In acute infections, primary closure of the joint after copious lavage is usually adequate. In more advanced cases, partial closure or

Infectious Diseases of the Dog and Cat, 3rd Edition

application of a drainage system may be considered. Both of these methods require intensive postsurgical management. Drainage, lavage, curettage, and inspection of joint surfaces have been achieved with minimal invasion using arthrocentesis and arthroscopy.⁴¹ Use of indwelling drains is generally not advised because they may act as a source of ascending infection for the joint.

Choice for antimicrobial therapy should be based on culture and susceptibility results. Initially, before obtaining culture results or in cases with negative results, antimicrobial choices should be based on the empirical criteria (see [Tables 86-3](#) and [86-4](#)). The drug should be bactericidal, active against β -lactamase-producing *Staphylococcus*, parenterally administered, and broad spectrum. Initially, antibiotics should be given IV for 48 to 72 hours and then orally for a minimum of 21 days. In more advanced cases, the antibiotic should be administered for at least 6 to 8 weeks. Posttreatment joint aspiration for cytology and culture should be considered in all cases.

Passive flexion and extension of the affected joint are advisable as soon as the patient tolerates the procedure. Exercise should be restricted to walks on a leash during the antimicrobial treatment period. For an additional 6 to 10 weeks, exercise should be increased gradually, but the dog should always be on a leash. Alternatively, or in addition, swimming is an excellent mode of physical therapy and can be encouraged as soon as all skin incisions or wounds are healed.

The prognosis is determined primarily by the amount of destruction of the articular cartilage and is difficult to estimate. Clinical evaluation over the next 1 to 2 months with radiographs on the second visit may begin to define the amount and severity of changes that have occurred; however, degenerative changes to the point at which the patient is showing clinical signs may take months.

Distinguishing infectious polyarthropathies from immune-mediated causes is warranted because immunosuppression can lead to disastrous consequences if systemic infections are present. A further problem is that infectious processes may be responsible for inciting immune-mediated joint diseases through the deposition of immune complexes or persistence of foreign antigens, or both, in synovial tissues. Nevertheless, immunosuppression is often reserved as a final modality in cases in which infection cannot be definitively incriminated. Because of the high frequency of tetracycline-susceptible organisms that cause polyarthritis, such as *Borrelia*, *Ehrlichia*, *Mycoplasma*, and L-forms, these drugs are often instituted as first treatment. Caution should be taken in attributing a favorable clinical response to an infection because tetracyclines are known to reduce their inflammatory effects (see Tetracyclines, [Chapter 34](#)).

Treatment of polyarthropathies associated with hematogenous bacterial agents is far more difficult for complete resolution. In these cases, diagnosis of the cause of the septic event must be addressed simultaneously with management of joint infection. Multiple arthrotomies are not feasible in most cases, and needle aspiration may be the only viable option for removal of a portion of suppurative material. Antibiotic therapy is the mainstay of treatment and should be aggressive, as described previously. Followup evaluation, physical therapy, and prognosis are also similar to those described for single joint treatment.

839

840

86.5 INFECTIOUS MYOSITIS

Inflammatory response in muscle can have infectious and noninfectious causes. Infectious inflammatory myositis can be divided into generalized or local disease. Most generalized infections are polymyopathies and are polysystemic. Muscular complications are part of the overall disease. In contrast, localized infectious myositis is usually a component of trauma-induced injury to the soft tissues of a confined region in which the regional musculature is involved. Noninfectious myopathies are usually classified as immune mediated; however, an

Infectious Diseases of the Dog and Cat, 3rd Edition

underlying infectious agent may have provoked an antigenic response against the muscle.³⁸ Classic examples of this syndrome in people are viral infections, which incite an immunologic attack against muscle. In either case, in this chapter, discussion is limited to the management of muscle inflammation directly caused by infectious agents.

86.5.1 Polymyositis

86.5.1.1 Etiology

Infectious polymyopathies can be caused by bacteria, viruses, and protozoa (see [Table 86-2](#)). Examples of these polymyopathies include feline immunodeficiency virus infection, clostridial and spirochetal infections, hepatozoonosis, toxoplasmosis, and neosporosis.^{5,27,32,98}

86.5.1.2 Clinical Findings

Clinical signs vary depending on potential infective agents. The site of infection can also markedly influence the observed abnormalities. Generalized inflammatory myopathies are characterized by signs such as weakness, stilted gait, muscle atrophy, dysphagia, dysphonia, trismus, and in dogs a megaesophagus. A puppy with myocarditis from parvovirus infection has signs that are far different from those in a cat with generalized toxoplasmosis or a dog with tetanus. Neosporosis of puppies may have less painful muscular involvement, which is exhibited clinically as paresis, paralysis, and rigid contracture of the affected area.

Leptospirosis, hepatozoonosis, or toxoplasmosis may cause significant generalized muscle pain.⁹⁶

Associated neural tissue inflammation may be present in some diseases, which amplifies clinical paresis.

With acute inflammation, swelling of the affected muscle regions also occurs. This condition is also seen in localized disease. Chronic disease is characterized by atrophy, fibrosis, and contracture.

86.5.1.3 Diagnosis

Polymyositis is determined based on clinical signs, elevated serum muscle enzyme (creatinine kinase [CK] and aspartate aminotransferase) activities, and electromyographic (EMG) changes. The short half-life of CK allows serial measures to determine whether the disease is progressing or elevations are artifactual. CK activity is increased in active inflammation or necrosis of muscle. Artifactual elevations occur from traumatic venipuncture, hemolysis, or high serum bilirubin, endurance, extended recumbency, and surgical procedures.⁹⁴ Ultrasonography, computed axial tomography, or MRI can be used as a noninvasive means to localize the location and severity of muscle inflammation for further testing. EMG findings can include continuous insertional discharges, high-frequency discharges, and normal nerve-conduction velocities. Biopsy of the muscle can often provide valuable information. Histologic evidence of necrosis and inflammation confirms polymyositis but may not provide the specific cause. Biopsy samples can identify the source of the myositis, if infectious agents, such as *Hepatozoon* schizonts, *Toxoplasma* or *Neospora* tachyzoites, or clostridial organisms, are seen in the tissue.^{5,32,73,98} Serial serologic titers can provide valuable information in toxoplasmal and leptospiral infections. Additional information on most aforementioned organisms can be found in the chapters specifically dedicated to these infectious agents.

86.5.1.4 Therapy

Therapy should be directed toward the specific agent. For example, toxoplasmosis is treated with clindamycin. Initial treatment should be parenteral for the first week if the animal is severely affected. Only

Infectious Diseases of the Dog and Cat, 3rd Edition

after clinical improvement is seen should oral administration be used. Antimicrobial treatment for myositis is usually continued for a minimum of 6 to 8 weeks. Supportive care is of equal importance in these cases because a protracted time frame of weeks occurs for the resolution of signs. For further information on the treatment of specific infections, consult [Tables 86-3](#) and [86-4](#) and respective chapters. When infectious agents are not found and immune-mediated polymyositis is suspected, immunosuppressive therapy may be required.

86.5.2 Localized Myositis

Localized infectious myopathies are not commonly diagnosed because they are usually part of extending soft-tissue infections. These focal infections are the result of trauma, either blunt in nature or a penetrating wound such as a bite. Common bacterial agents include the normal skin flora (usually *S. intermedius*), oral flora, and occasionally *Clostridium perfringens*.^{73,108} Certainly other bacteria should be considered with penetrating wounds, and cultures are advised. Clinical signs include fever and local or regional pain. Swelling with crepitus may be noted in cases of gas formation. Fistulation with drainage of foul-smelling discharge will also be apparent with anaerobic infections. Necrotizing fascitis and myositis, characterized by rapid spreading discoloration of overlying skin, fever, marked hyperesthesia, and progressive lower motor neuron paralysis are features of toxigenic gram-positive bacterial infections (see Streptococcal Toxic Shock Syndrome and Necrotizing Fascitis, [Chapter 35](#)). Leukocytosis, predominantly neutrophilia, and high CK activity are common. Radiographs are not generally beneficial in detecting localized swellings of soft tissues unless underlying osteomyelitis or diskospondylitis is present. Swelling and fluid accumulation can best be detected by fistulography, ultrasonography, and MRI.¹¹⁸ Drainage of any purulent material, surgical removal of the necrotic muscle, and lavage of the region are performed when possible with intrasurgical parenteral and subsequent antimicrobial therapy. Empiric therapy should be based on the type of wound and the most likely contaminant. In most instances, use of an agent that has gram-positive and anaerobic antibacterial activity is a good first choice. Penicillin and derivatives, metronidazole, and clindamycin are recommended for anaerobic infections.

87 CHAPTER 87 Cardiovascular Infections

Clay A. Calvert

Michelle Wall

87.1 BACTEREMIA

Bacteremia indicates the presence of bacteria in the blood, and although a presumptive diagnosis can be offered on the basis of clinical findings, it can be proven only by positive blood culture results. The term *septicemia* implies “toxemia” and associated inflammation along with pulmonary, cardiovascular, hepatic, and intestinal dysfunction.

87.1.1 Etiology

Bacteria normally are excluded from the blood stream by host defenses. On occasion, they do circumvent these barriers, gain access to the blood, and cause a transient bacteremia, a condition that is often unnoticed in clinically healthy individuals. For example, portal and systemic bacteremia (predominantly caused by gram-negative organisms) is found in clinically healthy dogs and is magnified in dogs with hepatic disease and portal hypertension.⁸⁷ The liver generally clears the bacteremia coming from the microflora-laden intestinal tract. However, bacteremia, particularly in the presence of immunosuppression, can lead to disastrous and overwhelming infection. Overwhelming bacteremia leads to sepsis, which often leads to decreased organ perfusion characterized by tachycardia, hypotension, gastrointestinal (GI) damage, liver dysfunction, lactic acidosis, and oliguria.

Any heavily colonized mucous membrane surface or localized site of infection can serve as a source for direct bacterial extension into the lymphatics or blood vessels. Many procedures in hospitals circumvent or alter host defense mechanisms. The use of intravenous (IV) and bladder catheters or respiratory, GI, and percutaneous endoscopic biopsies and surgery allow a direct means by which bacteria may gain access to body sites that are normally protected against such invasion. Commonly used medical treatments such as immunosuppressive agents, cytotoxic drugs, and radiation therapy diminish host defense mechanisms. Thus modern medicine and surgery provide the conditions for opportunistic bacterial infections to occur.

Bacteremia often leads to sepsis and may lead to septic shock. If treated quickly and aggressively, septic shock may be reversible; if not, it quickly becomes irreversible.⁵⁶ Bacterial virulence and the likelihood of septic shock depend on the presence of cell capsules isolating cell wall antigens from host inflammatory cells; microbial enzyme production facilitating rapid tissue penetration; and concentration of bacteria in the blood stream, which is related to size of the inoculum and duration of bacteremia.^{133,163}

Treatment outcome is related to whether irreversible changes have occurred. Often bacteremia in dogs and cats is diagnosed when it is in an advanced state. The release of mediators of septic shock, such as endotoxin, exotoxin, tumor necrosis factor (TNF), and some interleukins (ILs), is associated with hypotension, hepatic failure, and breakdown of the GI mucosa-blood barrier, all of which are associated with high mortality. Prevention of bacteremia, identification of high-risk patients (e.g., patients receiving chemotherapy, patients who are otherwise immunosuppressed or debilitated, patients undergoing invasive procedures), and early recognition of sepsis are critical to reducing overall mortality.

Infectious Diseases of the Dog and Cat, 3rd Edition

87.1.2 Epidemiology

It is safe to assume that the incidence of bacteremia in dogs and cats is significantly underestimated, particularly in referral and emergency hospitals. Affected dogs and cats can be any age, breed, or gender.

Although bacterial prostatitis has been identified in some bacteremic male dogs, a causal relationship is difficult to prove. Nonetheless, the prostate gland should be suspected as a potential nidus of bacteremia in intact male dogs.^{34,56} Chronic seeding of the blood stream by sites of infection such as bone, gingivae, and the prostate gland potentially predisposes them to bacterial endocarditis.^{31,34} Bacteruria is either a source or a consequence of bacteremia.

Various factors influence the relative frequency of etiologic agents among different hospitals. Surgical and trauma practices may experience a higher prevalence of gram-negative and anaerobic infections. The site of local infection and prior antibiotic therapy and whether the infection is nosocomial or community acquired determine the most likely offending microbes. The percentages of isolation of various organisms from dogs and cats with bacteremia and bacterial endocarditis are summarized in [Table 87-1](#). Because the recognized prevalence of bacteremia in cats has not equaled that of dogs, most of the discussion that follows concerns the disease in dogs. A discussion of endocarditis in cats follows the information on specific bacteria identified in dogs.

842

87.1.2.1 Staphylococci

Coagulase-positive staphylococci are among the most commonly isolated pathogens. Staphylococci can survive in the environment and be cultured from dried clinical material after several months. They are relatively heat resistant. Staphylococci are found in the nasopharynx and skin and can contaminate any site on the skin and mucous membranes. Multiplying staphylococci can overcome local phagocytic defenses and gain access to the lymphatics and blood stream. Staphylococcal bacteremia can lead to metastatic infections in the heart, lungs, and bones (see [Chapter 36](#)). Staphylococci secrete numerous enzymes and toxins that are implicated in their pathogenesis. Catalase can inhibit polymononuclear (PMN) free oxygen-radical-killing activity, and their toxins damage cell membranes and cause cell lysis. Manifestations of their infection vary from trivial, as in some pyodermas, to overwhelming sepsis. Coagulase-positive *Staphylococcus intermedius* (see Etiology, [Chapters 36](#) and [85](#)) have been common bacteria isolated from blood cultures of dogs with bacteremia alone, diskospondylitis, and endocarditis.^{31,34} Common sources for blood stream infection include abscesses, pyoderma, and wound infections. Staphylococci tend to spread from localized abscesses, wounds, and deep pyodermas into the blood stream by invading blood vessels and producing septic thrombi or lymphatics and incompetent lymph nodes. Metastatic foci of infection are common and often involve the spleen, kidneys, bones, joints, or heart valves.

Infectious Diseases of the Dog and Cat, 3rd Edition

^a Values are expressed as a percentage of those cases in which organisms were isolated or detected by genetic means and represent a compilation of the cited references. The percentage of dogs for which negative isolation results were obtained is not included.

Only a small percentage of local infections caused by *S. intermedius* gain access to the blood stream.⁴⁰ Nonetheless, enzymes such as staphylokinase, hyaluronidase, and protease can enable tissue invasion. Sepsis can result from enterotoxins that bind to T cells and macrophages, stimulating the production of cytokines.

One of the targets of *S. intermedius* is the endothelial cell.⁴⁰ Organisms bind to and are internalized by endothelial cells, where cytolytins are released that can disrupt the endothelium and allow access to tissue. They can survive inside of endothelial cells and phagocytic cells. This may explain their propensity to cause recurrent and refractory bacteremia.

S. intermedius is normally present on canine hair and skin, and an association of cutaneous infections with staphylococcal bacteremia in dogs is to be expected. These microbes also may gain entry into the blood stream of dogs from foci such as osteomyelitis, diskospondylitis, septic arthritis, aspiration pneumonia, and genitourinary infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

Most *S. intermedius* strains produce a β -lactamase that induces resistance to penicillin G and ampicillins. Stability of the β -lactam ring of methicillin is high and varies for cephalosporins. Staphylococci can become resistant to all β -lactam antibiotics and all cephalosporins. Resistance is increasing to quinolones, aminoglycosides, and macrolide antibiotics, such as clindamycin, as their indiscriminate use increases.

The coagulase-negative *Staphylococcus epidermidis* may be cultured from blood specimens but are often not fully identified in clinical microbiology laboratories. The majority of these are either contaminants or of no clinical importance. However, significant coagulase-negative staphylococcal bacteremia can occur in immunocompromised patients with indwelling IV catheters or profound neutropenia.

Intact skin and mucous membranes provide defense against staphylococcal invasion. When these defenses are breached, blood invasion can arise from any site but most often from localized skin or soft tissue infections, surgical wounds, and catheters. Various conditions may predispose animals to staphylococcal bacteremia. Debilitation resulting from malignancies, renal failure, diabetes mellitus, and liver disease are examples, as are compromise of immune protection by glucocorticoids, cytotoxic drugs, and other immunosuppressive agents.

A devastating complication of staphylococcal bacteremia is valvular endocarditis. Septic embolization of the kidneys and other organs may occur with chronic staphylococcal bacteremia and is consistently present with valvular endocarditis of the left side of the heart. Renal infarcts can be detected by excretory urograms and ultrasonograms. Proteinuria and pyuria are often present, and immune complex glomerulonephritis may be an additional complication. Other sites of septic embolization or abscess formation are the spleen, brain, joints, and lungs, including pulmonary arterial thromboembolism.

Disseminated intravascular coagulation (DIC) is another sequela of staphylococcal bacteremia, but its incidence is probably less than that associated with gram-negative bacteremia. Prolonged activated coagulation time, prothrombin time (PT), and activated partial thromboplastin time (APTT); thrombocytopenia; decreased plasma fibrinogen; and the presence of fibrin degradation products and D-dimers are consistent with the diagnosis. *Staphylococcus aureus* bacteremia in people occasionally triggers a septic shock syndrome (*toxic shock*), which can be virtually indistinguishable from gram-negative bacillary endotoxic shock.

87.1.2.2

Streptococci

Systemic streptococcal infections are common in dogs and cats (see [Chapter 35](#)). Streptococcal bacteremia can originate from cutaneous sites and the upper respiratory tract. Streptococcal pneumonia may be associated with a high incidence of subsequent bacteremia. In bacteremic dogs with various underlying illnesses, blood culture results may be positive for hemolytic *Streptococcus canis* and non- β -hemolytic *Streptococcus viridans* and enterococci. Most β -hemolytic streptococci enter the blood stream via the skin, whereas non- β -hemolytic streptococci usually enter via breaks in the mucous membranes. Non- β -hemolytic streptococci are normal skin commensals and occasionally may contaminate improperly collected blood culture specimens.

Group A streptococci (*Streptococcus pyogenes*) are enveloped in a hyaluronic acid capsule that retards phagocytosis by PMNs and macrophages. Toxins produced by *S. pyogenes* are pyrogenic, are cytotoxic, and enhance the susceptibility to the effects of endotoxin.⁴⁹ Group B streptococci can cause sepsis in dogs and cats and have been incriminated as a cause of bacteremia and death in the “fading puppy” syndrome. In people, bacteremia caused by group D streptococci (enterococci), including *Streptococcus faecium* and

Infectious Diseases of the Dog and Cat, 3rd Edition

Streptococcus faecalis, usually originates from the urinary tract but also can develop after manipulation of the lower bowel. Enterococcal bacteremia, which has been reported in dogs, is especially serious because enterococci are resistant to many antibiotics.

87.1.2.3

Gram-Positive Aerobic Bacilli

Diphtheroids, a heterogeneous group of bacteria including the genus *Corynebacterium*, are often interpreted as contaminants when isolated from blood culture because they normally inhabit skin and mucous membrane surfaces. *Corynebacterium* accounts for a minority of cases of bacteremia in dogs and has rarely been associated with endocarditis. *Bacillus* species are frequent blood culture contaminants. However, in the immunocompromised host, *Bacillus cereus* and *Bacillus subtilis* can gain access to the blood stream. *Corynebacterium* and *Bacillus* should be isolated from multiple blood cultures before diagnosing bacteremia as a result of these agents. *Erysipelothrix tonsillarum* strains have been isolated from the heart valves of dogs with endocarditis¹⁷³ (see [Chapter 35](#)).

87.1.2.4

Gram-Negative Bacilli

The term *gram-negative bacteremia* is typically applied to bacteremia caused by the Enterobacteriaceae and Pseudomonadaceae. Bacteremias resulting from gram-negative agents, such as *Pasteurella*, *Brucella*, *Bartonella*, and *Salmonella* species, which can also produce similar clinical manifestations, are usually considered discrete clinical entities. *Salmonella enteritidis* was the most common organism isolated from bacteremic cats in one study.⁵⁶ Gram-negative bacillary bacteremia usually represents a serious opportunistic infection that has developed subsequent to significant depression of host defenses. Gram-negative bacteremia is often associated with high mortality, and the number of such infections has increased along with the use of invasive medical devices and immunosuppressive therapy for malignancies and inflammatory diseases.

Gram-negative bacilli are ideally suited for opportunistic infections. Ubiquitous in the environment, they are major components of the fecal flora, are normal skin inhabitants, and are present in all hospital environments. They tend to be relatively resistant to moisture, drying, and some disinfectants. Some may persist and multiply in water. These agents tend to develop antibiotic resistance to a greater degree than gram-positive bacteria. Although antibiotic exposure per se does not induce resistance, it does provide a selective reproductive advantage to bacteria that are resistant.

Of bacteria of the family Enterobacteriaceae, *Escherichia coli* is the most common blood-stream isolate from animals. *E. coli* is abundant in the lower GI tract, which often serves as a reservoir for infection of other body sites. The urinary tract is another source. Oropharyngeal and fecal colonization with gram-negative bacilli may increase progressively in seriously ill hospitalized patients as their clinical status deteriorates. 843

Gram-negative bacteria not only gain access to the blood from extravascular foci but also may originate from IV and urinary catheters and from septic thrombophlebitic conditions. In extravascular infections, bacteria often gain access to the blood via lymphatics or invasion of small blood vessels within a site of infection. Other sources for blood stream invasion include drainage tubes, contaminated IV fluids, and contaminated aerosolization devices; disrupted mucosal barriers (e.g., after dental procedures or endoscopic examinations); and decubital ulcers. In contrast to staphylococcal bacteremia, gram-negative bacteremia in dogs and cats seldom is associated with septic thrombosis and metastatic abscess formation but is often rapidly progressive and likely to result in endotoxemia (see [Chapter 38](#)). 844

Although common in the environment and occasionally present on mucosal surfaces, *Pseudomonas* species have rarely been isolated from deeper tissues of healthy patients. They have been more common in otitis

Infectious Diseases of the Dog and Cat, 3rd Edition

externa, dermatitis, cystitis, and respiratory infections of dogs. Because *Pseudomonas* organisms are opportunists, their rapid colonization with subsequent development of bacteremia is much more likely to occur after disruption of host defenses, especially cutaneous barriers (surgery, IV catheters, and burns) and depletion of neutrophils, as occurs in patients who are receiving chemotherapy for cancer.⁴⁴ Extensive antibiotic use or contaminated IV fluids may also predispose patients to *Pseudomonas* bacteremia. Most reported cases of *Pseudomonas* bacteremia in dogs have been nosocomial.⁴⁴

Prevention is easier than treatment of gram-negative bacteremia. The use of IV and urinary catheters should be limited to instances in which they are absolutely necessary. They should be inserted and maintained under scrupulously sterile conditions and removed or changed within 3 to 5 days. Strict aseptic precautions in the management of wounds, use of tube drainage systems, prevention of decubitus, and limitation of prophylactic antibiotics are all important in preventing opportunistic infections for all patients, particularly those with weakened immune systems.

87.1.2.5 Anaerobic Bacteria

Anaerobic bacteria, particularly anaerobic gram-negative rods, are considered to be serious pathogens. Development of anaerobic blood stream infections may be encouraged by the presence of periodontal disease, deep abscesses, granulomas, peritonitis, osteomyelitis, septic arthritis, and septic pleural effusion (see [Chapter 41](#)). *Clostridium perfringens* is the most common canine isolate, whereas *Bacteroides* and *Fusobacterium* are commonly isolated from cats. A mechanically correctable lesion (abscess, perforated bowel, necrotic tissue) is often the source of anaerobic bacteremia. *Bacteroides* may enter the blood stream via intraabdominal sources, such as GI and genital inflammatory diseases. *Fusobacterium* bacteremia often originates from infections of the respiratory tract. Characteristics of anaerobic bacteremia include fever, thrombophlebitis, and icterus, particularly with *Bacteroides* bacteremia. Sequelae to anaerobic bacteremia include metastatic abscess formation and endocarditis. Clostridial bacteremia tends to have a relatively insidious clinical course without obvious signs of sepsis, although septic shock occurs occasionally.

87.1.2.6 Polymicrobial Bacteremia

Blood stream infection with multiple species of bacteria occurs in up to 20% of dogs and 30% of cats with positive blood culture results. Anaerobic bacteria, especially *Bacteroides* and *Clostridium*, are often components of polymicrobial infection in dogs. Clinical implications of polymicrobial compared with monomicrobial bacteremia are not clearly established, and higher mortality rates have not been observed in dogs or cats. Factors that can predispose patients to polymicrobial bacteremia include neutropenia, GI and urogenital tract obstruction and infection, bowel perforation and surgery, and prostatic surgery.

87.1.3 Pathogenesis

Bacteremia develops as a normal but transient phenomenon whenever bacteria-laden mucosal surfaces, such as the nasopharynx and the GI and genital mucosae, are traumatized. Transient bacteremia is usually low grade, with 10 or fewer colony-forming units per milliliter; bacteremia is normally cleared within 1 hour by normal host defenses. Complement-mediated bactericidal activity is highly efficient at eliminating low-grade bacteremia. Serum-resistant gram-negative aerobic bacilli such as *E. coli* can escape this bactericidal protection. Clinically important bacteremia may occur when the blood stream is seeded with high numbers of bacteria via venous and lymphatic drainage from sites of infections. Fluid accumulation, high tissue pressure, surgical or physical manipulation of abscesses, areas of cellulitis, or other infected tissues all favor lymphatic and venous

Infectious Diseases of the Dog and Cat, 3rd Edition

spread of bacteria to the systemic circulation. In most healthy individuals, bacteria are removed from the blood stream rapidly and effectively through phagocytosis by fixed tissue macrophages in the spleen and liver. Persistent bacteremia ensues when bacteria multiply at a rate that exceeds the mononuclear phagocyte system's ability to remove them. Serum from healthy patients is bactericidal, largely because of the presence of numerous humoral defense factors, including specific antibacterial antibodies of the IgM and IgG classes as well as complement proteins, properdin, and fibronectin. Bacterial capsules and other virulence factors may delay clearance of bloodborne bacteria, whereas bacteria that activate complement via the alternate (antibody-independent) pathway are cleared rapidly.

87.1.4 Sources of Infection and Risk Factors

Although not always identified, the most common sources of bacteremia include infections of the GI and genitourinary tracts, skin and wounds, respiratory tract, abdomen, and biliary tract. IV catheter-associated infections also occur.^{31,34} Bacteremia can be a complication of parenteral nutrition, and the catheter should always be considered a source of infection. Infection often begins locally in the catheter wound when the patient's cutaneous flora invade the tract during catheter insertion and thereafter. Hub contamination is also a source of infection. Catheter-related bacteremia is confirmed when catheter and blood culture results yield the same microbe. The most common organisms are staphylococci. Catheters should always be removed and cultured immediately if bacteremia is suspected.

Catheter-related bacteremia originates from the migration of bacteria from the venipuncture into the catheter tract and along the external surface of the catheter to the intravascular tip, which becomes colonized.⁸⁸ In addition, contamination of the hub can allow migration within the catheter lumen. Teflon and polyurethane are more resistant to bacterial colonization than polyethylene or polyvinyl chloride. Some bacteria, such as staphylococci, can bind to host fibronectin that is deposited on catheters. Peripheral venous catheters have a lower risk of blood stream infection than central venous catheters.⁸⁸ Catheters impregnated with chlorhexidine or silver sulfadiazine are resistant to infection. Sterile gloves should be worn during catheter placement, and the area should be sterile. Insertion and maintenance of IV catheters by inexperienced staff members increase the incidence of catheter-related bacteremia.

In cats with bacteremia, underlying predisposing causes included pyothorax, septic peritonitis, GI tract disease, pneumonia, endocarditis, pyelonephritis, osteomyelitis, pyometra, and bite wounds.²²

844

Various factors (Table 87-2) have been cited as predisposing patients to developing bacteremia. When considering mortality from bacteremia and sepsis, the single most important factor influencing outcome after infection is the severity of the patient's underlying disease. Death from bacteremia is much less likely to occur if the animal was healthy before the bacteremia developed.

845

Neutropenic patients are very susceptible to sepsis. Cancer chemotherapy-neutropenia is particularly dangerous because the destruction of GI crypt epithelial cells is usually a concomitant problem. Enteric bacteria gain access to the blood via the damaged mucosal barrier, and the neutropenia renders phagocytosis of these bacteria ineffective. To complicate matters, fever may be absent or minimal in a bacteremic patient because neutrophils are a component of the inflammatory process. The febrile neutropenic patient is a medical emergency. Patients who have had a splenectomy are also predisposed to bacterial sepsis because the spleen is an important component of the host's defense mechanisms.

Endoscopic procedures (see Chapter 55)
IV catheterization
Antimicrobial therapy (narrow spectrum or low dose)
Immunosuppressive therapy
Urogenital tract manipulations (see Chapter 91)

87.1.5 Time Course

Relating the time course of bacteremia to the infecting organism is not always possible. Peracute bacteremia, which develops over several hours, often in debilitated or immunosuppressed patients, may be the result of either gram-positive or gram-negative infection. Acute bacteremia develops over 12 to 24 hours and is usually the result of gram-negative or staphylococcal infection. Subacute bacteremia develops and persists for several weeks or longer and is often the result of gram-positive but occasionally anaerobic infections. Chronic bacteremia, lasting weeks to months, may result from infections with microorganisms of low toxicity (e.g., *Brucella canis* and *S. intermedius*); sequestration of bacterial colonies on heart valves or in bone; abscess formation in the liver, spleen, kidneys, or muscles; or partial response to antibacterial therapy.

Secondary arthropathies, glomerulopathies, embolic abscesses or thrombi, and splenomegaly are more often associated with infective endocarditis (IE) than with bacteremia alone ([Fig. 87-1](#); [Table 87-3](#)). Metastatic infection can result in life-threatening complications. Virtually all dogs with IE of the left side of the heart experience multiple continuous embolizations and renal infarctions, which may lead to renal failure. Subacute and chronic bacteremia can result in sustained antigenic stimulation of the immune system and increased circulating immunoglobulin. Circulating immune complexes (CICs) may be deposited in many tissues, leading to development of polyarthritis, myositis, vasculitis, and glomerulonephritis. Young, growing animals may develop metaphyseal embolization with resultant hypertrophic osteodystrophy.¹⁶⁶ In people, bacteremia has been found to result in hemolysis, presumably because of modified erythrocyte antigens that develop as a result of the circulating organism. A similar association of bacteremia with immune-mediated hemolytic anemia was not found in dogs.¹²⁸ Bacteria such as intraerythrocytic *Bartonella* species and hemotrophic mycoplasmas can induce hemolytic anemia (see [Chapters 54](#) and [31](#), respectively), as do many protozoan erythroparasites.

Infectious Diseases of the Dog and Cat, 3rd Edition

87.1.6 Clinical Findings

87.1.6.1 Dogs

Dogs with bacteremia usually display some combination of lethargy, anorexia, GI disturbances (such as vomiting and diarrhea), fever, lameness, and myalgia (see [Table 87-3](#)). The presence of lameness (which may be intermittent), joint pain, muscle pain, and stiffness may suggest either immune-mediated disease or septic embolization of various tissues. Either infective or, more likely, immune-mediated arthritis may develop, and bilaterally symmetric joint involvement is more typical of immune-based arthritis. Lumbar or abdominal pain that is elicited by palpation suggests the possibility of renal or splenic inflammation secondary to septic embolization, infarction, abscess formation, or diskospondylitis. Diskospondylitis can also result in paresis or paralysis, depending on the location and degree of spinal cord compression (see Musculoskeletal Infections, [Chapter 86](#)). In younger animals, metaphyseal osteomyelitis causing malaise, fever, anorexia, swollen limbs, and reluctance to move has been observed. Occasionally, erosion of an artery occurs after septic embolization, and hemorrhage results. Vasculitis and thrombophlebitis may produce hyperesthesia and lameness, with or without swelling of an extremity.

845

846

Fig 87-1 Sites of predilection for bacterial embolization in bacteremia are responsible for clinical illness that ensues. (Courtesy of University of Georgia, Athens Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 87-3 Clinical Signs in Dogs with Bacteremia or Bacterial Endocarditis

CLINICAL SIGNS	BACTEREMIA ALONE (n = 77)	INFECTIVE ENDOCARDITIS (n = 45)
Fever (> 39.4° C [102.9° F])	75	70
Lameness: total	19	34
Lameness: shifting	6	18
Vomiting	17	35
Heart murmur	6	74
Ventricular arrhythmia	5	27

Organ failure in bacteremic septic patients can quickly lead to septic shock. In the dog, the GI tract, liver, kidneys, and lungs (in this order) are most affected. Mucosal sloughing, characterized by vomiting and bloody diarrhea, often with mucosal remnants, is commonly seen with advanced sepsis. Hepatic failure is characterized by vomiting, anorexia, ascites, and icterus. Oliguria is usually the result of hypotension and shock. Splenic inflammation may lead to splenomegaly or abdominal discomfort. Endocarditis is associated with cardiac manifestations of a heart murmur with or without arrhythmias.

87.1.6.2 Cats

In cats with bacteremia, with or without endocarditis, signs were anorexia, pyrexia, and shifting leg lameness.³⁶ Heart murmurs are found in those with endocarditis. In the cat, respiratory failure can occur early in the course of sepsis. In some cats, endocarditis may be more gradual, permitting the infected valves to become dystrophic.^{115,138} With valvular lesions, although signs of sepsis have varied, cats invariably develop signs of right- or left-side congestive heart failure (CHF).

87.1.7 Diagnosis

87.1.7.1 Clinical Laboratory Findings

87.1.7.1.1 Dogs

The leukograms of dogs with bacteremia alone and with bacterial endocarditis are similar.³⁴ A neutrophilic leukocytosis with an appropriate left shift and monocytosis are present in most dogs with gram-positive or anaerobic bacteremia and in virtually all dogs with chronic IE at some point during the course of disease. Leukopenia and inappropriate left shift have been more common with bacteremia alone, usually in association with peracute and acute gram-negative infections.

A normocytic, normochromic, nonregenerative anemia and thrombocytopenia are common with subacute or chronic bacteremia in dogs or cats.^{22,34} With sepsis, hemoconcentration occurs after fluid losses from the intravascular space. Serum total solids tend to decrease because of the loss of protein from the intravascular compartment.

Serum chemistry abnormalities are common.³⁴ Hypoalbuminemia (less than 2.5 mg/dl), a twofold or greater elevation of alkaline phosphatase (ALP) activity, and hypoglycemia (less than 80 mg/dl) are

Infectious Diseases of the Dog and Cat, 3rd Edition

consistent with bacteremia. Hyperglycemia occurs during the early phase (hyperdynamic phase) of septic shock.

The liver is an important site of removal of bacteria from the blood. Increased serum ALP activity is associated with gram-positive and gram-negative infections, and bacterial toxins are associated with impaired bile metabolism and cholestasis. Hyperbilirubinemia, bilirubinuria, and icterus can also occur (reactive hepatopathy of sepsis, see [Chapter 90](#)).

846

Hypoalbuminemia is a common manifestation of most types of bacteremia.³⁴ Subacute and chronic bacteremia may result in transcapillary leakage as a result of immune-mediated or embolic vasculitis or bacterial toxins. Sepsis also has been associated with reduced hepatic synthesis of albumin, and as many as 50% of bacteremic dogs may have increased bromsulphalein retention, suggesting either reduced hepatic function or reduced hepatic arterial blood flow. Bile acid levels may also be increased, suggesting hepatic insufficiency. Hypocalcemia is often observed and usually attributed to hypoalbuminemia.

847

The mechanism of hypoglycemia involves the effects of bacteria or bacterial toxins on the intermediary metabolism of glucose. In contrast, hyperglycemia has been correlated with a higher postoperative mortality in dogs than normoglycemia or hypoglycemic septicemic dogs.³³ This finding may be related to the fact that hyperglycemia has been seen in patients with early, severe septicemia, and hypoglycemia develops in more chronically affected cases.

Hypercoagulability leading to DIC is a common sequela of bacteremia. Evidence of DIC (low fibrinogen, prolonged PT and APTT, and increased fibrinogen degradation products) is consistent with advanced sepsis wherein major organ failure, including cardiovascular collapse, may be imminent.^{93,107,119}

Septic patients often have a metabolic acidosis with respiratory compensation. The carbon dioxide tension can decrease severely to compensate for acidemia, but hypoxemia is uncommon in conscious patients.

Blood lactate levels are often increased in septic patients. Hemoconcentration and shock cause decreased oxygen delivery to the tissues, resulting in anaerobic metabolism. Cellular oxidative respiration is inhibited by an endotoxin or a mediator.¹⁶² Furthermore, septic patients tend to be in a hypermetabolic state, requiring increased oxygen delivery to tissues.

Proteinuria, occult hematuria, and pyuria may occur in association with bacteremia or, more commonly, with bacterial endocarditis in which renal infarction, glomerulonephritis, and renal microabscess formation are common sequelae. Proteinuria with acellular urinary sediment suggests glomerular or tubular renal proteinuria and may occur with renal injury from immune-complex deposition caused by bacteremia. Urinary tract infections may be either a cause or a result of bacteremia, and urine cultures should be submitted regardless of whether abnormalities are detected on urinalysis.

Test results for immune-mediated diseases, such as antinuclear antibody titer (ANA), rheumatoid factor (RF), and lupus erythematosus cell preparation, occasionally are positive in bacteremic patients, particularly those with IE.

Bacteremia is only occasionally diagnosed by direct microscopic examination of leukocytes in blood smears. Direct Gram's stains of peripheral blood are usually unrewarding because the number of microorganisms present is often much lower than the 10^5 ml necessary for detection. Wright stains of buffy coat smears may increase the rate of detection. Acridine orange is more sensitive than Gram stain,

Infectious Diseases of the Dog and Cat, 3rd Edition

because organisms can be detected at 10^4 /ml concentrations. Slides must be handled carefully to prevent inadvertent contamination, which may be revealed as extracellular bacteria.

A simple method of performing leukocyte smears involves placing one drop of freshly collected, nonclotted venous blood on a clean glass coverslip and incubating it in a moist Petri dish for 25 minutes at 37° C (98.6° F). The clot on the coverslip is gently washed off with normal (0.9%) saline, and the coverslip with attached leukocytes is immersed in fixative (methanol or glutaraldehyde) before Giemsa staining and microscopic examination.

87.1.7.1.2

Cats

In the most severe cases, cats have had prehepatic jaundice, associated with erythrocyte destruction, and neutrophilia with a left shift. In cats, neutrophilia with a left shift is common.²² Cats with sepsis often exhibit hypoxemia, hypercapnia, and metabolic acidosis. In addition, they often have hypoalbuminemia, low serum ALP activity, and hyperbilirubinemia.²²

87.1.7.2

Blood Culture

The definitive diagnosis of bacteremia requires compatible clinical signs and laboratory data and the isolation of the offending microbe from blood cultures. Primary or secondary sites of infection, urine, and, although rarely, joint fluid may also contain the organism. Preferably, the bacteria should be isolated from more than one blood sample. In addition, a source of infection should be sought and attempts made to isolate an organism from that site. Negative blood culture results in bacteremic patients can occur as a result of prior antimicrobial therapy, chronic low-grade infections such as diskospondylitis and endocarditis, intermittent shedding of the organism, causative agents other than bacteria, uremia, and right-sided endocarditis.

When an etiologic diagnosis is established with positive blood culture results, more appropriate and effective antibiotic therapy can be used. Low blood culture yields are a frequent complaint but probably reflect the effects of poor selection on the part of the clinician of proper blood culturing techniques (e.g., timing, volume, number of specimens) and inadequate laboratory processing (e.g., improper handling techniques, failure to culture for anaerobes). By adhering to recommended guidelines for obtaining and processing blood culture specimens, the diagnostic yield from blood cultures can be rewarding.

Although empiric multiple-antibiotic therapy often has been instituted in critically ill patients before obtaining culture results, the effort and expense required for blood culture have been justifiable because improper treatment may increase mortality from bacteremia. Furthermore, prior administration of antimicrobials appears to slow but not prevent bacterial isolation.⁵⁶

87.1.7.2.1

Indications

Blood cultures are indicated in acutely ill patients with fever; leukocytosis, especially with a marked left shift; neutropenia; and unexplained tachycardia, hypoglycemia, circulatory collapse, tachypnea or dyspnea, anuria or oliguria, icterus, thrombocytopenia, or DIC. Complementary cultures of urine and any other obvious sites of possible infection should also be obtained.

Bacteremia is usually continuous, although low level. Intermittent bacteremia usually reflects established infections extrinsic to the blood stream. Samples should be taken from either a freshly placed,

Infectious Diseases of the Dog and Cat, 3rd Edition

meticulously maintained jugular catheter or from several veins.^{32,56} Duration of antimicrobial therapy is an important factor in the detection of bacteria.⁸⁴ Therapy for only 2 to 3 days may not interfere; however, longer courses of therapy require the use of antibiotic removal devices or discontinuation of therapy before sampling. Suppression of bacteremia often persists longer than antibiotic blood levels.

One of the most critical factors is taking an adequate sample volume, because the concentration of organisms in bacteremic specimens is small. In addition, multiple sample collections have been recommended in an attempt to detect an intermittent bacteremia. For dogs and cats, it has been suggested that at least three blood cultures be obtained over 24 hours.^{31,33} In the case of critically ill, acutely septic patients, the three blood cultures should be obtained over 30 to 60 minutes before instituting antimicrobial treatment. However, for small animals, this may be too much blood. Taking larger volumes as recommended for human patients is often difficult in dogs and cats. The idea that bacteremias are intermittent or are correlated with fever spikes has also not been well substantiated. Therefore taking at least two specimens of sufficient volume from different vascular sites within a 10-minute interval may be sufficient to determine whether bacteria are present in the blood and whether positive blood culture results are a result of true bacteremia or contamination during collection. At least 5 to 10 ml of blood should be collected for each culture, because the chances of obtaining a positive result are directly related to the volume of blood cultured. The concentration of organisms is relatively low (fewer than five per milliliter) in the blood of most patients. It is recommended that as large a volume as practical be taken to maximize the chance of culturing an offending organism. A minimum of 20 ml is taken from large dogs, 10 ml from intermediate-size dogs, and 5 ml from cats and smaller dogs. If possible, a second specimen should be taken from a second venipuncture site within a short interval of the first. A blood-culture broth ratio of 1:10 must be maintained to counteract the bactericidal activity of serum. Anticoagulant and antiphagocytic effects of broth additives are diminished if dilution of blood in media is less than 1:8. Therefore the proper size blood culture bottle should be used for the intended blood sample volume.

847

848

87.1.7.2.2

Technique

Before venipuncture, thorough skin antisepsis, as for surgery, is the most effective means of avoiding culture contamination (Fig. 87-2, A).⁸⁹ Small numbers of bacteria may persist inside hair follicles and sweat and sebaceous glands, which may be penetrated by the needle. If the vein must be palpated after skin disinfection, a sterile glove should be worn. To minimize the risk of contamination, blood samples should not be drawn through an indwelling IV-catheter unless it is a recently and appropriately placed jugular catheter. Arterial blood specimens offer no advantage over venous blood specimens. Finding the same organism at two different surgically prepared sites reduces the likelihood that the organism is a contaminant, especially when sampling intervals are close.

The culture bottle diaphragm is disinfected with alcohol or iodine before sample inoculation (Fig. 87-2, B). Blood is inoculated immediately and directly into culture media using a syringe and new needle or a blood transfer set (Fig. 87-2, C). Only commercial culture bottles packed under vacuum and fitted with rubber diaphragms should be used for routine blood cultures to minimize the risk of contamination (Table 87-4). Air must not be allowed to enter into vacuum bottles during blood injection. The blood should be dispersed in the culture medium by gently inverting the bottle 2 or 3 times. Blood culture bottles should be inoculated and can be maintained at room temperature to avoid killing temperature-sensitive bacteria; however, incubation at 37° C is often used in the laboratory.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 87-2 Blood culture method. **A**, Blood specimen is taken from jugular vein after surgical preparation. **B**, Top of bottle containing liquid blood culture medium is disinfected with povidone iodine solution. **C**, Blood is placed in culture media after changing to new needle. (Courtesy University of Georgia, Athens, Ga.)

Half of each blood sample should be inoculated into an aerobic broth culture medium and the other half into an aerobic broth. These media should be capable of supporting growth of fastidious bacteria and when appropriate should contain a resin to remove antibiotics.

For catheter-related bacteremia, the catheter should be removed aseptically with a sterile forceps after local antisepsis of the insertion site with a swab soaked with 70% alcohol. A blood sample can be taken at the same time for culture. After removal of the catheter, the distal segment should be cut off and placed in a sterile, dry tube to be sent to the laboratory.

87.1.7.2.2.1

Liquid Media

Commercial multipurpose nutrient broth media, such as tryptic soy broth, trypticase soy broth, Columbia broth, and brain-heart infusion broth (Difco Laboratories, Detroit, Mich.) are all suitable for *qualitative* recovery of aerobic and anaerobic bacteria. Thioglycolate and thiol broth (Difco), intended for anaerobic blood culture only, should not be relied on for multipurpose cultures because aerobic (especially *Pseudomonas*) and facultative anaerobic bacteria are not reliably isolated. Most liquid media are bottled under vacuum with carbon dioxide added and usually are suitable to support the growth of clinically important anaerobes. The use of special anaerobic broth is rarely necessary.

Most commercial blood culture media contain 0.025% to 0.05% sodium polyanethol sulfonate (SPS), a polyanionic anticoagulant that also inhibits complement and lysozyme activity, interferes with phagocytosis, and inactivates therapeutic serum levels of aminoglycosides. Dilution of blood with liquid media is essential to neutralize serum and cellular antimicrobial properties. Even at 1:10 dilutions, serum may be bactericidal to coliforms, an effect that is counteracted by the addition of SPS.

848

However, SPS is inhibitory to mycoplasmas and should not be in media intended for their isolation.

849

Dilution of blood in culture broth usually lowers therapeutic concentrations of antibiotics to

Infectious Diseases of the Dog and Cat, 3rd Edition

noninhibitory levels. When high levels of lactam antibiotics are present in blood before culture, β -lactamase can be added to the culture media. Para-amino benzoic acid, available in some commercial blood culture media, competitively antagonizes the actions of sulfonamides and increases the blood culture yields from patients receiving sulfonamide drugs.

Table 87-4 Commercially Available Blood Culture Systems

INDICATED USE	COLLECTION MEDIA	MANUFACTURER
Aerobic and anaerobic	BBL SEPTI-CHEK with trypticase soy broth	Becton Dickinson Microbiology Systems, Franklin Lakes, N.J.
Pediatric patients	BBL SEPTI-CHEK with brain heart infusion	Becton Dickinson Microbiology Systems, Franklin Lakes, N.J.
Antimicrobial therapy	BBL SEPTI-CHEK with resins culture bottle	Becton Dickinson Microbiology Systems, Franklin Lakes, N.J.
Centrifugation lysis	ISOLATOR SYSTEM	Wampole Laboratories, Princeton, N.J.

Bacterial growth can be suppressed in blood culture vials containing blood from patients receiving antibiotics. Anionic and cationic resins have been incorporated into blood collection vials for antibiotic removal before broth culture. The effectiveness of removal varies.^{47,161}

In the laboratory, culture bottles are examined daily for evidence of microbial growth, which includes turbidity, hemolysis, gas production, or colony formation. In aerobic culturing, the broth should appear turbid within 24 hours of inoculation. In 95% of all instances wherein bacteria are isolated from blood culture media, isolation occurs within 7 days. Longer incubation may be necessary for specimens from patients who previously received antibiotic therapy or those with endocarditis caused by fastidious organisms such as *Bartonella* (see [Chapter 54](#)). In addition to visual inspection, routine (blind) subcultures onto solid culture media usually are performed for antimicrobial susceptibility testing between 7 and 14 hours after blood collection and again after 48 hours of incubation.

87.1.7.2.2.2

Lysis-Centrifugation

Although broth-based blood culture methods are sensitive, they provide no quantitative information about the number of microorganisms present. In contrast, inoculation of blood on solid agar allows for colony enumeration. Direct plating of freeze-thawed specimens of anticoagulated blood improves the sensitivity by freezing intracellular and phagocytized organisms. Only small volumes (1 ml) of blood can be directly plated. Lysis-centrifugation methods, with commercially prepared tubes (e.g., Wampole Isolator tubes, Carter-Wallace Inc., Cranbury, N.J.), allow for lysis of cellular elements followed by microbial concentration through centrifugation. These methods may also shorten the time to isolation of bloodborne organisms, but they are associated with an increased risk of bacterial contamination. Lysis methods also enhance the ability to recover intracellular organisms such as *Brucella*, *Mycobacterium*, *Histoplasma*, and *Bartonella*.

87.1.7.2.3

Interpretation of Results

It may be difficult to determine whether a positive culture result signifies actual bacteremia or simply indicates contamination. Contamination is best distinguished from bacteremia if multiple blood specimens are cultured. Knowledge of the normal canine and feline bacterial skin flora is helpful in interpreting blood culture results. Coagulase-negative staphylococci, β -hemolytic streptococci, *Micrococcus* species, and *Acinetobacter* species are normal skin commensals on the dog. *S. intermedius* is normally present on

Infectious Diseases of the Dog and Cat, 3rd Edition

canine hair, whereas *Micrococcus* organisms, β -hemolytic streptococci, and *Acinetobacter* species are normally present on feline skin. Recovery of diphtheroids, *Bacillus* species, and coagulase-negative staphylococci usually signifies contamination unless they are isolated from multiple specimens. Nonhemolytic streptococci and β -hemolytic streptococci from single cultures are also of uncertain significance. In all cases the significance of positive blood culture results should be interpreted in light of the patient's clinical status and the potential sources for bacteremia. Because of the high prevalence of *Bartonella* organisms in the blood of clinically healthy cats, the only way to confirm the endocarditis is by using immunologic stains or performing a postmortem culture of valvular tissues.¹⁹

87.1.7.3

Urine Culture

Culture of urine has been commonly used to detect organisms associated with bacteremia and diskospondylitis. The presumption has been that these positive culture results represent the source of infection. In contrast, bacteruria is likely a consequence of bloodborne bacteria reaching the kidney and being filtered by the glomerulus and from damage entering the renal tubule and urine. Bacteria are found in urine within minutes of IV infusion. Bacteremic animals with positive results for urine culture usually have no lower urinary tract signs, suggesting that the infection did not come from ascending infection.

87.1.8

Therapy

IV access lines are essential to the management of the bacteremic patient, not only for fluid and antibiotic administration but also for blood sampling. A urinary catheter is helpful for monitoring urine output in patients at risk for septic shock. Core and toe-web temperature readings should be monitored to assess peripheral blood flow and vasoconstriction.

Blood cultures and bacterial antibiotic susceptibility tests are essential for the proper treatment of bacteremia. It is important to choose a bactericidal antibiotic that has good tissue penetration and to use high (when permissible) IV doses for the first 5 to 10 days. Antimicrobial therapy should then be continued subcutaneously (SC) or orally for at least 3 weeks after IV administration. Bacteremia in debilitated patients or those with deep-seated or long-standing infections should be treated with IV and SC antibiotics for several weeks.

Despite the primary concern with the infectious agent, concomitant disorders should not be overlooked. In fact, the severity of comorbid disease is as important in treatment outcome as the invading organism itself. The ability to treat or control concomitant disease effectively may exert a more favorable influence on outcome than the chosen antibiotic regimen. Sources of infection should be identified and managed. Urinary and IV catheters should be removed when sepsis is suspected, and potential sites of infection should be drained, debrided, and otherwise treated.

In critically ill patients, antibiotic therapy should be instituted before the return of blood culture results, although this approach has inherent shortcomings, such as selection for microbial resistance. Subsequent therapeutic adjustments may be made on the basis of culture results. If administered at all, bacteriostatic antibiotics should conclude rather than initiate treatment.

849

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 87-5 Choice of Antimicrobial Therapy for Bacteremia or Endocarditis

ORGANISM	CONDITION OR SITE	FIRST CHOICE ^a	SECOND CHOICE ^a
<i>Staphylococcus intermedius</i>	Pyoderma	1cep, 2cep, brp	amg, ticar-clav, vanc, quin
<i>Escherichia coli</i>	Bowel compromise, peritonitis	amg, tms, quin	3cep, ticar-clav
β -hemolytic <i>Streptococcus</i>	Genital, navel, and skin infections	pen, amp, 1cep, amp-clav	2cep, clin, ticar, ticar-clav
<i>Bartonella</i> spp.	Vector-transmitted infections	doxy	quin, rif, azith
<i>Pseudomonas</i> spp.	Chronic wounds, leukopenia, burns, tracheostomy	amg, ^b quin	carb, ticar, 3cep ^c
Anaerobes	Abscesses, oral cavity lesions, bowel compromise, body cavity exudates	pen, met, clin	amp-clav, chlor

- a amg, Aminoglycoside; amp, ampicillin, amoxicillin; amp-clav, ampicillin-clavulanate, amoxicillin-clavulanate; azith, azithromycin; brp, β -lactamase-resistant penicillin; carb, carbenicillin; 1cep, first-generation cephalosporins; 2cep, second-generation cephalosporins; 3cep, third-generation cephalosporins; chlor, chloramphenicol; clin, clindamycin; doxy, doxycycline; ery, erythromycin; met, metronidazole; pen, penicillin; quin, fluoroquinolone; rif, rifampin; ticar, ticarcillin; ticar-clav, ticarcillin-clavulanate; tms, trimethoprim-sulfonamide; vanc, vancomycin.
- b May combine aminoglycoside with ticarcillin or carbenicillin for maximum efficacy.
- c Only certain cephalosporins in this group, such as ceftazidime, are effective against *Pseudomonas* species.

On the basis of predisposing infections or other factors, time course of infection, and known patterns of associated bacteria and their antimicrobial susceptibilities, the antibiotics most likely to be effective can be predicted (Table 87-5). This knowledge is important when blood culture results are negative and in critically ill patients before the return of blood culture results. Subsequently, appropriate adjustments in therapy may be necessary. In dogs and cats, staphylococci and streptococci are the most commonly encountered gram-positive pathogens, whereas the Enterobacteriaceae, such as *E. coli* and *Klebsiella*, and *Proteus*, and *Pseudomonas* organisms, are the most common gram-negative offenders.

Bactericidal rather than bacteriostatic antibiotics have been shown to result in higher concentrations of circulating endotoxin because bacteria die quickly in animals with experimental gram-negative bacteremia. However, in clinical practice, this does not translate into a clinically relevant syndrome in dogs.

Patients with bacteremia must be closely monitored (see also Endotoxemia, Chapter 38). Although clinical and hematologic evidence of improvement often occurs initially, relapse is common. Acquired antimicrobial resistance may develop rapidly. Clinical signs of resurging bacteremia include fever, which may be transient, deterioration of mucous membrane color, increasing capillary refill time, increasing rectal to toe-web temperature differential, decreasing blood pressure, and tachycardia. Detection of these signs of early deterioration indicates a need for intensification of therapy, including adjustments of antibiotic administration. It also should prompt a search for a persistent focus of infection (e.g., abscess, catheter) that may be treatable.

87.1.8.1 Antibiotics

For additional information on specific drugs discussed next, see Chapter 34 and the Drug Formulary, Appendix 8. The penicillin family of antibiotics includes the narrow-spectrum penicillin G; intermediate-spectrum ampicillin; and the extended-spectrum carbenicillin, ticarcillin, ticarcillin-clavulanate,

Infectious Diseases of the Dog and Cat, 3rd Edition

and piperacillin (Table 87-6). A common misconception is that ampicillin is a broad-spectrum antibiotic. Most coagulase-positive staphylococcal isolates are resistant to penicillin and ampicillin, and these are poor empiric choices for serious and life-threatening infections. Penicillin G should be restricted to streptococcal and some anaerobic infections.

The extended-spectrum penicillins—carbenicillin, ticarcillin, ticarcillin-clavulanate, and piperacillin—are useful agents when antibiogram results indicate their effect against a highly resistant microbe. These antibiotics have a spectrum that includes that of ampicillin plus extended gram-negative activity, including activity against *Pseudomonas* and *Proteus* species. Ticarcillin is more potent than carbenicillin, and piperacillin is active against many anaerobes. With the exception of ticarcillin-clavulanate, these penicillins lack resistance to β -lactamase produced by staphylococci.

The first-generation cephalosporins are useful in the treatment of potentially life-threatening infections because of their activity against *Staphylococcus* and *Streptococcus* species, as well as a greater spectrum of activity than ampicillin against gram-negative bacteria. These antibiotics include cephalothin, cefazolin, and cephapirin but like many antibiotics are not effective against enterococci and *Pseudomonas* species and are susceptible to the β -lactamase activity of *Bacteroides fragilis*. Second- and third-generation cephalosporins (such as cefoxitin and cefotaxime, respectively) are generally effective against gram-negative bacteria that are resistant to the first-generation family. Cefoxitin is effective for resistant anaerobes, and cefotaxime is effective for bacterial infections involving the central nervous system (CNS) and gram-negative infections with demonstrated resistance to aminoglycoside and fluoroquinolone antibiotics. Cephalosporins are also useful when the nephrotoxic aminoglycosides are contraindicated. The third-generation cephalosporins, with the exception of ceftazidime, are generally ineffective against *Pseudomonas*. Cost is often a factor limiting the administration of the third-generation family.

Ceftiofur is a near third-generation cephalosporin that has an antibacterial spectrum similar to that of cefotaxime, but it has a longer half-life^{28,175} and is less expensive (see Drug Formulary, Appendix 8). Ceftiofur is variably effective against *S. intermedius* and ineffective against *Pseudomonas* and *Bordetella* species. In addition, its anaerobic spectrum is narrow, and inadequate data have been collected concerning its effect on streptococcal species. In vitro activity against *Fusobacterium* is generally good, but it is poor against *Bacteroides* species.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 87-6 Antimicrobial Dosages for Bacteremia with or without Endocarditis in Dogs and Cats

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS) ^c
Penicillin	B	20–40 × 10 ³ U/kg	IV	4–6	7–14
Imipenem	B	10 mg/kg	IV	8	7–14
Carbenicillin	B	40–50 mg/kg	IV	6–8	7–14
Piperacillin	B	30 mg/kg	IV	6	7–14
Ampicillin	B	20–40 mg/kg	IV, SC	6–8	7–14
Amoxicillin-clavulanate		20 mg/kg	PO	12	Follow-up
Ticarcillin	D	30–50 mg/kg	IV, SC	6–8	7–14
Ticarcillin-clavulanate	D	20–50 mg/kg	IV	6–8	7–14
	C	40 mg/kg	IV	6	7–14
Cefazolin (first generation)	B	20–30 mg/kg	IV, SC	8	7–14
Cefapirin (first generation)	B	15–30 mg/kg	IV, SC	8	7–14
Cefoxitin (second generation)	B	20 mg/kg	IV	8	7–14
Cefuroxime (second generation)		15 mg/kg		8	
Cefotaxime (third generation)	B	20–80 mg/kg	IV	8	7–14
Ceftiofur (third generation)		2.2–4.4 mg/kg	SC	12	Follow-up
Gentamicin ^d	B	4–6 mg/kg	IV	24	7–14
Amikacin ^d	B	7–10 mg/kg	IV	24	7–14
Trimethoprim-sulfonamide	D	15 mg/kg	IV	8–12	7–14
	B	30 mg/kg	SC, PO	12–24	Follow-up
Metronidazole	B	8–15 mg/kg	IV, PO	8	5–7
Clindamycin	B	10 mg/kg	IV	8–12	7–14
	B	10–11 mg/kg	PO	12	Follow-up
Chloramphenicol	D	15–25 mg/kg	IV	6–8	7–14
	C	10–15 mg/kg	IV	6–8	4–7
Ciprofloxacin ^e	B	10–15 mg/kg	PO	12	14
Enrofloxacin ^e	D	5–7 mg/kg	IV	24	4–7
	D	5–15 mg/kg	PO	24	Follow-up
	C	5 mg/kg	PO	24	Follow-up
Azithromycin	B	5–10 mg/kg	PO	12	Follow-up

B, Dog and cat; D, dog; C, cat; IV, intravenous; SC, subcutaneous; PO, by mouth.

- a For additional information about the drugs listed, see [Appendix 8](#).
- b Dose per administration at specified interval.
- c After the animal is stabilized, subcutaneous or oral therapy should be continued when possible for periods of 3 to 6 additional weeks (see text).
- d Renal function and urinalysis must be closely monitored for signs of nephrotoxicity at this dosage and frequency. Reduce dose to 1–2 mg/kg every 8 hr if renal compromise is anticipated.
- e For dosages of other quinolones, see [Chapter 34](#) and the Drug Formulary, [Appendix 8](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

Aminoglycosides are highly effective against *Staphylococcus* and many gram-negative bacteria. They are not effective against anaerobes and many streptococci and have limited activity in necrotic tissue and acid pH milieu. The primary limitation of gentamicin, amikacin, and tobramycin is nephrotoxicity, therefore other agents are required for extended antibiotic therapy. The incidence of gentamicin-associated acute renal failure has increased markedly since 3-times-daily administration has been used for systemic infections. Dehydration and sodium and potassium depletion predispose patients to nephrotoxicosis, as does administration for longer than 5 to 7 days. Aminoglycosides demonstrate more rapid bactericidal action for severe sepsis than do the penicillins and cephalosporins. They also invoke postantibacterial effects (i.e., bactericidal action after the serum concentration has decreased below the minimum inhibitory concentration).

Fluoroquinolones are often a good choice instead of the third-generation cephalosporins for gram-negative bacteremias not involving the CNS. The fluoroquinolones are very useful for the treatment of bacteremia, having bactericidal action at achievable concentrations. Like the aminoglycosides, they exhibit postantibacterial effects. They are effective against *Pseudomonas* and Enterobacteriaceae but are generally ineffective against anaerobes and enterococci. Efficacy against streptococci is limited. Ciprofloxacin is approved for IV administration in humans, and enrofloxacin solution has been diluted and given slowly IV to dogs. Enrofloxacin should not be injected into sodium containing fluid bags, IV lines, or IV catheters. A combination of enrofloxacin plus clindamycin may be as effective as and less toxic than ampicillin, gentamicin, and metronidazole for life-threatening sepsis caused by unknown bacteria. However, clindamycin is a bacteriostatic antibiotic.

In general, first-generation cephalosporins and β -lactamase resistant penicillins are effective in vitro against gram-positive bacteria, whereas aminoglycosides, first-generation cephalosporins, and fluoroquinolones are effective against gram-negative agents. Thus a combination of an aminoglycoside, such as gentamicin or amikacin, with ampicillin, ticarcillin, piperacillin, or first-generation cephalosporin is a good choice for immediate treatment of life-threatening bacteremia in the absence of laboratory identification of an organism or its antibiotic susceptibility. The combination of first-generation cephalosporins and aminoglycosides, however, is not very effective against anaerobic bacteria. When an anaerobic infection is suspected, clindamycin, metronidazole, or cefoxitin is recommended. Despite in vitro susceptibility testing, trimethoprim-sulfonamide is a poor choice for anaerobic infections. Penicillin formerly was the preferred drug for anaerobic bacteremia. However, those infections caused by *Bacteroides* species are becoming increasingly resistant to penicillins and first-generation cephalosporins.

A highly effective triple therapy for dogs with sepsis, particularly for intraabdominal infections, is a β -lactam drug (ampicillin, ticarcillin, piperacillin, or first-generation cephalosporin) with an aminoglycoside and metronidazole. The combination of enrofloxacin and clindamycin is also effective and suggested when renal function is impaired.⁵⁶ Another nonaminoglycoside regimen is referred to as the *double β -lactam regimen*.⁸⁸ The regimen may consist of the combination of either ampicillin plus the third-generation cephalosporin ceftazidime or a second-generation plus a third-generation cephalosporin.

The advent of β -lactam antibiotics with broad-spectrum activity that achieve high serum bactericidal levels has made monotherapy an option for empirical treatment. The third-generation and “fourth-generation” cephalosporins and the carbapenems are candidates. Although ceftazidime has been used, it may be ineffective against some gram-negative and anaerobic isolates. Cefepime overcomes some of these limitations. Imipenem has the broadest spectrum of activity of any antibiotic and is effective against many anaerobes.

Infectious Diseases of the Dog and Cat, 3rd Edition

For cats, an antimicrobial spectrum encompassing gram-negative and anaerobic bacteria, such as *Bacteroides* species and *Propionibacterium* spp., is recommended. Piperacillin or clindamycin plus a first-generation cephalosporin are recommended.

To ensure adequate serum antibiotic concentrations, the upper limit of the usual dosage range of antimicrobial drugs is recommended (see Table 87-6). Parenteral treatment is desirable for 5 to 10 days, although this approach is not always practical. SC administration of ampicillin, cephalothin, ceftiofur, or clindamycin may be substituted for the IV route after 5 to 10 days of IV treatment. Except in animals with endocarditis or other internal sources of infection, such as bone, lung, and prostate gland, most properly treated bacteremic episodes are short lived. Ideally, oral antibiotic therapy should be instituted only after 5 days of IV therapy and even then only after clinical and hematologic normalization have been documented.

Combination antibiotic therapy is often provided for gram-negative infections because they may be associated with rapid progression and high mortality. Although clinical evidence supports the use of carbenicillin or ticarcillin with aminoglycosides for *Pseudomonas* and *Proteus*, these drugs must be given separately because of known in vitro incompatibilities. Amikacin, unlike tobramycin and gentamicin, is not inactivated in vitro by penicillins. Administration of some antibiotics such as aminoglycosides, cephalosporins, metronidazole, and enrofloxacin is recommended by infusion in a compatible solution over 30 to 60 minutes.

87.1.8.2 The Febrile Granulocytopenic Patient

The risk of bacterial infection increases substantially when the neutrophil count is less than 500/ μ l, although monocytes may compensate for neutropenia to an extent.^{17,81} The lungs, oropharynx, urinary tract, and gut are frequent sources of infections in neutropenic patients. Some of the signs of infection are diminished in neutropenic patients because the cells that mediate the inflammatory response are absent. This may manifest as reduced pulmonary infiltrates with pneumonia, relatively nonpurulent exudates, and absence of pyuria with urinary tract infections. Furthermore, localized infections can quickly disseminate. In fact, patients with signs consistent with sepsis and neutropenia can present a diagnostic challenge as the clinician attempts to determine whether the neutropenia antedated the sepsis or is a response to overwhelming inflammation. An increase in band neutrophils that is higher than 20%, called *bandemia*, suggests appropriate granulocytopoietic activity.^{17,81} Sepsis, especially gram-negative, causes accelerated platelet destruction, possibly as a result of binding of bacterial immune complexes to the platelet.⁹⁹

When a new fever develops in a neutropenic patient, an empirical bactericidal, broad-spectrum antibiotic regimen should be quickly implemented as soon as blood culture specimens are obtained. Bacteremia in neutropenic patients can disseminate quickly and may prove rapidly lethal.⁹⁷ The majority of these patients do not have an obvious source of infection. Blood cultures (preferably three sets) should be performed. If a catheter is in place, a culture should be obtained through it if possible, the catheter removed, and the tip cultured. Gram-positive bacteria, especially staphylococci, are the most common causes of catheter-related infections.¹³⁶ Even subtle indications of inflammation must be considered as potential sites of infection in the face of granulocytopenia.

The appropriate role for quinolones in neutropenic patients has yet to be fully defined.⁸⁸ Because of their relatively poor activity against some gram-positive microbes, they should not be used alone for empirical therapy.

Infectious Diseases of the Dog and Cat, 3rd Edition

The combination of β -lactams with β -lactamase inhibitors (clavulanate and sulbactam) has produced powerful antibiotics such as ticarcillin plus clavulanate, which can be combined with an aminoglycoside for the empiric treatment of neutropenic, febrile patients.⁸⁸

87.1.9 Prognosis

Many factors influence the natural course of bacteremia, including adequacy of therapy, severity of bacteremia, source of infection, delay before treatment, and presence of concomitant disorders, as well as the age and prior health status of the patient. The prognosis is better when abscesses, cellulitis, skin and wound infections are the sources of bacteremia than when gram-negative bacteria and endotoxemia are present. Mortality of bacteremic dogs with hypoalbuminemia, high serum ALP, and hypoglycemia is significantly higher than that of dogs without or with only one of these abnormalities.³⁴ Late relapse and death have occurred in some dogs when bacteriostatic antibiotics were chosen for treatment. Premature termination of antibiotic therapy may also result in relapse and death in bacteremic dogs, particularly those associated with antimicrobial-restricted sites, pneumonia, abscesses, and cellulitis. Relapse after IV antibiotic therapy that was maintained for only 1 to 2 days followed by oral antibiotics is common. Oral antibiotic therapy alone is dangerous when relied on either as initial treatment or after only a few days of IV antibiotic treatment.

The indiscriminate use of glucocorticoids (even with antibiotics as prophylaxis) is detrimental to bacteremic patients. One reason that glucocorticoids are administered to bacteremic dogs is the similarity in clinical manifestations of bacteremia and immune-mediated diseases.

Aspirin has been shown to reduce the virulence of staphylococcal endocarditis in people.⁸³ *S. aureus*, a nonmotile organism, has the affinity to bind substrates such as damaged heart valvular surfaces. The interaction of platelets and proteins facilitates this binding. Acetylsalicylic acid has been used in vitro and in vivo in experimental infections to reduce bacterial vegetations. Clinical studies are still needed, but the possibility of reducing bacterial adherence may be important as a prevention or therapy of endocarditis along with antimicrobial drugs. 852 853

Prophylactic antibiotic treatment usually is ineffective unless it is used when surgical or dental procedures (see [Chapters 55](#) and [89](#)) are performed or when the type of bacteria and its susceptibility are known. Bacterial resistance to frequently administered antibiotics is common. Thus effective prophylactic antibiotic therapy may require combinations of antibiotics. Even then, the tendency to select for resistant bacteria increases. In human medicine, antimicrobial treatment is recommended as a prophylaxis for endocarditis in patients undergoing dental procedures with underlying cardiac valvular defects.⁷⁷ Use of bactericidal antibiotics such as amoxicillin within 1 hour before the procedure is recommended (see Oral Infections, [Chapter 89](#)).

87.2 SEPSIS

Sepsis is defined as the systemic inflammatory response syndrome that occurs during infection (see also [Chapter 38](#)).²¹ Sepsis occurs when bacteria proliferate at a nidus of infection and either invade the circulation or remain local and release inflammatory mediators such as exotoxins and teichoic acid from staphylococci and endotoxins from gram-negative bacteria. Endotoxin produced by gram-negative bacteria is composed of lipid, polysaccharide, and protein, and it is the lipid portion that is responsible for toxicity. These microbe-derived products can stimulate the release of endogenous host-derived factors from plasma protein precursors, monocyte macrophages, endothelial cells, and neutrophils.^{68,102,103,184} It has been thought that the theory was that sepsis represented an

Infectious Diseases of the Dog and Cat, 3rd Edition

uncontrolled inflammatory response.¹⁸⁰ However, sepsis not only is caused by an immune system gone awry but also may be associated with an immune system that becomes compromised and unable to eradicate pathogens as sepsis worsens. Bacterial sepsis is associated with hepatic, intestinal, renal, pulmonary, and cardiovascular dysfunction; hypothermia; oliguria; respiratory failure; and lactic acidosis. When sepsis results in systemic arterial hypotension, the syndrome is referred to as *septic shock*. The cause of death in septic patients is not clearly defined. Potential causes include refractory shock, respiratory distress syndrome, renal failure, and hepatic failure. Although myocardial depression occurs, cardiac output is usually preserved because of cardiac dilation and sinus tachycardia.¹⁴⁹

87.2.1 Incidence

Sepsis in dogs and cats is common. Advances in veterinary care have contributed to the incidence through the increase use of cytotoxic and immunosuppressive drug treatments, invasive procedures, extensive surgery, and the widespread use of IV catheters.

87.2.2 Bacteria

Gram-positive and gram-negative bacteria can cause septic shock. Staphylococci, streptococci, and *E. coli* are probably the most commonly involved microbes. Rickettsemia can probably produce a similar syndrome. Any infectious site can lead to sepsis, and frequent causes are abscesses, deep pyodermas, infected wounds, cellulitis, prostate infections, pneumonia, peritonitis, and infected surgery sites. Sites of infection are more difficult to identify in neutropenic and immunosuppressed patients because inapparent infections can lead to blood stream incursion. Not only are nosocomial infections common in intensive care facilities because of the concentration of sick patients and bacterial contamination but also because bacteria causing nosocomial infections are often antibiotic resistant.

87.2.3 Pathogenesis

Numerous factors can initiate the pathway leading to sepsis. Exotoxins are produced by staphylococci, *Pseudomonas aeruginosa*, and others. Structural components of microbes such as teichoic acid antigens from staphylococci, the polysaccharide capsule of some streptococci, and the lipopolysaccharide (LPS) associated with the cell membrane of gram-negative organisms can initiate the toxic septic cascade.^{68,102,104,184} LPS can be bound by a binding protein, which stimulates monocytes and macrophages to produce cytokines, such as TNF and ILs, that play a major role in the response to infection or endotoxin. Endotoxins interact with macrophages, neutrophils, and vascular endothelia by binding to cell receptors, causing a release of mediators of sepsis, the magnitude of which is directly related to the endotoxin concentration.^{23,133} Endotoxin can activate the complement cascade, which can lead to vasodilation, increased vascular permeability, platelet aggregation and activation, and neutrophil aggregation. Subsequently, increased bradykinin levels also contribute to vasodilation and hypotension. Some cytokines cause the release of arachidonic acid metabolites from endothelial cells and leukocytes, which can cause vasodilation, platelet aggregation, and neutrophil activation. LPS activation of factor XII leads to extrinsic and intrinsic coagulation pathway activation, which can lead to DIC.

Numerous trials of antiinflammatory treatments using glucocorticoids, antiendotoxin antibodies, TNF antagonists, IL-1-receptor antagonists, and others have failed to demonstrate a positive influence on survival and have thus called into question whether uncontrolled inflammation exerts a negative influence on

Infectious Diseases of the Dog and Cat, 3rd Edition

survival.^{69,134,180,185} The animal studies suggesting sepsis is attributable to hyperinflammation used large doses of endotoxin or bacteria, which invoked levels of circulating cytokines, such as TNF, that are much higher than levels encountered clinically.^{52,139,144,159,178} Initially, sepsis is associated with increases in inflammatory mediators; but as sepsis persists, a shift toward an antiinflammatory immunosuppressive state occurs.^{108,140}

Macrophages and activated CD4 T cells can secrete inflammatory cytokines such as TNF- α , interferon (IFN)- α , and IL-2.¹⁴⁵ Other mediators, arising principally from neutrophils, platelets, and vascular endothelia, include leukotrienes, prostaglandins, and platelet-activating factors.^{23,153,169} All of these mediators interact with inflammatory cells, vascular endothelia, and platelets in a complex way to modulates immune function.²³ Cytokines such as IL-4 and IL-10 are also secreted by CD4 T cells but contribute to antiinflammatory immunosuppression.¹⁴⁵

Inflammatory mediators exert a negative impact on cardiovascular, pulmonary, GI, vascular, and hematologic integrity. TNF has been associated with hypotension and respiratory dysfunction. IL-1 causes fever, neutropenia followed by neutrophilia, and pulmonary vascular sequestration of granulocytes.¹⁶ Platelet-activating factor causes platelet activation and aggregation; neutrophil activation, aggregation, and chemotaxis; increased vascular permeability; and GI ulceration. Thromboxane, a product of the prostaglandin cascade, is associated with vasoconstriction and platelet aggregation.^{23,143} Leukotrienes are chemotactic and increase vascular permeability.¹⁵³ Cytokines and other inflammatory mediators also invoke secondary mediators of sepsis such as vasopressin, angiotensin II, catecholamines, histamine, and serotonin.⁸⁰ Organ failure associated with septic shock is the result of hypoxia, free-radical and lysozyme damage, thrombosis, and necrosis.^{39,80,134,180,185}

It was believed that death of many cell types occurred in septic patients. However, this has been shown to be false. The two cell types that do undergo accelerated death in septic patients are lymphocytes and GI cells.

853

Sepsis probably accelerates apoptosis of these cell types, which normally undergo a rapid turnover rate via that process. Drugs that block apoptosis of lymphocytes and GI cells have been shown to improve survival in animal models,^{86,141} although no such drugs are currently clinically available.

854

87.2.4

Clinical Manifestations

Patients may have signs related to a primary focus of infection. A careful history, physical examination, imaging studies, and laboratory data often permit identification of the infection focus. Debilitated, immunosuppressed, and neutropenic patients are more challenging in this regard. Although the exception to the rule, patients with sepsis, particularly debilitated, uremic, or immunosuppressed patients, may not develop a fever. This lack of an acute-phase response may reflect advanced sepsis immunosuppression and may be associated with a worse prognosis. However, in most patients one or more signs of systemic inflammatory response are present. These include fever, tachycardia, tachypnea, and an inflammatory leukogram. Septic shock is characterized by hypotension, lactic acidemia, and progressive organ dysfunction. Multiple organ dysfunction syndrome includes tissue hypoperfusion (oliguria, lactic acidosis, cool extremities), renal failure (oliguria), hepatic failure (hyperbilirubinemia), and respiratory distress syndrome. DIC and respiratory distress syndrome are terminal events.^{68,103,104,184}

Infectious Diseases of the Dog and Cat, 3rd Edition

87.2.5 Therapy

At least three approaches to treating sepsis exist. First, a nidus of infection, if present and identified, should be treated by surgery, offending foreign bodies or catheters removed, and high-dose, IV bactericidal antibiotics administered (see Bacteremia Therapy and Therapy, [Chapters 37](#) and [38](#)). Second, cardiovascular, respiratory, and organ dysfunction physiology may be reversible. Third, it may be possible to manipulate the toxic mediators of sepsis.^{68,103,104,184}

Early aggressive fluid therapy to maintain cardiac output is vital to survival. Reversible septic shock in patients with adequate intravascular volume is often associated with brick-red mucous membranes, tachycardia, high cardiac output, and normal or low blood pressure. Hypodynamic shock occurs in patients with decreased intravascular fluid volume, and affected individuals tend to be pale, cold, tachycardic, and hypotensive. Rescue with rapid, aggressive fluid therapy is possible, unless irreversible shock (elevated blood lactate concentration, hepatic failure, oliguria, hypotension, cold extremities) has developed. Patients with irreversible shock cannot be stabilized by fluid therapy because of massive fluid leakage through permeable endothelium, vasodilation, and possibly myocardial failure.⁴⁵ Rapid restoration of organ perfusion and tissue oxygen delivery are essential for the management of the patient in septic shock (see also Endotoxemia, [Chapter 38](#)). Rapid fluid therapy (crystalloid fluid, colloid-crystalloid mixture, or hypertonic solution⁷) is required to raise the central venous pressure within 15 minutes. Aggressive volume resuscitation is initiated at 10 ml/kg/hour for 1 to 2 hours. Colloid is recommended if the serum albumin is less than 2 g/dl or crystalloid in all others. High volumes of fluids are required for the treatment of septic shock, and crystalloid fluid volumes can be decreased by the addition of a colloid. Hetastarch 120 or dextran 70 is usually administered for this purpose. At high dosages, both can prolong clotting times by decreasing platelet function and fibrin clot strength, though this is rarely clinically significant. Another treatment for cardiovascular support is the administration of hypertonic solutions. Hypertonic saline and glucose-insulin-potassium solutions are the two most often administered hypertonic solutions ([Table 87-7](#)). Glucose-insulin-potassium improves cardiovascular function and helps prevent hypoglycemia. Insulin therapy may exert a favorable influence on survival.¹⁷⁸ After the hypertonic solutions are administered, crystalloid administration is continued. Serum albumin, potassium, and erythrocyte concentrations decrease after aggressive fluid therapy, and peripheral edema is a common sequela.

Table 87-7 Fluid Therapy in Septic Shock

FLUID	VOLUME	COMMENTS
Hypertonic saline	4 ml/kg	Once
Glucose-insulin potassium	10% volume bolus, remainder infused over 4–5 hr (1g glucose, 1U insulin, 0.25 mEq K/kg in 250 ml of lactated Ringer's solution or 0.45% saline-5% glucose)	May be repeated as needed
Colloids		
Hetastarch 120, Dextran 70	Maximum: 20 ml/kg for first 24 hr, then 10 ml/kg/24 hr	Constant rate infusion, or intermittent infusions over 4–6 hr

Rapid-acting, powerful inotropes, such as dopamine and dobutamine (3 to 5 µg/kg/min) are indicated if fluid therapy fails to establish or maintain adequate tissue oxygen perfusion. If hypotension persists, a dobutamine infusion rate is increased to as high as 20 µg/kg/min. Monitoring of heart rate and rhythm, core-to-toe-web temperature differential, central venous pressure, and urine output is important. The mean systolic blood pressure should be improved and be greater than 75 mm Hg.

Infectious Diseases of the Dog and Cat, 3rd Edition

DIC often develops during sepsis. Anti-DIC prophylaxis is recommended if the clotting time and platelet count are mildly deranged. Synthetic colloids can help, but if crystalloids only are administered, low-dose heparin (75 to 100 U/kg SC every 8 hours) is suggested to inhibit coagulation and maintain blood flow in the microcirculation.¹⁶⁹ Plasma transfusion provides clotting factors and antithrombin III, which helps prevent and control DIC. Acute and end-stage DIC is more difficult to treat, requiring more intense heparinization along with coagulation factor replacement. Anemic patients should receive whole blood or packed erythrocyte transfusions.

A balance between oxygen consumption and oxygen delivery should be maintained. Adequate oxygenation is critical and supplemental oxygen should be a routine component of treatment. Oxygen therapy can be administered by a cage, a mask, or an intranasal catheter.

In the future, treatments that inhibit or potentiate the action of mediators may become useful. High-dose glucocorticoid administration can inhibit mediator release in some animal models of endotoxemia, but in clinical practice the use of these agents at supraphysiologic dosages is detrimental.⁴⁸ Because severely septic patients may have relative adrenal insufficiency, physiologic dosages are beneficial.⁵

Recombinant activated protein C, an anticoagulant, may be a useful treatment. It inactivates factors Va and VIIIa, thereby preventing thrombin formation.¹¹⁷ Inhibition of thrombin formation reduces inflammation by inhibiting platelet activation, neutrophil recruitment, and mast cell degranulation. Activated protein C prevents inflammation by blocking not only the production of cytokines by monocytes but also cell adhesion. Hemorrhage is a potential adverse effect of activated protein C.

854

855

Plasma may be valuable in the treatment of sepsis. Plasma and polyvalent immunoglobulin infusion may provide protective antibodies against virulent proteins and superantigens. Enhancement of neutralization of a wide variety of superantigens and opsonization of bacteria may be provided. Plasma protease inhibitors, α -2-macroglobulin and α -1-protease inhibitor, are useful in patients with pancreatitis-related sepsis because they bind with circulating digestive enzymes.

Pentoxifylline (10 mg/kg, given every 8 hours) and its metabolites improve blood flow and microcirculation tissue oxygen delivery by decreasing blood viscosity and increasing the flexibility of erythrocytes and leukocytes. Furthermore, neutrophil adhesion and activation may be decreased. Another potential benefit of pentoxifylline is its ability to scavenge oxygen-free radicals. Pentoxifylline also inhibits the complement cascade and cytokine production.

Pentoxifylline serum concentrations are increased by concomitant administration of theophylline, cimetidine, and fluoroquinolones. Renal impairment may also lead to toxicity by reducing pentoxifylline clearance. Toxic effects include nervousness, tremors, and seizures. Adverse effects of pentoxifylline that may be encountered at therapeutic serum concentrations include dyspnea, epistaxis, nasal congestion, and angioedema. Bleeding tendencies are enhanced by pentoxifylline administration.

In patients with a hyperinflammatory response, strategies to block the action of cytokines, such as TNF- α and IL-1- β , may decrease cell injury.¹⁸⁵ Monoclonal antibodies to TNF and an IL-1 receptor antagonist are being developed for use in humans.¹⁸⁵ However, antiinflammatory drugs, including those that block TNF and IL-1 receptors, used in neutropenic patients and in those in an advanced stage of sepsis when the patient is immunosuppressed may be detrimental.^{68,141,185} Rather, immune stimulation with agents such as IFN- γ can enhance macrophage function and may be beneficial.^{55,134,140,145}

Infectious Diseases of the Dog and Cat, 3rd Edition

The pathogenesis of sepsis is complex and interdependent. Manipulation of the inflammatory response awaits the accurate recognition of stages of the septic cascade. Recognition of the components that represent the body's appropriate compensatory response to sepsis that have salutary effects, markers of harmful hyperinflammation, and the terminal immunosuppressive stage when immune stimulation may be beneficial, must be standardized. Furthermore, rigorous trials will be required before mediator inhibition can become an accepted component of therapy for sepsis.

87.3 INFECTIVE ENDOCARDITIS

Endocarditis denotes inflammation of the endocardial surface of the heart.³¹ IE, also referred to as *vegetative endocarditis* or *bacterial endocarditis*, is the invasion by an infectious microbe of the endothelial surface of the heart, usually the valves. It is not known if infective microbes colonize microscopic sterile lesions or directly invade normal endothelium.

87.3.1 Pathogenesis

When infectious microbes colonize a heart valve, they not only produce proliferative lesions (vegetations) but also destroy valvular tissue. The vegetations vary in size and shape, from small warty nodules to large, cauliflower-like masses (Fig. 87-3). The vegetations comprise three layers¹: a large inner layer of platelets, fibrin, erythrocytes, leukocytes, and bacteria²; a middle layer of bacteria; and an outer layer of fibrin.³ The bacterial colonies are found beneath the surface of the vegetation, and infiltration by phagocytic cells is minimal. This protected environment allows extremely high bacterial concentrations to develop. Deep within the fibrin-platelet matrix, bacteria often are in a state of reduced metabolic activity.

Fig 87-3 Aortic valve of dog with IE. One of the valve leaflets was pale, was cauliflower-like, was firm on palpation, and appeared to be calcified. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

87.3.1.1 Bacteremia, Adherence, and Infectious Endocarditis

Bacteremia, either transient or permanent, must occur for IE to develop.³⁴ Surface changes may occur that result in deposition of platelets and fibrin that lead to a sterile vegetation. Bacteria must then reach this site, adhere to it, and then colonize. Certain bacterial strains are more capable of adhering and colonizing with a relatively low inoculum. Opossums and pigs can develop IE without prior valve damage,¹⁷⁷ and the same may be true of dogs. The most common bacteria of IE, streptococci and coagulase-positive staphylococci, adhere more quickly to the normal aortic valve than bacteria that uncommonly cause IE. Furthermore, the propensity to cause IE varies with the serotype of *S. aureus* in experimental models.

Organisms causing IE must be capable of adhering to a platelet-fibrin matrix. Production of adherence factors by bacteria facilitates the development of IE. Such factors include dextran and fibronectin-binding protein. Some strains of bacteria have been found to be potent stimulators of platelet aggregation, especially IE-producing streptococci and staphylococci. Clumping factor produced by coagulase-positive staphylococci favors attachment to fibrinogen and platelet-fibrin clots.¹³⁰ Culmination in IE involves the endothelium, hemostatic mechanisms, the host's immune system, surface properties of the microorganisms, and peripheral events that initiate bacteremia (Table 87-8). That the intact endothelium is resistant to infection can be deduced from the relative infrequency of IE compared to the known frequency of microbiemia.^{33,34} Although phagocytic cells remove microbes from the blood, platelet-fibrin depositions may occur spontaneously, and at these sites microorganisms may adhere and initiate IE before the immune system can obliterate the infection. Adherence of coagulase-positive staphylococci to platelets is an important virulence factor. Furthermore, aspirin reduces *Staphylococcus*-induced platelet aggregation and adherence to fibrin.

855

Table 87-8 Pathogenesis of Clinical Signs of Infectious Endocarditis

856

Valvular insufficiency and congestive heart failure
Bacteremia
Septic embolization and organ infarction
Metastatic infection and myocarditis
Immunopathologic sequelae and immune complex deposition
Glomerulonephritis
Uveitis
Polyarthrititis
Meningitis

When staphylococci adhere to damaged valves, tissue thromboplastin is generated, which locally activates the clotting cascade, generating thrombin production. Thrombin elicits the secretion of a low molecular-weight protein with antimicrobial properties. Bacteria that are resistant to this factor are more likely to cause endocarditis. Once lodged on heart valves, bacteria must elude local defenses, including platelet microbicidal proteins and leukocytes if they are to survive. The presence of bacteria stimulates thrombosis mediated by thromboplastin generated from leukocytes adhering to fibrin.^{12,104,172} Chronic,

Infectious Diseases of the Dog and Cat, 3rd Edition

low-grade microbiemia increases the risk of IE.³² Infective microorganisms in the blood must be capable of adhering to a platelet-fibrin matrix. Not only are leukocytes within this matrix unable to phagocytize bacteria, but the bacteria are very concentrated. Very few granulocytes are within the vegetation, and layers of fibrin, platelets, and erythrocytes protect the microorganisms.

The progression of the valvular lesion varies with the properties of the infecting organism. Some highly virulent organisms cause rapid necrosis and degeneration of the valve and more acute signs of heart failure. Other organisms of lower virulence produce a more gradual valvular injury and progressive cardiac signs. These organisms, such as *Bartonella*, often produce slowly enlarging vegetative lesions that increase in size over weeks or months and may become hardened or calcified. Resolution of an established endocardial proliferation is difficult because the colonies of bacteria are entrapped in an avascular coagulum of platelets, inflammatory cells, and fibrin that impedes antimicrobial drugs or immune defenses.

87.3.1.2

Valve Involvement

Heart valves are subject to constant trauma as they open and close. The incidence of IE appears to be directly related to the force placed on each valve. Lesions are generally located where high pressure and velocity of blood flow occurs. Prior valve or endocardial damage is one of the most important risk factors in the development of infection. The aortic valve is most commonly infected, followed in frequency by the mitral valve (Fig. 87-4). The tricuspid and pulmonic valves are seldom involved.³¹⁻³⁴ In a study of 45 dogs, 22 had aortic, 16 had mitral, 1 had both aortic and mitral, and 1 had tricuspid valve involvement.³¹ The higher frequency of individual valves parallels the higher rate and pressure of blood flow in those regions.

87.3.2

Epidemiology

The prevalence of IE is much lower than dilated cardiomyopathy and myxomatous mitral valve degeneration. The incidences at two referral institutions were both approximately five cases per year.³¹ Typically, affected dogs are 4 to 8 years old and medium or large sized; less than 10% weigh less than 10 kg.³¹ Affected dogs are seldom younger than 2 or older than 10 years of age. German shepherds, boxers, golden retrievers, Labrador retrievers, and rottweilers may be overrepresented.³¹ Males are affected more often than females; a 2:1 ratio, possibly a result of chronic bacterial prostatitis, has been reported.³¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 87-4 Opened left side of heart of dog with combined mitral (*arrow*) and aortic (*arrowhead*) valve bacterial endocarditis. Subendocardial hemorrhage is shown adjacent to portions of mitral valve. LA, Left atrium; A, aorta. (Courtesy University of Georgia, Athens, Ga.)

Vegetative endocarditis has been described in cats.* Organisms have included gram-positive and gram-negative bacteria, including *Bartonella* species (see [Table 87-1](#)). Evidence of concurrent disease has been found in some cats with endocarditis, including feline infectious peritonitis, thoracic lymphoma, mammary carcinoma, and megacolon.³⁶

87.3.2.1 Predisposing Factors

Numerous factors predispose individuals to the development of microbiemia and IE. However, a common misconception is that IE is associated with structural heart disease. Mitral valve prolapse in humans is a common preexisting heart disorder in patients with IE. However, mitral valve prolapse is common, and the percentage of patients that develop IE is small. The risk of IE in patients with prolapse and regurgitation is fivefold to eightfold higher. Dogs with the highest incidence of myxomatous mitral valve degeneration (old, small-breed dogs) have a very low incidence of IE. Furthermore, IE is seldom associated with congenital heart diseases in dogs, with the exception of subvalvular aortic stenosis (SAS).³¹ With SAS, turbulent, high-velocity blood flow in the outflow tract may produce micro-trauma on the valve leaflets and facilitate microbe colonization. Boxers, rottweilers, and golden retrievers have relatively high incidences of IE and SAS.^{31,97} Less than 10% of dogs with SAS develop IE, and possibly less than 10% of dogs with IE have SAS.^{31,97} Establishing or eliminating an ultrasound diagnosis of SAS with aortic valve IE is occasionally difficult because the vegetation may obscure the SAS lesion.

Predisposing factors for microbiemia include procedures involving the gingiva, oropharynx, GI tract, or infected tissues.³⁴ Endothelial damage can be produced by IV catheters. Portals of entry for microbes are also provided by wounds, biopsy sites, surgery, and urinary catheters. Although gingivitis and stomatitis may

856

857

Infectious Diseases of the Dog and Cat, 3rd Edition

be associated with bacteremia and bacterial endocarditis, dogs with the highest prevalence of oral infections (old, small-breed dogs) seldom develop IE.³¹ Hypercoagulability associated with malignancies, DIC, hypercortisolemia, or immune-mediated diseases may predispose an individual to IE. Any abnormality that either is associated with chronic bacteremia (gingivitis, urinary or prostatic infection, pyoderma, and wounds) or impairs host defenses (such as neoplasia, diabetes mellitus, hyperadrenocorticism, exogenous glucocorticoids, or other immunosuppressive therapies) increases the risk of IE.^{33,34} The source of infection may be suspected but is proven in less than 50% of dogs with IE.^{31,33,34}

Damaged endothelium exposes the extracellular polysaccharide dextran, which facilitates the attachment of some bacterial species. Because of the limited species of microbes that account for the vast majority of IE cases, it can be deduced that certain organisms (such as coagulase-positive staphylococci and some streptococci) have an increased ability to colonize the endocardium. Fibronectin can be produced by endothelial cells and platelets in response to vascular injury, and receptors for fibronectin are present on the surface of some bacteria, including coagulase-positive staphylococci and some streptococci. Fibronectin can facilitate the adherence of some bacteria, including staphylococci, to intact endothelium.

* References 35, 36, 53, 115, 138, 164, 183.

87.3.2.2

Glucocorticoids

Dogs affected with IE often have a history of receiving glucocorticoids.³¹ In some instances, glucocorticoids were administered in the weeks preceding the development of IE as a component of treatment for illness that was associated with unrecognized bacteremia, for the treatment of skin disease, or for the treatment for presumed immune-mediated disease. Dogs receiving glucocorticoids have shorter survival rates than nonrecipients.³¹

87.3.2.3

Infective Microbes

The vast majority of IE cases are the result of bacteria. Rickettsial agents are occasionally identified, but fungal IE is rare in dogs.^{31,32,34} Although the range of microbial species capable of causing IE is large, only a few species account for most infections. Greater than 50% of infections in dogs are the result of coagulase-positive staphylococci and streptococci.^{31,34,174} The association of streptococci and IE may be more closely related to the frequency with which they enter the blood stream and their ability to adhere to normal endocardium than their innate virulence. *S. intermedius* is the leading cause of IE in dogs. Although many species of gram-negative bacteria are capable of causing IE, they account for a small proportion of the total.

The prevalence of IE caused by anaerobic bacteria is unknown but as in humans is probably low. In humans, an important subgroup of cases are caused by a group of nutritionally fastidious gram-negative bacilli, *Hemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*—a group often referred to by the acronym *HACEK*. Similarly, other fastidious agents such as *Brucella* species, *Bartonella* species, *Tropheryma whippelii*, *Coxiella burnetii*, and *Chlamydia* species have been incriminated as causative agents in culture-negative IE cases in humans.¹²⁷

Bartonella species have been identified as an important cause of IE in dogs and cats (see [Chapter 54](#)). The prevalence of *Bartonella*, as well as other exotic organisms, is probably geographically variable. *Bartonella vinsonii* ssp. *berkhoffii*, *Bartonella clarridgeiae*, and a *Bartonella clarridgeiae*-like organism have been

Infectious Diseases of the Dog and Cat, 3rd Edition

identified as a cause of endocarditis of dogs.^{24,42} Additionally mitral valve endocarditis in a dog was caused by *Bartonella washoensis*.⁴³ *Bartonella henselae*, *Bartonella elizabethae*, and *Bartonella clarridgeiae* have been associated with systemic diseases and detection of *Bartonella* or their genomic DNA in blood of dogs.^{74, 98,125,148}

Factors predisposing to fungal infections in humans, such as prosthetic valve replacement, IV drug abuse, chronic immunosuppressive therapy, and chronic broad-spectrum antibiotic usage are less common in dogs. In humans, *Candida* and *Aspergillus* species account for most cases of fungal IE.

87.3.2.4 Pathophysiology

Aside from the constitutional signs of infection, which are mediated by cytokines, the clinical manifestations of IE are the result of valvular destruction, embolic phenomena, and immune-complex disease. CHF is the usual outcome in dogs with aortic valve IE (see [Table 87-8](#)).³⁴

Embolization leads to organ infarction and metastatic infection.³¹ Embolization is a frequent cause of clinical signs and clinical deterioration. Even in the absence of clinical evidence, dogs always develop systemic emboli, and the kidneys are almost always infarcted. Emboli are usually present in many organs and tissues.^{31,34}

Persistent bacteremia stimulates cell-mediated and humoral immune systems. CICs containing IgG, IgA, IgM, and complement may be deposited subendothelially along glomerular basement membranes, in joint capsules, and in blood vessels, leading to glomerulonephritis, arthritis, and vasculitis. Nonspecific antibodies can result in an increase in γ globulins and RF. Antiendocardial antibodies might be produced. Clinical signs of IE frequently mimic those of immune-mediated disorders, and positive immune-test results, such as Coombs' tests and ANA tests, can result from antigen-antibody-complement interactions.³¹ RF, ANA, and CICs contribute to the development of polyarthritis, renal disease, and myocarditis.

87.3.3 Clinical Findings

IE shares many clinical features with nonendocarditis microbiemia. The manifestations of IE can mimic vasculitis, DIC, brucellosis, glomerulonephritis, malignancies, and immune-mediated diseases. Clinical findings in patients with possible endocarditis tend to be either sensitive or specific. For example, a diagnosis of IE based on fever and heart murmur would be sensitive but not very specific. On the other hand, the finding of an echocardiographic typical aortic valve lesion is specific.

Clinical signs associated with IE can be related to virtually any organ system. Fever is usual but is often not high grade. Fever is most likely to be absent in patients with chronic IE, with CHF, with renal failure, that are old, and that are receiving antibiotic treatment. Sequelae of IE include CHF, renal failure, proteinuria, splenomegaly, splenic abscess, musculoskeletal pain and weakness, kidney embolization, and signs consistent with embolism of the CNS.

Clinical signs and diagnostic abnormalities associated with IE are often nonspecific and frequently include extracardiac manifestations. The interval between the initiating bacteremic event and diagnosis of IE is usually uncertain, and a predisposing factor is not always evident.³¹ Occasionally, a history of an illness exists that in retrospect may have initiated bacteremia 1 to 3 months before the diagnosis of IE.³¹ Affected dogs may have

Infectious Diseases of the Dog and Cat, 3rd Edition

signs of systemic infection, including fever and leukocytosis. Septic or sterile embolization or infarction, metastatic infections, and organ failure are responsible for many of the clinical signs.^{31,34} These clinical signs are diverse and misleading—IE has frequently been called *the great imitator*. Owners variably report lethargy, depression, weakness, anorexia, weight loss, lameness, neurologic signs, and signs consistent with CHF. Often, fever is absent at the time of diagnosis because the bacteremia is low grade or because of previous therapy with antibiotics, glucocorticoids, or nonsteroidal antiinflammatory drugs.^{31,34}

857

858

87.3.3.1 Heart Murmurs

Cardiac sequelae include valvular insufficiency because infection destroys the valvular tissue and interferes with function. The severity of destruction varies with chronicity and the virulence of the organism. IE is a cause of an aortic regurgitation murmur, and the aorta is the most commonly infected valve. Systolic murmurs result from mitral regurgitation or systolic flow turbulence generated by aortic valve vegetation. A murmur of recent onset, especially with a diastolic component, in the presence of fever is very suggestive of IE.³¹ The femoral pulses associated with mitral valve IE are typically normal, although they may be weak if left-sided CHF is present.³¹ The femoral pulses associated with aortic valve IE may be normal. However, they may be hyperdynamic and bounding because the systolic pulse pressure with aortic regurgitation is increased because of volume overload and resultant increased stroke volume, and the diastolic pressure is low because of arterial blood runoff back into the left ventricle during diastole. Thus not only may the diastolic pressure be low, but the systolic pressure wave duration may be shortened.

87.3.3.2 Lameness

Lameness is an occasional finding rarely caused by septic emboli but is usually the result of immune-mediated arthritis.³¹ Synovial tissue may contain IgG, IgM, and complement, indicating an immune basis for the arthropathy.

87.3.3.3 Organ Failure

The affected dog may show signs consistent with CHF, usually on the left side, including coughing, dyspnea, pulmonary crackles (pulmonary edema), shortness of breath, weakness, or collapse.³¹ CHF is most frequently associated with aortic valve IE. When the left side of the heart appears radiographically to be a normal size but pulmonary edema is present, the clinician should consider IE, because dramatic heart enlargement may not have time to develop in cases of acute IE. The index of suspicion of IE rises in dogs that have no history of a heart murmur or are not prone to cardiomyopathy or myxomatous valvular degeneration.³¹

Renal failure is another complication that may detract from recognition of IE. Renal failure is usually due to chronic infarction and glomerulonephritis.^{31,33}

87.3.3.4 Polysystemic Signs

The constitutional signs of IE can mimic those of any polysystemic disease.³¹ Many differential diagnoses must be considered, including immune-mediated diseases, rickettsial infections, bacteremia alone, sequelae of neoplasia, causes of CHF, and causes of renal failure.^{24,31,33,34} Localized signs, such as lameness, edema,

Infectious Diseases of the Dog and Cat, 3rd Edition

and pain often arise from complications of infection.³¹ To avoid overlooking IE, the possibility should be investigated when one or more of the elements of endocarditis exist: (1) an unexplained fever, (2) a heart murmur of recent onset, (3) a source of infection, and (4) embolic phenomena.

87.3.3.5 Systemic Embolization

Embolization is a constant and important complication of IE but is often undetected before death. The presence of infection-related antiphospholipid antibodies may be a risk factor for embolic events. The kidneys consistently exhibit old and new infarcts that contribute to proteinuria and renal failure (Fig. 87-5, A). Other organs that may be infarcted include spleen (Fig. 87-5, B), brain (Fig. 87-5, C), and intestinal mucosa (Fig. 87-5, D). Pathologic kidney symptoms are consistently found in dogs with IE; infarction, glomerulonephritis, and abscess are the three pathologic processes, abscesses being least common. The liver and iliac or mesenteric arteries may be embolized. Splenic septic abscesses may contribute to persistent fever and leukocytosis.

87.3.4 Diagnosis

The diagnosis of IE requires integration of clinical and laboratory data. The most important criteria for the diagnosis of IE are (1) multiple positive blood culture results of usual culprit microbes, such as *S. intermedius* or streptococci; (2) typical electrocardiogram (ECG) findings, such as oscillating valvular mass; and (3) a murmur of recent onset, especially if it is diastolic. Clinical findings supportive of the diagnosis of IE include fever, an inflammatory leukogram, embolic phenomena, evidence of glomerulonephritis, and positive results for immune tests such as for RF and ANA. IE shares many clinical features with nonendocarditis microbiemia. The manifestations of IE also can mimic vasculitis, DIC, rickettsemia, brucellosis, glomerulonephritis, malignancies, and immune-mediated diseases. The advent of ECG has greatly facilitated the diagnosis. Because the aortic valve is usually involved, if IE is suspected ultrasonographic recognition is seldom difficult. Diagnosis of mitral valve IE is more difficult because the lesions of myxomatous degeneration can resemble those of IE. It should be recognized that those dogs with the highest incidence of myxomatous degeneration of the mitral valve (old, small-breed dogs) seldom are affected with IE. Signalment, clinical findings, femoral pulse characteristics, confirmation of bacteremia, and a murmur of recent onset, especially a diastolic murmur, are important to the diagnosis of IE if ECG is not available (Table 87-9).

87.3.4.1 Clinical Laboratory Findings

Hematologic findings of systemic inflammation are often absent. This may be a result of prior antibiotic or steroid administration or chronic, low-grade bacteremia.^{31,34} Hematologic abnormalities include anemia, usually normocytic-normochromic and nonregenerative; thrombocytopenia; an inflammatory leukogram; and monocytosis. Left shift of the leukogram may be absent, mild, or moderate depending on the chronicity. Proteinuria, microscopic hematuria, casts, and bacteruria are variably present on urinalysis. Although an inflammatory leukogram does not always result, monocytosis is present in 90% of cases.^{31,34} In some instances, mature neutrophilia and monocytosis indicate low-grade, chronic inflammation.

Thrombocytopenia can be attributed to systemic vasculitis and immune or coagulatory consumption.^{31,34}

A septic triad of low serum albumin concentration, high serum ALP activity, and low blood glucose levels can be seen in dogs with bacteremia and endocarditis. The high serum ALP activity is likely a result of the effect of bacterial toxins on biliary flow and excretion; icterus may be found in severe instances. The hypoglycemia is caused by effects of bacteria or their toxins on glucose metabolism.

Infectious Diseases of the Dog and Cat, 3rd Edition

Azotemia may be prerenal or caused by infarction and glomerulopathy. With embolization, the urine often contains protein, blood, casts, bacteria, or all of these.^{31,33} Urine culture is recommended, not only because bacteria are filtered from the blood into the urine but also because the urinary tract may be a source of infection.^{31,33} Patients with glomerular disease have proteinuria; however, the urinary sediment does not contain cells.

The presence of bacteria in endocardial vegetations stimulates the humoral immune system to produce nonspecific antibodies. This can result in an increase in γ -globulins, and antiendocardial antibodies may be produced. CICs are produced, and their concentrations correlate with extracardiac manifestations such as arthritis, splenomegaly, and glomerulonephritis. RF (anti-IgG IgM antibody) develops in some patients with IE, and the titers decrease with antibiotic therapy. ANAs may also develop and may contribute to fever, pain, and musculoskeletal symptoms. Opsonic (IgG), agglutinating (IgG, IgM), and complement-fixing (IgG, IgM) antibody synthesis are typical.

87.3.4.2 Identification of Bacteremia

Blood cultures should always be performed in an attempt to identify the offending organisms, but they lack sensitivity and specificity.^{32,34,56} Performed properly, positive blood culture results are often obtained³¹⁻³³ (in the authors' experience, in approximately 30% to 50% of patients). Decreased sensitivity may be

Infectious Diseases of the Dog and Cat, 3rd Edition

explained by improper laboratory techniques, the failure to culture for anaerobes, low bacterial concentrations in blood, endogenous bactericidal factors (complement and phagocytes), intermittent shedding of the organism, chronic IE with encapsulated vegetative lesions, or infections with fastidious slow-growing organisms such as *Bartonella*.^{24,25,33,56}

The term *culture-negative IE* refers to active IE cases with multiple negative culture results. Many such cases are the result of antibiotic treatment that is sufficient to suppress bacteremia but not sterilize the vegetation. Other causes are *Bartonella* species, slow-growing bacteria such as HACEK, some streptococci, *Mycobacterium* species, nutritionally fastidious microbes requiring special procedures or supplemental media, and anaerobic microbes.^{84,181}

Many negative blood culture results in humans with IE are caused by infection with *Bartonella* species, which are fastidious, gram-negative organisms.²⁶ The prevalence of *Bartonella*-IE is being recognized with increasing frequency in dogs and cats as newer culture methods and the polymerase chain reaction (PCR) have been used. *Bartonella* organisms reside within the erythrocytes of their reservoir host and are present in low numbers in inadvertent hosts, making them difficult to isolate from blood cultures because special techniques are recommended.²⁴⁻²⁶ *Bartonella* species can occasionally be isolated by prolonged incubation and subculture in broth media onto endothelial cell tissue.^{57,106,168} Tissue culture methods may be required for obligate, intracellular organisms, such as *Coxiella* species, and for *Chlamydia*. Extraction of nucleic acid from blood and subsequent PCR amplification has been beneficial in the early diagnosis of bacteremia and confirmation of infection with fastidious or unculturable agents.^{25,26} Because some anaerobes and members of the HACEK group are slow growing, holding cultures for 4 weeks may increase the recovery rate. In postmortem or surgical specimens, PCR of infected valvular tissue has greatly enhanced the detection and identification of organisms causing endocarditis in people that is blood-culture negative.¹⁵⁵

87.3.4.3

Special Diagnostics

The diagnosis of IE requires integration of clinical and laboratory findings. Arrhythmias, usually atrial or ventricular premature contractions, are present in at least 50% to 75% of documented cases, seldom life threatening, and best evaluated by long-term continuous ECG monitoring, either cage side or by Holter recording. Other less common ECG abnormalities include bundle branch blocks and atrioventricular blocks. Radiographic interpretation may reveal chamber enlargements or no abnormalities. Chamber enlargement, most commonly left atrial, is usually present when IE is chronic.³¹ If overt or impending left-sided CHF is present, pulmonary edema, distention of the pulmonary veins, or both are present.³¹

859

860

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 87-9 Criteria for the Antemortem Diagnosis of Infective Endocarditis

Without Echocardiographic Examination
All of the following criteria should be met:
A murmur of recent onset
Positive blood culture results (preferably with more than one of the same microbe)
Clinical findings and laboratory data consistent with bacteremia and endocarditis
With Echocardiographic Examination
<i>Aortic valve:</i> Echocardiographic appearance is pathognomonic.
<i>Mitral valve:</i> Echocardiographic appearance is suggestive of endocarditis.
Supportive Clinical Findings
Signalment
Murmur of recent onset
Weak or hyperdynamic pulse
Fever
Limb edema
Joint swelling
Lameness
Limb ischemia
Limb hyperesthesia
Inflammatory leukogram
Positive blood culture results

ECG is the best diagnostic tool but is neither 100% sensitive nor 100% specific. Modern, two-dimensional equipment can detect small lesions. Detection of an echogenic oscillating vegetative mass on the aortic or mitral valve is a strong indication of the presence of IE. Both the M-mode and two-dimensional appearance of aortic valve vegetations is virtually pathognomonic for IE (Fig. 87-6). Echoes from vegetations on the mitral valve are usually on the cranial (anterior) leaflet but are not pathognomonic (although in some cases, the lesion is so large, is oscillating, or both that IE should be suspected). Operator skill and experience, as well as image quality, influence interpretation. Furthermore, results must be considered in the context of other clinical and laboratory findings. A false-positive test interpretation is most commonly attributable to mitral valve myxomatous degeneration. The clinician should always take into consideration the signalment and the history of the dog in question. The signalment associated with IE is largely different from that of dogs with advanced myxomatous degeneration. The presence of a new heart murmur is of special importance if the breed or age of the patient is not characteristic of dogs affected by myxomatous valvular degeneration.

Infectious Diseases of the Dog and Cat, 3rd Edition

Chamber enlargements and altered contractility may be evident.³¹ Decreased contractility is typical of the high-pressure volume overload of advanced aortic valve IE but not of the low-pressure volume overload of mitral valve IE. Decreased contractility may also be related to chronicity of volume overload. Diastolic fluttering of the anterior (cranial) mitral valve leaflet is indicative of aortic insufficiency and therefore suggestive of IE. This fluttering is the result of the jet of aortic regurgitation striking the anterior (cranial) mitral valve leaflet when it is open in diastole. Color flow imaging is used to identify hemodynamic consequences of IE, such as valvular regurgitation or left ventricular outflow tract turbulence (Fig. 87-7, A and B). Doppler interrogation of aortic regurgitation is used to confirm the severity (Fig. 87-7, C and D). The spectral display of severe aortic regurgitation is characterized by a rapid deceleration of regurgitant velocity during diastole. A steep slope of regurgitation indicates a large regurgitant volume. Severe aortic regurgitation is incompatible with survival.

Fig 87-6 M-mode echocardiogram of thickened aortic valve (AV). This echocardiographic image is typical of aortic valve vegetations.

87.3.5 Therapy

87.3.5.1 Antibiotics and Other Drugs

Within the vegetation, organisms are protected, become metabolically dormant, and are less vulnerable to the killing activities of antimicrobials.³² Prolonged parenteral administration of one or more bactericidal antibiotics is recommended. The goal of treatment is to kill the organism and minimize and manage the consequences of infection. Therapy ideally is based on blood culture antibiogram results, but treatment is usually initiated before results are received.^{181,182} In spite of in vitro antibiotic susceptibility, complete eradication takes weeks to achieve. The difficulty of cure is a result of impaired host defense in a tightly encased fibrin meshwork in which the bacterial colonies are relatively free from phagocytes. Furthermore, the bacteria within these vegetations reach tremendous concentrations. At these high populations the bacteria may be in a state of reduced metabolic activity and cell division. They are less susceptible to antibiotics requiring cell wall synthesis and division for maximum activity.

Infectious Diseases of the Dog and Cat, 3rd Edition

Antimicrobial therapy should be bactericidal, and antibiotic serum concentrations should be high (Table 87-10), because antibiotics reach the central areas of avascular vegetations by passive diffusion. High concentrations are needed, therefore parenteral treatment is preferred to oral therapy. The fluoroquinolones may penetrate better into vegetations than some cephalosporins.⁴⁶ Antibiotic combinations should rapidly produce a bactericidal effect, such as those produced by the synergism of a penicillin plus an aminoglycoside. High serum concentrations are mandatory, and antibiotic serum concentrations should be maintained at the high end of the therapeutic range for at least 1 month. At least 1 to 2 weeks of IV antibiotic therapy is recommended, which is followed by SC administration for several weeks if possible; then oral bactericidal antibiotics should be continued for several months (see Table 87-5). When switching from parenteral to oral therapy, the oral bioavailability of the drug should be considered, and higher oral than parenteral doses should be used. For example, absorption of the oral penicillins and cephalosporins is lower, and levels can only be obtained by increasing the dosage. Lipid-soluble drugs such as clindamycin achieve a similar peak serum concentration by oral or parenteral dosing.

860

861

Fig 87-7 Two-dimensional echocardiogram in left apical, long axis, two-chamber imaging plane. **A**, During systole, aortic valve leaflet thickened by vegetation (*arrow*) is opened into aorta (*A*). Vegetations are also seen on mitral valve leaflets (*arrowhead*), which reside between left atrium (*LA*) and left ventricle (*LV*). **B**, In diastole, vegetative aortic valve is closed, and portion of vegetation is protruding (*arrowhead*) into left ventricle (*LV*). Open cranial (anterior) mitral valve leaflet is also thickened by vegetation (*arrow*). **C**, Color-flow Doppler imaging in systole demonstrating turbulent mitral regurgitation (*arrowhead*). **D**, Color-flow Doppler imaging in diastole demonstrating turbulent jet of aortic regurgitation (*arrowhead*). *LA*, Left atrium.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 87-10 Principles of Antibiotic Therapy of Infective Endocarditis

1. Use bactericidal antibiotics.
2. Ensure high antibiotic serum concentrations by administering high dosages intravenously (IV).
3. Continue IV antibiotic administration for at least 1 to 2 weeks.
4. When IV administration of antibiotics is no longer practical, replace with subcutaneous (SC) administration.
5. Continue antibiotic therapy for at least 2 to 3 months.
6. Use oral antibiotics only after at least 1 month of IV and SC administration.

The most common infective bacteria are known, and their antimicrobial susceptibility patterns are somewhat predictable and the same as those associated with bacteremia alone (see [Table 87-5](#)). The choice for SC antibiotic administration should ideally be based on an antibiogram, but if blood culture results are negative or cultures not performed, ceftiofur, azithromycin, or ticarcillin may be used.

IE caused by anaerobes is uncommon in humans, but mortality is high. Penicillin, metronidazole, ticarcillin-clavulanate, or imipenem are good choices. Clindamycin is not recommended in humans because of its lack of bactericidal action. The HACEK organisms are sensitive to newer third-generation cephalosporins (ceftriazone or cefotaxime), which are the antibiotics of choice.¹⁸¹

P. aeruginosa-endocarditis is usually responsive to the combination of tobramycin and either extended-spectrum penicillin (ticarcillin, piperacillin) or ceftazidime.

Bacteriostatic antibiotics are generally ineffective in the treatment of IE. Failure to control the infection and latent relapses are common. An apparent response to tetracycline, erythromycin, or clindamycin should not be interpreted as indicative of successful treatment.

861

Table 87-11 Supportive Therapy for Infectious Endocarditis

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Enalapril or benazepril	B	0.25 mg/kg	PO	12–24	prn
	D	0.5 mg/kg	PO	12–24	prn
Spironolactone	D	1–2 mg/kg	PO	12	prn
Digoxin	D	0.005–0.01 mg/kg	PO	12	prn
	C	0.008–0.01 mg/kg	PO	24	prn
Pimobendan	D	0.3 mg/kg	PO	12	prn
Furosemide	D	0.5–2.0 mg/kg	PO	12	prn
	C	1–4 mg/kg	PO, SC, IV	12	prn
Amlodipine or felodipine	D	0.1 mg/kg	PO	12	Varies ^c
	C	0.625 mg/cat	PO	24	prn

B, Dog and cat; D, dog; C, cat; PO, by mouth; SC, subcutaneous; IV, intravenous; prn, as needed.

a For additional information about the drugs listed, see [Appendix 8](#).

b Dose per administration at specified interval.

c Should be titrated every 4 to 7 days to a maximum of 0.4 mg/kg every 12 hours PO.

862

Infectious Diseases of the Dog and Cat, 3rd Edition

Supportive therapy is always a component of treatment (Table 87-11). Acid-base, fluid, and electrolyte balance must be addressed. Nutritional support may be an important component of therapy and may be maintained by either parenteral or tube alimentation. The consequences of valvular destruction must be addressed. Although a positive influence on disease progression is unproven, angiotensin-converting enzyme (ACE) inhibition is usually recommended if unequivocal left atrial or left ventricular enlargement develops. Enalapril or benazepril are common choices. Spironolactone, an aldosterone antagonist, may be added to the regimen as cardiac enlargement progresses. A diuretic and possibly digoxin should be used if CHF is overt. Furosemide is the diuretic of choice. A serum digoxin concentration should be obtained after 7 days of treatment from a sample drawn at 6 hours after the morning dosage. For most laboratories, a desirable serum digoxin concentration is 1 to 1.5 ng/ml. Pimobendan is probably a better choice than digoxin. In addition to superior therapeutic index and inotropic action, it also has arteriolar dilating activity.

Augmented afterload reduction may be a useful adjunct to ACE inhibition. Adjuvant afterload reduction (arteriolar dilation) may result in reduction of aortic or mitral regurgitant volume. When the total peripheral arteriolar resistance is decreased by increasing the total arteriolar cross-sectional area, the change in relative resistance to systolic and diastolic blood flow facilitates increased forward stroke volume and decreased aortic regurgitation. Systemic blood pressure should be monitored as adjuvant afterload reduction is initiated and up titrated. Amlodipine and felodipine are effective afterload reducers (see Table 87-11). Indirect blood pressure monitoring is important, although it is subject to inaccuracies. Dogs that subsequently developed signs of hypotension have consistently had lower indirect blood pressures compared with pretreatment and during early-dose titration. Up titration should be stopped if the systolic blood pressure is less than approximately 110 mm Hg or if the mitral regurgitation velocity measured by Doppler ultrasound is 4.5 to 5 m/s. This velocity range correlates with a systolic systemic blood pressure between 100 and 120 mm Hg. If clinical signs of hypotension (lethargy, trembling, weakness, anorexia) occur, amlodipine should be withdrawn for 24 hours and then reinstituted at the previous lower dosage. Severe hypotension is seldom encountered but requires IV fluid administration.

87.3.5.2 Anticoagulant Therapy

Anticoagulant therapy has not been shown to prevent embolization and may increase the risk of hemorrhage.¹⁷⁶ The role of aspirin in preventing embolization is being evaluated.¹⁰⁴ Studies confirm the use of aspirin in reducing the size of vegetations and microbial density within vegetations.¹³⁶ Aspirin may reduce bacterial dissemination and embolic events.¹⁰⁴

87.3.6 Prognosis

The prognosis for long-term survival is poor.³¹⁻³⁴ Early diagnosis followed immediately by aggressive antibiotic therapy is critical for long-term survival, especially when the aortic valve is infected. Unfortunately, early diagnosis is difficult, and valvular damage is often advanced by the time of diagnosis. Aortic valve endocarditis is associated with a grave prognosis, for animals with this condition develop left-sided CHF, often within 1 to 3 months and almost always within 6 months of diagnosis. The trend in treating human patients with aortic valve endocarditis is to perform early valve replacement therapy.

Infectious Diseases of the Dog and Cat, 3rd Edition

87.3.7 Prevention

Chemoprophylaxis is controversial, for the risk-benefit ratio and economic rationale can be questioned, and clinical studies supporting efficacy are limited. The prophylactic use of antibiotics before medical procedures that cause bacteremia does not reduce the incidence of IE; this is not surprising because only a small proportion of all cases are attributable to such procedures. Chemoprophylaxis, even if effective, is not applicable to the majority of cases. However, the mortality associated with IE warrants chemoprophylaxis in patients at increased risk.

It is recommended to use prophylactic antibiotics when dental scaling, dental extractions, or surgery are performed in dogs with congenital heart diseases. Such procedure-focused chemoprophylaxis should not be initiated several days before the procedure because of the potential to select for antibiotic resistant organisms.

862

Rather, it should be administered just before and after the procedure (see [Chapter 89](#)). For oral and dental procedures in patients that are at increased risk, ticarcillin or a first-generation cephalosporin, administered IV 1 hour before and repeated 6 hours after the procedure, is reasonable. Incision and drainage of infected skin are associated with coagulase-positive staphylococci, and either a first-generation cephalosporin, ticarcillin, or ticarcillin-clavulanate is a good choice for prophylaxis. Maintenance of oral hygiene is a more important preventive than procedure-focused chemoprophylaxis.

863

The male urinary tract is suspected to be a common source of chronic bacteremia, therefore castration can be viewed as a prophylactic measure because it reduces the risk of bacterial prostatitis.

87.4 INFECTIOUS MYOCARDITIS

Myocarditis (inflammation of the myocytes, interstitium, and vasculature) may result from primary or secondary causes. Active and chronic myocardial disease may be associated with infectious diseases of dogs ([Table 87-12](#)), and the relevant chapters should be consulted for additional information. Myocarditis secondary to infectious agents may be subclinical if the inflammation is focal and limited. Severe or diffuse myocarditis results in fever, malaise, weakness, cardiac arrhythmia, and CHF. CHF caused by necrotizing myocarditis can be a lethal complication of neonatal canine parvovirus infection,^{1,135} but it is rare because of the widespread existence of immune dams. PCR for viruses in paraffin-embedded myocardium from dogs with dilated cardiomyopathy and myocarditis have been screened for presence of canine parvovirus, adenovirus types 1 and 2, and herpesvirus.¹²² Only adenovirus 1 nucleic acid sequences were detected in the heart of one dog. Natural West Nile virus infection in canids has been associated with myocarditis that accompanies the encephalitis.^{30,111} Myocarditis, the feline panleukopenia virus genome, or both were detected in cats with idiopathic hypertrophic, dilated, and restrictive cardiomyopathy, suggesting a possible role of viral infection and inflammation in the pathogenesis of cardiomyopathy in this species.¹²⁴ Results were negative for herpesvirus, calicivirus, and coronavirus. In people, coxsackievirus B3 was detected in the heart muscle of approximately 50% of people with dilated cardiomyopathy.^{51,66,92,95} The presumption is that injury by this cardiotropic virus leads to the production of autoantibodies specific for heart muscle and infiltrates of immune cells. Chlamydial infections have also been associated with myocarditis as they have been with endocarditis in people. Chlamydial infections lead to the activation of autoaggressive lymphocytes reactive to heart-specific antigens because of molecular mimicry with bacterial antigens.¹⁵¹ Neither of these human pathogens has been incriminated as a cause of myocarditis in dogs or cats; however, a similar mechanism of autoimmune myocarditis may be triggered by myocardial infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 87-12 Infectious Causes of Myocarditis

Unknown
Transmissible myocarditis-diaphragmitis of cats

Suppurative myocarditis that resulted in syncope was found in two sibling boxer puppies and was associated with *Citrobacter koseri* infection.³⁷ As a saprophyte the organism is considered to be an opportunist, and concurrent

Infectious Diseases of the Dog and Cat, 3rd Edition

immunosuppression, possibly by parvovirus infection, was suspected in the dogs. Similar to their propensity to cause endocarditis, *Bartonella* species have been identified as the cause of myocarditis and endocarditis in dogs and cats (see [Chapter 54](#)). Cardiac arrhythmias, endocarditis, or myocarditis was identified in dogs with weight loss, syncope, collapse, or sudden death, often without fever.²⁴ Cats experimentally or naturally infected with *B. henselae* or *B. clarridgeiae* have had lymphocytic myocarditis histologically in association with inflammation of other organs, including concurrent endocarditis.¹⁰¹

Dogs infected with *Trypanosoma cruzi* develop granulomatous myocarditis that can cause heart failure and heart rhythm disturbance.^{10,114} *Neospora caninum* and *Borrelia burgdorferi* can infect the myocardium, but the disease is usually mild and overshadowed by clinical signs associated with other organ or system involvement. However, sudden death has occurred as a result of *Neospora* myocarditis.¹⁴²

The diagnosis of myocarditis is usually made when ventricular tachyarrhythmias, with or without ST segment changes, are detected in patients with evidence of systemic diseases. The interpretation of elevated levels of the myocardial fraction of serum muscle enzymes such as creatinine kinase (CK), lactic dehydrogenase, and aspartate aminotransferase has not been evaluated in dogs. Specific serologic testing is available for some of the underlying diseases. Therapy is directed at the primary infectious agent, control of cardiac arrhythmia, and treatment of CHF.

87.5 TRANSMISSIBLE MYOCARDITIS-DIAPHRAGMITIS OF CATS

Transmissible myocarditis-diaphragmitis is a sporadic disease, primarily affects adult cats, and occurs most commonly in the summer months. It has been reported in California and Florida.^{78,150}

863

Although the disease can be experimentally transmitted between cats, the organism has not been identified.¹⁵⁰ A viral agent may be involved, and the disease resembles coxsackievirus B infection of people and other animals.¹¹⁰ Clinical signs in cats include transient fever occurring 9 to 30 days after inoculation and usually lasting for 1 to 3 days. Some cats have a second fever spike. Lethargy, rough hair coat, and anorexia correlate with the fever. Hematologic and biochemical abnormalities are absent except for high serum CK activity in some cats. Gross necropsy findings during the febrile period are pale foci surrounded by hemorrhage in the ventricular myocardium and diaphragm. Gross lesions were absent in cats that had recovered. Myonecrosis and cellular infiltration predominantly composed of neutrophils but occasionally including macrophages have been found in heart and diaphragmatic muscle. In acutely infected cats, lymphoid tissues showed reactive changes and mild neutrophilic-histocytic infiltrates in the liver and renal interstitium.

864

Evidence in people shows that viral myocarditis may result in development of chronic inflammatory heart disease and dilated cardiomyopathy. Whether this infection in cats has any relationship to some cases of feline cardiomyopathy remains to be determined.

87.6 INFECTIOUS PERICARDIAL EFFUSION

87.6.1 Etiology

Many causes have been attributed to pericardial effusion in dogs and cats ([Tables 87-13](#) and [87-14](#)). Pericarditis (inflammation of the fibrous and serous layers of the pericardium) caused by infectious agents is uncommon but can be a sequelae of the bacteremia of staphylococci, streptococci, and *E. coli*. Pericarditis may result from local (pleural or pulmonary) infections, secondary to trauma, or from hematogenous spread of

Infectious Diseases of the Dog and Cat, 3rd Edition

microorganisms.⁷⁰ Anaerobic bacteria and *Actinomyces*, *Nocardia*, *Mycobacterium*, and *Aspergillus* species are most likely to spread from pleural infections or migrating foreign bodies (see [Chapters 41, 49, 50, and 64](#)). Hematogenous infections of the pericardium can occur when infectious organisms embolize in the myocardial or pericardial vasculature. Bacteremias and viral infections, such as feline infectious peritonitis (see [Chapter 11](#)), can cause effusive pericarditis. Many viruses have been associated with pericarditis in people. Idiopathic pericardial effusion (IPE) in dogs is characterized by a hemorrhagic effusion but no identifiable cause. PCR was used to screen 10 IPE effusions for the presence of nucleic acid from coxsackie virus B, influenza type A virus, adenovirus type 2, parvovirus B19, cytomegalovirus, *B. burgdorferi*, and *Chlamydia pneumoniae*.¹⁸⁷ One specimen had positive tests results for influenza type A virus, and another tested positive for cytomegalovirus.

Table 87-13 Causes of Pericardial Effusion in 42 Dogs

CAUSE	NUMBER OF DOGS WITH SIGNS
Neoplastic	24 (57%)
Idiopathic hemorrhagic	8 (19%)
Cardiac	6 (14%)
Traumatic	2 (5%)
Uremic	1 (2%)
Infectious	1 (2%)
Data from Berg RJ, Wingfield W. 1994. Pericardial effusion in the dog: a review of 42 cases. <i>J Am Anim Hosp Assoc</i> 20:721–730.	

Pericarditis may be effusive or constrictive, but in the dog and cat it is almost always effusive. Effusions of infectious pericarditis are either modified transudates or exudates and usually serosanguineous or bloody.

87.6.2

Clinical Findings

The infectious nature of the underlying agent and the severity of pericardial effusion determine the findings of the patient's history. A recent history of fever and an inflammatory leukogram is occasional. Weight loss, weakness, dyspnea, and abdominal effusion are variable signs. Fever is an inconsistent finding, varying with the infectious agent and time course of the disease. As the severity of the pericardial effusion worsens, dyspnea, weakness, and abdominal effusion become pronounced.

The principal physical findings reflect external cardiac compression. As the effusion becomes more extensive, the intrapericardial pressure rises to or exceeds right atrial diastolic pressure. Intracardiac pressure increases, ventricular diastolic filling is impaired, and stroke volume is reduced. The central venous pressure is increased, and venous return to the right atrium is impaired, resulting in signs of right-sided heart failure. Jugular pulses and distention of the jugular veins are often present. Subsequently, increased venous pressure can lead to pleural and abdominal effusions. The triad of increased central venous pressure, as with evident jugular pulses, weak peripheral arterial pulses, and muffled heart sounds, is suggestive of pericardial effusion but can also occur with dilated cardiomyopathy.

When the effusion is severe, the heart and lung sounds are not clearly audible. Mucous membrane color is often pale, and the peripheral pulses are weak because of decreased cardiac output. A reflex tachycardia is often present.

Infectious Diseases of the Dog and Cat, 3rd Edition

87.6.3 Diagnosis

Thoracic radiographs are always abnormal when pericardial effusion is severe enough to produce cardiovascular impairment. However, because the pericardial and cardiac silhouettes cannot be distinguished by simple radiographs, the size of the heart and the severity of effusion cannot be accurately determined. In some cases, pleural effusion may partially obscure the pericardial-cardiac silhouette.

Massive effusion is characterized by a greatly enlarged, round cardiac silhouette in which the borders are smooth without the normal protrusions produced by the chambers. The silhouette is flattened where it contacts the thoracic walls. The parenchymal lung fields are not affected unless the lungs are the primary source of infection. The lobar arteries may appear small because of decreased right ventricular output.

Table 87-14 Causes of Pericardial Effusion in 84 Cats

CAUSE	NUMBER OF CATS WITH SIGNS
Cardiac	20 (24%)
Feline infectious peritonitis	16 (19%)
Neoplastic	13 (15%)
Infectious (other than feline infectious peritonitis)	12 (14%)
Renal failure	9 (11%)
Coagulopathies	7 (8%)
Miscellaneous	5 (6%)
Iatrogenic	2 (2%)
Data from Rush JE et al. 1987. Retrospective study of pericardial disease in cats, <i>Proc Am Coll Vet Intern Med</i> 5:922; Harpster NK. The cardiovascular system. In Holzworth J (ed). 1987. p 820. <i>Diseases of the cat: medicine and surgery</i> . WB Saunders, Philadelphia, PA.	

ECG changes may be present, particularly when the degree of effusion is severe. Low-voltage complexes, electrical alternans, and ST segment changes may be present. ECG is an accurate means of determining the presence and severity of effusion and cardiac function. In many cases, two-dimensional ultrasound examination is helpful in the detection of intrapericardial masses.

Pericardiocentesis is performed immediately if severe cardiovascular impairment has occurred secondary to severe effusions. Otherwise, pericardiocentesis is performed after radiographic, electrocardiographic, and ECG examinations.

Cytologic analysis and microbial culture of the effusion should always be performed. Infectious pericardial effusion is either serosanguineous or (more often) bloody. The protein content is greater than 2.5 mg/dl and is often in excess of 3.5 mg/dl. Neutrophils and to a lesser extent, erythrocytes, are the predominant cell types. Macrophages and reactive mesothelial cells are usually present, especially when the effusion is chronic. Erythrophagia and hemosiderocytes may be observed. Degenerate neutrophils and infectious agents may be detected. When the latter are absent, hemorrhagic effusions caused by neoplasia, idiopathic benign (hemorrhagic) pericardial effusion, and infectious pericarditis cannot be distinguished by cytology. The presence of pyrexia, an inflammatory leukogram, or other biochemical data associated with bacteremia or sepsis are variably and inconsistently associated with infectious pericarditis.

Infectious Diseases of the Dog and Cat, 3rd Edition

87.6.4 Therapy

If the cause of a systemic infection is evident, aggressive antimicrobial therapy is indicated as soon as appropriate samples for culture are procured. In some cases the infectious nature of the effusion is not appreciated until the results of cytology and culture are obtained.

Continuous drainage via surgical intervention or an indwelling pericardial catheter along with antimicrobial therapy is appropriate but usually not necessary. Usually, pericardiocentesis, which may have to be repeated, plus aggressive antibiotic treatment is curative in dogs. When bacterial pericarditis is discovered latently via pericardial fluid culture, and pericardiocentesis must be repeated, an appropriate nonmyocardiotoxic antibiotic can be injected into the pericardial sac in an attempt to reach higher therapeutic concentrations.

Constrictive pericarditis-epicarditis may occur and is recognized at surgery. Although a pericardectomy can be performed, extensive fibrin deposition on the epicardium is difficult to remove. Stripping of the epicardium is tedious and associated with complications, such as tearing of the myocardium and heart rhythm disturbances.

Bacterial infection, although producing fibrinous pericarditis and epicarditis, can often be treated successfully once the pericardium is removed. Antimicrobial therapy should involve broad-spectrum, bactericidal drugs administered IV at high dosages when feasible and should always be guided by antimicrobial susceptibility results.

87.7 INFECTION AND CORONARY VASCULAR DISEASE

Serologic studies, pathologic changes, and animal studies have provided evidence of an association between *Chlamydia pneumoniae* infection in people and coronary artery disease, atherosclerosis, and myocardial infarction.¹²³ No such associations have been made in dogs and cats, and these pathologic changes are not as frequently observed as they are in humans.

88 CHAPTER 88 Bacterial Respiratory Infections

Craig E. Greene

Carol Norris Reinero

The respiratory system is divided into the upper and lower tracts and the pleural cavity. The upper respiratory tract consists of the nasal passages, nasopharynx, pharynx, larynx, and extrathoracic trachea. The lower respiratory tract consists of the intrathoracic trachea, bronchi, and alveoli. Specific diseases caused by viruses, fungi, protozoa, rickettsiae, *Mycoplasma*, and certain bacteria such as *Actinomyces* and *Nocardia* that infect primarily the respiratory system are covered in other chapters. This discussion focuses on bacterial infections of the respiratory system produced by invasion of normal microflora, by specific bacterial pathogens, or after impairment of normal host defense mechanisms. The normal microflora of the respiratory tract are discussed because these organisms frequently become involved in both upper and lower respiratory tract infections.

88.1 NORMAL BACTERIAL FLORA

88.1.1 Upper Respiratory Tract

Surveys of the bacterial microflora of the nasal cavities, tonsils, and pharynx of clinically healthy dogs and cats have found many types of aerobic and facultative anaerobic bacteria (Tables 88-1 and 88-2). Greater numbers of organisms are routinely cultured from the rostral than from the caudal nasal cavity. Because of marked individual variations, expecting to find the same organisms as flora of the nasal cavity and pharynx in each animal is not possible, but the presence of a certain range of flora can be predicted.

88.1.2 Lower Respiratory Tract

Bacteria are prevented from entering the lower respiratory tract by filtration of inspired air in the nasal turbinates, sneezing or coughing of inhaled particulate matter, and mucociliary clearance mechanisms. Despite these barriers, the normal tracheobronchial tree and lung are not continuously sterile. Airways down to the first bronchial division are contaminated with low numbers of organisms in clinically healthy animals. Studies using guarded culture swabs or tissue samples of the lower trachea of clinically healthy dogs have found some bacteria in 40% to 50% of samples (Table 88-3). Small numbers of bacteria (fewer than 2×10^3 colony-forming units [CFU]/ml) are also frequently cultured from the lower airways of healthy cats (Table 88-4). Oropharyngeal bacteria are aspirated and may be present for an unknown interval in the normal tracheobronchial tree and lung. Aerobic bacteria were isolated from 37% of lung tissue samples, whereas only 10% of dogs examined had no growth from cultures of multiple samples of their lung.⁷⁵ Most of the bacteria cultured from the trachea and lungs are identical to those found in the pharynx of these same dogs. This bacterial population has the potential to cause or complicate clinical respiratory infection and clouds interpretation of airway and lung cultures. Finding large (more than 10^5 CFU/ml) concentrations of bacteria or cytologic evidence of inflammatory cells in tracheobronchial washings makes their presence of more concern to the clinician.

Infectious Diseases of the Dog and Cat, 3rd Edition

88.2 UPPER RESPIRATORY TRACT INFECTIONS

88.2.1 Bacterial Rhinitis

Primary bacterial rhinitis is rare in the dog and cat. Bacterial rhinitis is commonly secondary to nasal trauma, allergic rhinitis, or inhalation of foreign material; reflux of liquids or food into the nose caused by pharyngeal, esophageal, or gastric dysfunction; viral, fungal, or parasitic infections; neoplasia; dental disease; oronasal fistula; and bacterial bronchopneumonia. One of the author's (CEG) beliefs asserts that once primary inflammation and mucosal injury begins, commensal microflora can proliferate as a secondary result, leading to chronic inflammatory rhinitis. This disease has been termed idiopathic lymphoplasmacytic or neutrophilic rhinitis, depending on the histopathologic findings.^{67,147} It is characterized by chronic recurrent nasal discharge, fluid accumulation in the nasal passages and nasal sinuses, and eventual turbinate and bony loss (Fig. 88-1). This low-grade, progressive osteomyelitis likely develops because of the large number of bacterial flora residing within the nasal passages and the thin epithelial barrier over the fragile turbinate bones. Once it begins, the osteomyelitis becomes more difficult to control because infected necrotic bone acts as a sequestrum for continued osteomyelitis that becomes progressively more difficult to control with systemic or topical antimicrobials. Fungi such as *Alternaria* (see Chapter 67), *Aspergillus* and *Penicillium* (see Chapter 64), and *Cryptococcus* (see Chapter 61) may also colonize and produce disease in airways affected by bacteria or other processes while also producing nasal or disseminated disease in otherwise immunocompromised dogs and cats.

Clinical signs of bacterial rhinitis include sneezing, mucopurulent nasal discharge, ocular discharge secondary to nasolacrimal duct obstruction, and cough with gagging or retching. Epistaxis occurs infrequently with bacterial rhinitis but may be associated with underlying disease such as fungal rhinitis or neoplasia. Pawing at the face or nose indicates severe nasal irritation, often caused by foreign bodies lodged in the nasal cavity. Ulceration of the external nares and accumulation of crusted exudate occur in severe or chronic cases. Depigmentation of the external nares can also occur with chronic bacterial rhinitis as a result of the epithelial ulceration; however, it has been more commonly reported as a feature of nasal aspergillosis in dogs (see Chapter 64). Stenotic nares are seen in brachycephalic breeds and cats with long-standing rhinitis that develop infection at an early age in life. This nasal deformity is caused by damage to nasal bones and is similar to atrophic rhinitis in swine. For a discussion of nasopharyngeal polyps in cats, see otitis media and otitis interna in Chapter 86, Musculoskeletal Infections.

Because primary bacterial rhinitis is uncommon, a thorough search for underlying problems should be performed. Cryptococcal antigen testing of serum is helpful before invasive diagnostics because it will detect this disease before an anesthetic workup or invasive diagnostic tests (see Chapter 61). Diagnostic techniques include skull and nasal radiographs, endoscopic examination of the nasal passages, thorough oropharyngeal examination, cytologic examination of exudate, and biopsy. These techniques are usually performed with the patient under general anesthesia.¹¹⁸

- a Collected by bronchoscopic alveolar lavage. Organisms isolated from the upper respiratory tract are found in lesser concentrations in the lower airways down to first bronchial division of healthy cats. Colony counts under 2×10^3 CFU/ml. No anaerobic bacteria or *Mycoplasma* isolated in healthy cats.
- b Collected by endotracheal tube bronchial lavage, transtracheal lavage.
- c Animals with these isolates have been septicemic, either as a cause or effect.⁷

Fig 88-1 Computerized tomographic scan from a cat with severe turbinate loss and deviated nasal septum (*arrow*) within the nasal passages. (Courtesy University of Georgia, Athens, Ga.)

The radiographic features of chronic rhinitis are increased density of the nasal cavity as a result of excessive secretion accumulation. The turbinates are rarely destroyed, and the vomer bone is intact unless the disease is advanced. The frontal sinuses usually do not have increased density. Oblique views of the skull should be taken to evaluate the upper dental arcade. Dental film is ideal for evaluating infection of the tooth roots and the nasal sinuses of cats.

Computed tomography (CT), available at referral centers, has been shown to be superior to nasal radiography for evaluating the nasal cavities and frontal sinuses and in discriminating between cavitated and mass lesions¹¹⁸ Compared with radiography, CT is more sensitive in localizing and determining the extent of nasal disease.^{23,120} The potential of rhinoscopy to detect significant abnormalities depends on the instrument and the amount of exudate or hemorrhage obscuring the field of view. Radiography or CT should be performed before rhinoscopic examination because nasal bleeding induced by rhinoscopy can obscure lesions on nasal imaging and because prior localization of the lesion is useful in guiding the rhinoscopist to the area of interest (e.g., the site of a foreign body or dental infection). Rhinoscopy is invaluable in the evaluation of neoplasia, inflammatory rhinitis, aspergillosis, and foreign bodies.¹³⁰ Purulent exudate and friable, hyperemic mucosa with or without ulceration are seen in bacterial rhinitis.

Infectious Diseases of the Dog and Cat, 3rd Edition

Without resorting to surgical biopsy, cytologic specimens can be obtained by flushing, swabbing, brushing, fine-needle aspiration, and impression smears of obtained tissue fragments.¹⁷ With bacterial rhinitis, cytologic specimens of lesions or exudates will demonstrate with septic, purulent exudates. Cytologic evaluation may be helpful in assessing if inflammatory versus neoplastic processes are causing nasal disease; however, superficial inflammation can often overlay deeper neoplastic disease that can be missed by cytologic evaluation alone. Therefore the observed inflammation may often be a secondary phenomenon. Furthermore, cytologic evaluation detects only acute inflammatory responses and misses chronic inflammatory changes found with corresponding histopathologic evaluation.⁸⁵ Bacterial cultures are difficult to interpret because they often yield a mixed population similar to that of the normal nasal flora and are not routinely recommended. Occasionally, a pure culture of a pathogen is helpful in choosing an appropriate antimicrobial based on susceptibility testing. However, the isolation of a predominant organism from such a contaminated site may indicate only that it is the most vigorous in its *in vitro* growth at the conditions implemented. Therefore cultures of the nasal area can often be misleading. Because of the rarity of primary bacterial rhinitis, clinicians must be cautious about over-interpreting bacterial cultures obtained from swabs, lavages, or biopsies of the nasal passages and realize that bacterial growth is likely secondary to an underlying problem that needs to be addressed before the bacterial infection will completely resolve.

Histopathologic specimens can be obtained by fluid flushes, punch biopsy, traumatic catheterization, and endoscopic biopsy forceps. In cats, the correlation of gross rhinoscopic mucosal abnormalities with histologic evidence of inflammation has been weak⁶⁷; therefore histologic evaluation of biopsy specimens is essential, whether or not lesions are seen via rhinoscopy. Biopsy of nasal turbinates and mucosae may be helpful in identifying nasal diseases associated with bacterial rhinitis.

Bacterial rhinitis will often resolve without specific antibacterial therapy if the underlying problem, such as a foreign body, oronasal fistula, or dental disease, is corrected. In some patients, signs of rhinitis are temporary and may improve without treatment. Persistent or recurring signs require a further diagnostic workup. Although broad-spectrum antibacterials may appear to have a short-term benefit, the majority of patients will relapse with clinical signs of nasal disease until the underlying problem has been identified and addressed. Once significant bacterial osteomyelitis has developed, the process can be self-perpetuating. Therefore a complete nasal workup is strongly advised. Other nonspecific adjuncts to therapy include nebulization or vaporization, which helps mobilize secretions in the clogged nasal passages and soothes irritated mucous membranes, and sympathomimetic nasal decongestants, such as phenylephrine and oxymetazoline, in patients with copious serous or mucoid nasal discharges. However, nasal decongestants are contraindicated in patients with thick tenacious, mucopurulent nasal discharges because the exudates may become more viscous and difficult to expel. Glucocorticoid-responsive rhinitis associated with lymphoplasmacytic infiltrates of nasal mucosa, which may mimic bacterial rhinitis, has been described in the dog. The decision to institute glucocorticoid therapy is made after all other causes of nasal discharge have been ruled out and no evidence of a primary infectious process has been found during diagnostic evaluation.

88.2.2 Chronic Sinusitis

Chronic bacterial sinusitis is uncommon in the dog, although mucous accumulation does occur when nasal diseases occlude normal drainage of the frontal sinus through the sinus ostium. Chronic sinusitis in cats occurs as a result of mucosal and bone damage secondary to feline viral respiratory infections (see [Chapter 16](#)). Severe mucosal ulceration and turbinate destruction allow secondary bacterial infection of the nose and frontal sinuses. This syndrome is often called the “chronic snuffler” because the clinical signs in cats include chronic snorting and snuffling breathing, purulent nasal discharge, and sneezing. Many young cats with this syndrome are

868

Infectious Diseases of the Dog and Cat, 3rd Edition

869

infected with feline leukemia virus (see [Chapter 13](#)), which may influence their response to treatment. Acute sinusitis often accompanies a large number of inflammatory conditions of the upper respiratory tract caused by inhaled irritants, allergens, and viral agents. In chronic cases, a wide variety of aerobic and anaerobic bacteria may be involved, similar to the situation found in people.³⁹ Although the relationship of these organisms to the pathogenesis of this infection is not completely understood, antimicrobial treatment should be based on broad-spectrum antimicrobial therapy.

Treatment of bacterial sinusitis is often frustrating because the underlying pathogenesis of the disease syndrome is poorly understood, and many patients fail to respond to all forms of symptomatic therapy. A course of broad-spectrum antibacterial (anaerobic and aerobic) therapy with good penetration into bone and secretions is recommended. Furthermore, given that opportunistic fungal infections are also involved, therapy against these organisms should be considered (see Nasal Aspergillosis and Penicilliosis, [Chapter 64](#)). The nasal cavity can be vigorously flushed with saline with or without antiseptic solutions to remove the exudate and inhibit bacterial growth. Drug penetration into the normal canine sinus is poor for the few antibacterials that have been evaluated and is probably similar in cats. Drug penetration will obviously increase with inflammation, but actual levels are unknown. Broad-spectrum antibacterials are used for prolonged periods (2 to 4 months) after bacterial culture and susceptibility testing. Nasal decongestants may be helpful in individual cats, but they can exacerbate the problem by drying the exudate. Surgical turbinectomy and sinus trephination may be helpful in establishing drainage of these areas and removing inspissated pockets of exudate. Nasal flushing and systemic antibacterials can be used subsequently to surgical intervention. More aggressive surgical approaches have included sinus obliteration and reconstruction of apertures into the frontal sinuses.

88.2.3 Tonsillitis and Pharyngitis

Tonsillitis is usually bilateral but may occasionally occur as a unilateral disease when a foreign body is trapped in the tonsillar crypt. Primary tonsillitis usually occurs in young, small-breed dogs that exhibit clinical signs of malaise, gagging cough with retching, fever, and inappetence. Inspection will often reveal a bright-red tonsil with an associated pharyngitis ([Fig. 88-2](#)). Punctate hemorrhages on the tonsil and purulent exudate in the tonsillar crypt may also be visible. The tonsil will be friable and will easily bleed on manipulation. Tonsillitis is not always associated with gross enlargement of the tonsil; in fact, the benign appearance of the tonsil in some cases may be in sharp contrast to the severity of clinical signs. Specific bacteria associated with primary tonsillitis have not been studied.

Fig 88-2 Tonsils are protruding and hyperemic in a dog with tonsillitis. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Tonsillitis most commonly occurs secondarily to a preexisting disease process. Primary diseases commonly associated with a secondary tonsillitis include chronic vomiting or regurgitation, chronic gingivitis or periodontitis, tracheobronchitis, and nasopharyngeal irritation caused by rhinitis.

Inflamed swollen tonsils are not an absolute indication for treatment. Elimination of preexisting problems usually results in resolution of the tonsillitis. If clinical signs are severe or persistent, then broad-spectrum antibacterial therapy for 10 to 14 days should be considered. Tonsillectomy is indicated when primary tonsillitis is a recurrent problem or hyperplastic tonsils protrude from the crypts, causing mechanical interference with breathing and swallowing.

Primary pharyngitis is uncommon but may occur concurrently with tonsillitis. Pharyngitis is usually a secondary problem as part of a widespread oral or systemic disease. Pharyngitis often accompanies viral or bacterial upper respiratory tract infections, pharyngeal foreign bodies, and retropharyngeal abscesses. Treatment is aimed at underlying diseases, such as removal of foreign bodies or surgical drainage of abscesses. Broad-spectrum antibacterial therapy may be used for 7 to 14 days.

88.2.4 Laryngitis

Laryngitis usually occurs as part of a widespread viral or bacterial respiratory infection such as canine tracheobronchitis or feline rhinotracheitis. Other common causes of acute noninfectious laryngitis are trauma to the larynx during endotracheal intubation and prolonged barking or dyspnea. Treatment is aimed at the coexisting infectious problem.

88.3 LOWER RESPIRATORY TRACT INFECTIONS

88.3.1 Tracheobronchitis

Canine infectious tracheobronchitis (“kennel cough”) is a highly contagious respiratory disease of dogs and is characterized by coughing. This syndrome is associated with a wide variety of viral, mycoplasmal, and bacterial agents. The diagnosis is usually made based on history and physical examination alone. [Chapter 6](#) discusses this syndrome in detail. *Bordetella bronchiseptica* is the bacterial pathogen that can be a primary respiratory pathogen in dogs without accompanying viral or *Mycoplasma* infection.^{8,70,82} In cats, controversy exists about whether *B. bronchiseptica* is a primary or secondary pathogen, and although the organism has been associated with tracheobronchitis, conjunctivitis, rhinitis, and pneumonia, many culture-positive cats are clinically healthy (see [Chapter 16](#)). Of interest, an association between elevated culture positivity in cats (usually displaying minimal clinical signs) and contact with dogs with kennel cough has been identified, leading to speculation of interspecies transmission and the role cats may serve in maintaining the organism in the environment.^{10,40}

Human infections with *B. bronchiseptica* have been reported,⁴⁰ although the organism has a preference for infecting animals, and *B. pertussis* and *B. parapertussis* cause whooping cough in people (see Public Health Considerations, [Chapter 6](#)).^{100,148} When human infections with *B. bronchiseptica* occur, they are often acquired through animal contact.

Widespread resistance of *B. bronchiseptica* isolates to cephalosporins and ampicillin has been reported⁴⁰; therefore routine, indiscriminant use of antibiotics for all dogs with kennel cough should probably be avoided to minimize antibiotic resistance. If antibiotics are administered, those not active against *B. bronchiseptica* (see

869

870

Infectious Diseases of the Dog and Cat, 3rd Edition

previous discussion) and those achieving low concentrations in airway tissues and fluids (e.g., amoxicillin-clavulanate and gentamicin administered parenterally) should be avoided.⁷⁰

88.3.2 Chronic Bronchial Disease

The role of primary bacterial infections in initiating chronic bronchitis has not been determined. More commonly, chronic inflammation of the lower airways results in secondary bacterial infection. Severe bronchiolitis obliterans and organizing pneumonia has been observed in a dog.¹¹⁰ Although infectious agents can cause this syndrome, toxic or irritant causes have been suspected. Bronchitis and bronchiolitis has been reported in a cat caused by cilia-associated respiratory bacillus-like organisms.¹¹³ These silver-staining organisms were found in close parallel arrangement in association with mucosal cilia and the presence of airway inflammation. In dogs, chronic bronchitis leads to bronchiectasis. Bronchiectasis is more prevalent in certain breeds such as the American cocker spaniel, West Highland white terrier, miniature poodle, Siberian husky, English springer spaniel, and dogs over 10 years of age.⁵⁶

Clinical signs of chronic bronchial disease in dogs are a chronic cough of 2 months or longer without signs of respiratory distress or tachypnea. Unlike pneumonia, constitutional signs of inappetence, weight loss, nasal discharge, or mental depression are usually absent. Thoracic radiographic abnormalities are either absent or consist of interstitial or peribronchial infiltration, or both. Cytologic abnormalities of increased airway mucus without hemorrhage have been characterized by increased neutrophils with occasional degenerate, occasional bacteria, and increased eosinophils in some dogs.⁵⁶ Culture results of airway washings usually yield a low number of a variety of bacterial agents. Quantitative bacterial cultures of bronchoalveolar lavage fluid are recommended to differentiate between airway colonization and infection. In dogs, chronic bronchitis is not commonly associated with clinically relevant bacterial growth when quantitative bacterial cultures and cytologic examination of lavage fluid is performed.¹⁰⁸ The role of infection in feline bronchial disease is poorly defined. Culture results of tracheal and bronchial exudates of clinically healthy cats often reveal a mixed pattern of low numbers of organisms (fewer than 5×10^3 organisms/ml), which probably reflect airway contamination rather than infection when greater than 10^5 organisms/ml is expected (see Table 88-4).¹⁰¹ The role of *Mycoplasma* is intriguing because these organisms can be isolated in airway washings from cats with chronic bronchial disease^{21,105} but not in those from healthy cats.¹⁰⁵ *Mycoplasma* degrade neural endopeptidase and prolong the effect of substance P, a potent bronchoconstrictor,¹²⁵ which may be involved in feline asthma, although this has yet to be proven. Bacterial infection may damage airway epithelium, resulting in chronic inflammation. In rare cases, cycles of repeated infection and inflammation in cats can lead to bronchiectasis and emphysema as a sequelae.⁹⁷ Bronchiectasis in dogs, as a result of and a contributor to infection, has also been described.^{53,108}

88.3.3 Bacterial Pneumonia

88.3.3.1 Etiology

Many infectious agents cause pulmonary parenchymal inflammation (Table 88-5) (Fig. 88-3, A and B). This section focuses on bacterial infections; information on other infections can be found in their respective chapters. Bacteria enter the lower respiratory tract primarily by inhalation or aspiration of aerosols, oropharyngeal flora, foreign materials, or gastroesophageal contents; by local extension; or by hematogenous spread of extrapulmonary infections. Normal clearance mechanisms are generally effective unless the

Infectious Diseases of the Dog and Cat, 3rd Edition

inoculum is greater than 10^7 organisms/ml or gastric acid is aspirated concurrently. Whether a respiratory infection will develop after bacterial colonization depends on the complex interplay of many factors, including size of the inoculum, virulence of the organism, and resistance of the host. Clinical conditions that predispose the animal to bacterial pneumonia include preexisting viral, mycoplasmal, or fungal respiratory infections; regurgitation, dysphagia, and vomiting; reduced levels of consciousness (stupor, coma); severe metabolic disorders (diabetic ketoacidosis, uremia, hyperadrenocorticism); thoracic trauma or surgery; immunosuppressive therapy (anticancer chemotherapeutic agents, glucocorticoids); immunodeficiency diseases; neoplasia; and functional or anatomic disorders (tracheal hypoplasia, primary ciliary dyskinesia).

a See Tables 88-4 and 88-6 for additional isolates.

For aspiration pneumonia, risks are increased by recumbency or sedation, nasogastric or endotracheal intubation, debilitation, and esophageal or neuromuscular paralysis. Other factors are mechanical ventilation, concurrent illness, old age, and abdominal or thoracic surgery.⁶⁶

Bacterial pneumonia is more common in the dog than it is in the cat. Of the primary bacterial pathogens, *B. bronchiseptica* appears to be the most common organism implicated in canine pneumonia. *Streptococcus zooepidemicus* may also be a primary pathogen (see Group C Streptococcal Infections, Chapter 35). Most isolates in dogs with pneumonia are thought to be opportunistic invaders, the most common of which are

870

871

Infectious Diseases of the Dog and Cat, 3rd Edition

staphylococci, streptococci, *Escherichia coli*, *Pasteurella multocida*, *Pseudomonas* spp., and *Klebsiella pneumoniae* (Table 88-6).¹³² A single pathogen is isolated in the majority of cases, but mixed infections are common. Gram-negative isolates predominate in both single and mixed infections.

Fig 88-3 Lungs from dogs with bronchopneumonia. Surface (A) and cross section (B) of lung lobes showing inflammation and exudation. (Courtesy Veterinary Pathology, University of Georgia, Athens, Ga.)

Less is known about bacterial pneumonia in cats, in part, because cats with pneumonia may not show clinical signs and may lack abnormalities on hemograms and thoracic radiography.⁷⁹ In fatal pneumonia of cats, the bacterial species isolated included *Streptococcus canis*, *P. multocida*, *E. coli*, *Fusobacterium* spp., *Pseudomonas* spp., *Bacillus* spp., *Enterobacter cloacae*, *Enterococcus* spp., β -hemolytic *Streptococcus*, *B. bronchiseptica*, Eugonic fermentor-4a, *Peptostreptococcus* spp., and *Porphyromonas* spp.⁷⁹ As in dogs, single isolates were most common, but mixed infections were also seen.

88.3.3.1.1

B. bronchiseptica

This upper respiratory tract inhabitant is the most common bacterial agent associated with tracheobronchitis in dogs and can cause pneumonia and bacteremia (Figs. 88-4 and 88-5). *B.*

bronchiseptica can be a significant cause of pneumonia and mortality in kittens.^{142,146} However, in a recent study evaluating bacterial growth from lower airway cultures in 133 client-owned cats with respiratory disease, *B. bronchiseptica* was not found to be a significant pathogen.¹²⁸ For further information on lower respiratory tract disease caused by this organism in dogs and cats, see Chapters 6 and 16, respectively.

88.3.3.1.2

Streptococcus

As facultatively anaerobic gram-positive cocci, they are isolated from tracheal washings in 14% to 47% of dogs with pneumonia. Although less pathogenic α -hemolytic strains have been isolated, the predominant pathogens are β -hemolytic, with groups C and G being most important in dogs and cats (see also Chapter 35). Some virulence factors identified for hemolytic group A streptococci, which affect people, are capsular polysaccharides, surface protein A, and pneumolysin, a toxin that inhibits cilia, disrupts the alveolar capillary barrier, and interferes with neutrophil chemotaxis and lymphocyte function. Some of these factors are probably important in animal infections. In addition, nonvirulence products include

Infectious Diseases of the Dog and Cat, 3rd Edition

neuraminidases that promote attachment, immunoglobulin proteases, adhesins, erythrogenic toxins, hyaluronidases, streptokinases, and streptolysins.¹⁴

Once streptococci reach the alveoli, development and progression of pneumonia depend on virulence factors of the offending agent. With the most virulent strains, vascular leakage and edema are mediated by pneumolysin and hyaluronidase. This fluid exudation facilitates spread of organisms throughout lung lobes. Less virulent strains damage some type 1 epithelial cells, whereas more virulent strains denude large areas of the epithelial surface from the basement membrane. More extensive epithelial loss results in type 2 pneumocyte proliferation and fibroplasia, leading to permanent pulmonary scarring.

Infectious Diseases of the Dog and Cat, 3rd Edition

Severe pneumonia with high mortality associated with group C streptococci has been reported in dogs, usually secondary to concurrent viral infection. Many persistent streptococcal pneumonias occur in dogs with concurrent immunodeficiencies. Streptococcal pneumonias may be associated with hematogenous spread of infection to meninges, joints, kidneys, heart valves, spleen, lymph nodes, and other organs.

88.3.3.1.3

E. coli

These facultatively anaerobic bacilli are commensal flora of predominantly the lower gastrointestinal (GI) tract and are isolated from 17% to 43% of transtracheal washes from dogs with pneumonia. As gram-negative organisms, they contain endotoxin and can form antiphagocytic polysaccharide capsules and cell-injurious exotoxins. They also form fimbrial adhesins to bind to respiratory epithelial cells and siderophores, which allow them to compete for iron from the bound iron in host tissues and secretions.

E. coli usually enters the lower respiratory tract through aspiration from colonized nasal and oropharyngeal areas. In addition, bacteremic spread from the genitourinary or GI tract is possible but less frequently documented in dogs. Pneumonia has also occurred in dogs secondary to viral infections with long-term antibiotic or glucocorticoid therapy or with myelosuppressive or immunodeficiency diseases.⁷¹ Persistent pneumonias have involved mixed infections with other organisms in dogs with immunodeficiencies. Complications of *E. coli* pneumonia are dissemination of infection to other organs such as the meninges, joints, uveal tracts, or glomeruli; disseminated intravascular coagulation; and endotoxin-induced lung injury, resulting in acute respiratory distress.

88.3.3.1.4

Pasteurella

These facultatively anaerobic coccobacilli are isolated in up to 45% of transtracheal washings from dogs with pneumonia. *Pasteurella* are among the indigenous microflora of the nasopharynx and large airways of dogs and cats (see also Bite Infections, [Chapter 53](#)). Concurrent viral infections and other stresses to the host lead to proliferation and subsequent migration of *Pasteurella* to lower airways. Reduced defense mechanisms lead to impaired bacterial clearance from the lung, with resultant pneumonia. *Pasteurella* form adhesin, promoting their epithelial attachment, and polysaccharide capsule, which interferes with phagocytosis. Exotoxin production has not been documented as a feature of *Pasteurella* infections in dogs and cats, as is the case in other animals. However, gram-negative bacterial endotoxin decreases the quantity and increases the surface tension of pulmonary surfactant, altering pulmonary mechanics and gas exchange. Bacterial proliferation results in an influx of inflammatory cells and cytokine mediators, resulting in fibrinopurulent exudation typical of *Pasteurella* pneumonia. Once they develop, such pneumonias may be slow to resolve, and abscesses or pleuritis may develop.

88.3.3.1.5

Eugonic Fermenter-4

Group eugonic fermenter-4 (EF-4) is a collection of unclassified bacterial strains designated by the Centers for Disease Control and Prevention, Atlanta, Georgia. These bacteria, ecologically and culturally similar to *Pasteurella* spp., have been isolated as commensal and opportunistic flora from the oral cavity of dogs and cats (see [Table 89-1](#)) and from local infections in people as contaminating organisms of dog and cat bite wounds (see [Chapter 53](#)). The precise means by which EF-4 organisms produce respiratory, local, or systemic infections is unknown. Localized infections in dogs and cats have involved primarily cranial infections such as keratitis, retrobulbar abscess, otitis, sinusitis, and stomatitis. Infections probably arise as a result of contamination from the oropharyngeal area. Gingivitis has commonly been recognized

Infectious Diseases of the Dog and Cat, 3rd Edition

in cats that develop EF-4 infection.^{79,143} When pneumonia develops, inhalation or hematogenous dissemination of the organism from an oral site is suspected. Concurrent immunosuppression may be important for the organism to colonize other regions of the body.

Both domestic^{36,65,84} and exotic^{38,76,109} cats and domestic dogs^{84,138} have been affected.²⁵ Anorexia, hypersalivation, and dyspnea have been the main clinical signs of respiratory infection. Sudden death, with or without premonitory signs, has been noted in some cases. Abdominal distention from exudative peritonitis was noted in one puppy. An epizootic outbreak of fatal pneumonia was identified in a closed research colony of cats.¹⁴³

Diagnosis has been made primarily by culture of the abscess wounds at necropsy. The organism can be cultivated on blood agar, incubated aerobically or anaerobically, and classified by its biochemical reactions. In a few cases in cats, premortem leukopenia and nonregenerative anemia have been found. Multifocal nodular abscess formation is the typical pathologic finding in the lungs. The lesions are grossly indistinguishable from multifocal neoplasms or granulomas. Extrapulmonary lesions have included similar multifocal abscesses in the liver, peritoneal cavity, and lymph nodes. The abscesses are histologically characterized by neutrophilic and mononuclear infiltrates sometimes surrounding visible colonies of gram-negative bacteria.

Therapy for this type of infection is unknown but can be expected to be similar to that for plague (see [Chapter 47](#) and [Table 47-1](#)).

88.3.3.1.6

Bergeyella (Weeksellia) zoohelcum

This organism, which is a microfloral resident of the oropharyngeal region of dogs and cats, has been linked to respiratory infection in a cat.³³ A 9-month-old cat developed oculonasal discharge that did not respond to therapy with amoxicillin-clavulanate or doxycycline. Weight loss and lower respiratory tract signs of anorexia, dyspnea, and harsh ausculted lung sounds were present. Temporary improvement was observed with treatment of marbofloxacin and prednisolone; however, the cat became anorectic and was euthanized. Of the antibacterials used for treatment, in vitro susceptibility testing of the organism indicated resistance only to tetracyclines. Necrotizing upper and lower respiratory tract infection was found. Infections by this organism have been primarily in people with infected bite wounds caused by dogs or cats (see [Chapter 53](#)).

88.3.3.2

Pathogenesis

Bacteria enter the distal airways and alveoli and elicit phagocytosis by resident alveolar macrophages, as well as neutrophilic recruitment. Virulence of organisms is important in their colonization and persistence in respiratory tissues. Adherence of organisms occurs through specific binding of ligands or adhesins to complementary receptors on mucosal surfaces. Bacterial pili are adhesive structures, whereas cell surface glycoproteins, glycolipids, and proteoglycans are the cell receptors.^{19,112} In addition to attachment of organisms to respiratory surfaces, failure of host defenses such as mucociliary clearance is a primary mechanism that contributes to infections of the upper respiratory tract and bronchi. The mucosal surface is covered by a thin mucous layer that is propelled toward the larynx at up to 1 cm/minute by ciliated epithelial cells. Mucus reaching the larynx is usually swallowed or sometimes expectorated. Some pathogenic bacteria, such as *Pseudomonas aeruginosa*, *B. bronchiseptica*, *Mycoplasma pneumoniae*, coagulase-positive staphylococci, and β -hemolytic streptococci, interfere with ciliary movement or affect respiratory epithelial

Infectious Diseases of the Dog and Cat, 3rd Edition

function.⁶³ Some organism by-products act on neutrophils, which produce ciliastatic hydrogen peroxide. Viruses such as canine distemper virus, canine parainfluenza virus type 2, and canine adenovirus-2 damage ciliated epithelial cells, resulting in decreased mucociliary clearance and secondary bacterial infections.

Mucociliary clearance requires functional cilia and appropriate levels and consistency of mucus, which is formed of glycoproteins, glycolipids, and other proteins. Two active ion transport mechanisms adjust the level of periciliary fluid to maximize the mucociliary clearance.¹³ Bacterial infection makes mucus more voluminous, less compliant, and more difficult to propel the embedded bacteria, which remain stationary.^{47,126}

Bacterial pneumonia after aspiration of contaminated materials occurs frequently as a nosocomial event from intubation associated with surgery or after recovery from anesthesia. Disorders that predispose patients to aspiration are swallowing impairment, laryngeal paralysis, megaesophagus, hiatal hernia, and regurgitation or vomiting from any cause. Conditions such as periodontal disease and intestinal stasis also increase the bacterial load in aspirated GI secretions.

88.3.3.3

Clinical Findings

History and clinical signs of canine bacterial pneumonia include cough (usually moist, productive), variable fever, dyspnea, serous or mucopurulent nasal discharge, inappetence, depression, weight loss, and dehydration. Auscultation usually reveals abnormal lung sounds, including increased intensity of bronchial breath sounds, crackles, and wheezes. Other physical examination abnormalities include tachypnea, weakness, exercise intolerance, and productive coughing. Aspiration pneumonia should be suspected in any animal that develops these signs while hospitalized or after episodes of vomiting or regurgitation.

In contrast to dogs, cats with pneumonia often lack clinical signs, especially cough. In a study of cats with fatal infectious pneumonia (of which 54% were bacterial in origin), 36% lacked clinical signs referable to the respiratory tract.⁷⁹ Of the cats displaying respiratory signs, tachypnea or dyspnea and nasal discharge were most common; cough was present only in 8%. Systemic signs of illness (anorexia, lethargy, and fever) were absent in 41% of these cats, despite histologic evidence of disseminated infectious disease in 74%. A high index of suspicion for pneumonia is required in cats, especially if evidence of infection exists in other organs. In a review of 21 cases of lower respiratory tract infection in cats that were not all fatal, signs were chronic cough (11), acute cough (6), dyspnea (2), anorexia (1), and neurologic signs (1).⁴⁵

88.3.3.4

Diagnosis

In dogs, the diagnosis of bacterial pneumonia is suspected based on history and physical examination and is confirmed by hematologic findings, thoracic radiography, and microbiologic and cytologic examination of material from the tracheobronchial tree or lung. A neutrophilic leukocytosis with a left shift is frequently found on a complete blood count (CBC), but may be present in a low percentage of dogs. Arterial blood gas values correlate well with the degree of physiologic disruption in patients with bacterial pneumonia and are sensitive monitors of progress during treatment. Thoracic radiographs reveal an alveolar pattern characterized by increased pulmonary density in which margins are indistinct and in which air bronchograms may be seen (Fig. 88-6). A patchy or lobar alveolar pattern will be present in a cranial ventral lung lobe distribution.

Infectious Diseases of the Dog and Cat, 3rd Edition

In cats with infectious pneumonia, clinical signs, results of a CBC, and findings on thoracic radiography may not be abnormal.⁷⁹ When hematologic abnormalities are present, leukocytosis or leukopenia, neutrophilia, and left shift have all been reported. Thoracic radiographic abnormalities can include pulmonary infiltrates characterized by mixed bronchointerstitial or bronchoalveolar patterns or alveolar or interstitial patterns. Interstitial patterns are more typically a result of chronic bronchitis (see later discussion) or, as is the case in cats, caused by pulmonary fibrosis.²⁴ Although infections with certain pathogens may result in pulmonary fibrosis, the idiopathic form may be caused by a metabolic defect in type II pneumocytes.¹⁴⁵

873

The definitive method of establishing a diagnosis of bacterial pneumonia is to obtain aspirates, washings, or brushings for microbiologic and cytologic examinations. Multiple procedures that bypass the oropharynx have been recommended to obtain these specimens. Blood cultures can also be helpful in identifying the etiologic agent causing bacterial pneumonia. In cases in which radiography, cytology, and culture fail to provide a definitive diagnosis (generally when secondary bacterial infections complicate an underlying interstitial lung disease or neoplastic process), histologic examination of the lung may be necessary.^{95,96} Thoracic surgery may also be necessary for removal of a nidus of infection, for example, with foreign body pneumonia.

874

88.3.3.4.1

Transtracheal Aspiration

Because animals are unable to expectorate sputum, and because it bypasses the oropharyngeal area, the method of transtracheal washing and aspiration is safe, simple, and clinically valuable for obtaining tracheobronchial and pulmonary material for culture and cytologic examination. The technique is well tolerated by most large dogs and requires only minimal restraint of the unanesthetized patient. Small dogs and cats tolerate endotracheal washings better.

Fig 88-6 Radiograph of lung of dog with severe bronchopneumonia.
(Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 88-7 **A**, Placement of catheter for transtracheal wash at area of surgical preparation. **B**, Diagram showing position of catheter in the trachea. (Courtesy University of Georgia, Athens, Ga.)

Materials needed to perform transtracheal aspiration are listed in Table 88-7. Sedation is not required in most dogs, with the exception of the hyperexcitable miniature and toy breeds, for which narcotics are the drugs of choice. The animal is allowed to sit or is placed in sternal recumbency with its neck extended. The area of the larynx is clipped and scrubbed as for surgery. The cricoid cartilage, identified by palpating the tracheal rings from the midcervical region toward the larynx, is the first prominent ventral ridge at the larynx. Cranial to the cricoid cartilage and between the thyroid cartilages is the cricothyroid ligament. From 0.5 to 1 ml of 2% lidocaine is injected subcutaneously over the cricothyroid ligament. The needle and catheter are then directed caudoventrally through the skin and cricothyroid ligament into the larynx in a single motion (Fig. 88-7, A). In larger dogs, the catheter can be inserted into the lower regions of the trachea between cartilage rings to facilitate recovery of flushing solutions. The catheter is passed into the trachea, and the needle is withdrawn from the larynx (see Fig. 88-7, B). The needle guard is then applied to prevent the catheter from being cut by the needle. Paroxysms of coughing can be expected as the catheter is passed into the trachea.

874

875

Table 88-7 Materials Required for Performing Transtracheal Aspiration

16-gauge × 12-inch through-the-needle IV catheter ^a or 19-gauge × 8-inch through-the-needle IV catheter ^b (for small dogs and cats)
Clippers
Surgical scrub
1 ml of 2% lidocaine
20-ml syringe
Sterile water or saline (nonbacteriostatic)
Surgical gloves (optional when using a through-the-needle catheter)

a BD Intracath™, 16 gauge, 12 inch; Bard Biomedical, Murray Hill, N.J.

Infectious Diseases of the Dog and Cat, 3rd Edition

b BD Intracath™, 19 gauge, 8 inch; Bard Biomedical, Murray Hill, N.J.

A syringe generally containing up to 15 to 20 ml of sterile, nonbacteriostatic saline is attached to the catheter and injected. As the animal coughs, suction is applied with the syringe. Resistance suggests that tenacious secretions are being collected in the catheter. If only air is aspirated, the syringe is disconnected, the air is expelled, and another 15 to 20 ml of fluid is injected and reaspirated. This procedure is repeated until respiratory secretions, which will appear as a cloudy fluid, are aspirated into the syringe. Up to 1 ml/kg of solution can be safely injected into the airway during a single flush without causing significant respiratory insufficiency. The largest amount of aspirate will be collected when the animal is coughing. When the specimen has been obtained, the syringe is detached and capped to prevent contamination. The catheter is removed and a light bandage is applied to prevent subcutaneous hemorrhage or emphysema. The specimen is mixed in the syringe and divided into aliquots for cytologic and microbiologic examination (see later discussion).

Although complications from transtracheal washing and aspiration are uncommon, the procedure is not without risk. As is the case with the majority of invasive diagnostic procedures, risk is significantly decreased with experience. The procedure is considerably more difficult in cats and small dogs than it is in larger dogs. Transtracheal washing should not be attempted in the fractious or uncooperative patient without adequate chemical and manual restraint.

The most common complication associated with transtracheal washing is subcutaneous emphysema, which occurs when persistent coughing or dyspnea causes air to leak from the puncture site into the cervical subcutaneous tissues. Other complications include endotracheal hemorrhage, tracheal laceration, cardiac arrhythmia, and infection at the puncture site.

88.3.3.4.2

Endotracheal Wash

This technique involves general anesthesia and short-acting barbiturates. After endotracheal intubation with a sterilized endotracheal tube, a polypropylene urinary catheter is passed down through the lumen to the level of the carina. Two or more 10- to 15-ml aliquots (up to 5 ml/kg/aliquot in cats and small dogs) of sterile 0.9% saline solution are administered through the catheter, each followed immediately by aspiration attempts. Several advantages have been noted: washings can be obtained without producing tracheal injury and minimal equipment is needed, and it is technically simpler to perform in cats and small dogs. Disadvantages are oropharyngeal contamination, as is the case for bronchoscopy (see later discussion), and airway visualization is not possible.

88.3.3.4.3

Bronchoalveolar Lavage: Blind Technique

This technique is performed using general anesthesia with or without the aid of an endoscope.⁵⁸ A blind technique can be used without an endoscope by positioning the animal in lateral recumbency and placing a single-lumen endotracheal tube just rostral to the carina. The cuff is inflated, and a syringe adaptor is connected to the end of the tube. Aliquots (5 ml/kg) of warmed sterile 0.9% saline are infused via syringe. Immediately after each aliquot, mild suction is applied to the syringe. The animal is tilted with its head lowered and caudal end elevated to assist in fluid recovery. The syringe is immediately disconnected after the fluid is taken, and 100% oxygen is given through the endotracheal tube for 5 minutes. Alternatively, in cats and small dogs, a 7-French polypropylene catheter can be introduced through the endotracheal tube until it is wedged (i.e., until gentle resistance is felt). Saline is lavaged through a syringe attached to the polypropylene tube and gently reaspirated.

Infectious Diseases of the Dog and Cat, 3rd Edition

88.3.3.4.4

Bronchoalveolar Lavage: Bronchoscopic Technique

Tracheobronchoscopy is valuable for direct visualization of the airways and for obtaining brush catheter specimens for cytologic and microbiologic examination. The procedure requires that the patient be maintained under general anesthesia, which may be of concern in those with bacterial pneumonia. Intravenous anesthetic agents and a speculum will allow a thorough tracheobronchial examination with a rigid bronchoscope passed through the mouth. Brush catheters and suction cannulas may be passed through the lumen of the rigid bronchoscope to obtain specimens.

The transoral approach with a flexible fiberoptic bronchoscope inserted through an endotracheal tube is preferred. The patient is anesthetized, using standard procedures, intubated, and maintained on inhalation anesthesia or an intravenous anesthetic. An endotracheal tube T-adapter allows oxygen and anesthetic gas to flow without leakage to the patient while allowing placement of the flexible endoscope through the endotracheal tube. This technique is successful in moderate- to large-sized dogs during lengthy procedures. Small dogs and cats are given an intravenous anesthetic, and a flexible or small-diameter rigid fiberoptic endoscope is passed directly into the trachea and wedged in a terminal bronchus. During wedge lavage in cats and small dogs, oxygen may be infused alongside the bronchoscope through a 5-French diameter tube. Brush catheters are passed through the biopsy channel of the endoscope to obtain specimens.

Because of contamination from the oropharynx, bacterial cultures obtained with sterile, open-end, brush-in-catheter systems passed through the endoscope have been considered unreliable in the past. A commercially available catheter (Microbiology Specimen Brush, Microvasive Inc., Milford, Mass.) that enhances the ability to obtain reliable cultures of lower airway secretions through a bronchoscope has been developed. This system consists of a sterile brush contained within a telescoping double catheter occluded by a polyethylene glycol plug. This system is passed through the instrumentation channel of the bronchoscope. The brush is extended into the secretions to be cultured and then retracted into the inner catheter. The entire brush-in-telescope, double-catheter system is removed from the endoscope. The brush is advanced out of the catheter where the wire is transected with sterile scissors. The brush is placed in trypticase soy broth. The only disadvantage is the expense of a catheter system that can be used only once.

The advantages of tracheobronchoscopy are numerous when compared with other diagnostic techniques. Endoscopy allows the direct visualization of the tracheobronchial tree and the lesions associated with bacterial pneumonia, thereby allowing a better assessment of the patient's clinical status and prognosis. The cytologic preparations collected by bronchoalveolar lavage through the endoscope are superior to those obtained by transtracheal washing because cells and proteinaceous materials are obtained from the deeper portions of the lungs.⁵⁷ Quantitating bacteria obtained by airway washings is needed to distinguish lower airway contamination from actual infection. Bronchoalveolar lavage (BAL) quantitative cultures and quantitating intracellular bacteria on Gram-stained BAL cytologic specimens has been useful in identifying lower respiratory tract infections in dogs.¹⁰⁸ In this procedure, 10 to 25 ml of sterile saline were flushed into and withdrawn through the biopsy channel of a freshly rinsed bronchoscope with its tip wedged in the airway at the site of visible inflammatory changes. Bacterial colony counts of at least 1.7×10^3 CFU/ml of BAL fluid were considered significant. Correspondingly, more than two intracellular bacteria, visualized after examining 50 microscopic fields, was also considered indicative of lower airway infection. Dogs with chronic bronchitis had no evidence of bacterial infection using these criteria. When indicated, transbronchial biopsy specimens may also be taken, although these are not without risk.

875

876

Infectious Diseases of the Dog and Cat, 3rd Edition

88.3.3.4.5 Fine-Needle Lung Aspiration

Transthoracic fine-needle aspiration can be used to procure material for microbial culture and cytologic examination directly from the lung. Fine-needle aspiration may be more beneficial than lavage is (especially tracheal washings and blind BAL) when focal lesions are present and should be considered before employing more aggressive diagnostics, such as a thoracotomy. The fine-needle aspiration techniques (blind, ultrasound-guided, or fluoroscopically guided), indications, contraindications, and complications have been reviewed elsewhere.³² The fine-needle method has much less risk compared with transthoracic “true-cut” needle biopsy, which can cause severe pulmonary hemorrhage or pneumothorax. Using the fine-needle method, specimens can generally be classified as being neoplastic, inflammatory, or nondiagnostic. The recommended size of the needle is 25 or 27 gauge and 1.5 inches in length. The needle is advanced into the lung and moved in and out several times before gentle suction is applied with a 6-ml syringe.

88.3.3.4.6 Cytologic and Microbiologic Examination

Preparation of material for cytologic evaluation can be done using several methods. Visible strands of exudate may be teased onto a microscope slide, smeared, and stained. Small quantities of material can be centrifuged and smears made of the sediment. New methylene blue wet mounts and Wright-Giemsa's or Gram's stain of air-dried smears can be used for identification of cellular elements and bacteria. Bacterial infections are associated with degenerate neutrophils and intracellular bacteria; excess mucus, proteinaceous material, and activated alveolar macrophages may be present. Bacteria are demonstrable only in fraction of washings from pneumonic animals, and their absence in cytologic specimens, especially if the patient has been placed on antibiotic therapy, does not rule out bacterial pneumonia.

All collection methods of airway washings can be associated with pharyngeal contamination. This explanation answers the question as to why many lower airway washings contain artifact, resident nasopharyngeal microflora. Pharyngeal contamination is detected by the presence in cytologic preparations of squamous epithelium or *Simonsiella* (*Caryophanon*), a characteristic genus of oral bacteria, which appears as “stacked coins.”

Because of the delay in bacterial culture, the organisms are classified as being rods or cocci or other recognizable bacterial or fungal elements. Anaerobes, *Actinomyces*, and *Nocardia* are often larger, pleomorphic, or filamentous. Acid-fast staining will help detect *Nocardia* or *Mycobacterium*. Additional staining may identify specific yeast or filamentous fungi (see [Chapter 56](#)). Mycoplasmas may be obtained if special media is used (see [Chapter 32](#)).

88.3.3.4.7 Bacteriologic Culture

An aliquot of aspirated material can be cultured directly for aerobic and anaerobic bacteria. Gram-negative organisms are most commonly cultured, whereas gram-positive and anaerobic bacteria and *Mycoplasma* are less commonly isolated. Secretions that coat the distal end of the catheter can be cultured if the amount of aspirated material is minimal. Sensitivity of transtracheal washing and aspiration for recovery of bacteria is good, but because larger airways may contain low levels of microflora, specificity for infection rather than contamination cannot be determined. For BAL specimens, quantitative cultures are recommended in conjunction with examination of a Gram-stained specimen to enhance diagnostic

Infectious Diseases of the Dog and Cat, 3rd Edition

sensitivity and specificity.¹⁰⁸ Clinically relevant bacterial growth in BAL specimens from dogs are over 1.7×10^3 CFU/ml of BAL fluid. Bacterial infection can also be diagnosed with microscopic examination of 50 fields on a Gram-stained slide revealing more than two intracellular bacteria.¹⁰⁸ False-negative results may be obtained if antimicrobial therapy has not been discontinued for at least 1 week before sampling.

88.3.3.4.8

Blood Cultures

Blood cultures have been recommended in people with bacterial pneumonia to help isolate the infectious agent. Documented bacteremia is also thought to be a poor prognostic finding. No studies in animals have been done that document the value of blood cultures in establishing a prognosis or isolating the bacterial agent in cases of pneumonia. Up to 50% of dogs with experimentally induced streptococcal pneumonia have been blood culture positive within 48 hours of onset of clinical signs.⁹⁰ Cats with histologically confirmed infectious pneumonia most commonly developed pneumonia from hematogenous spread; however, blood cultures were not performed in these cats.⁷⁹

88.3.3.4.9

Pulmonary Biopsy

Histopathologic evaluation of pulmonary tissue is the ultimate test to determine the underlying process within the lung parenchyma (Figs. 88-8 and 88-9). This assessment must be coupled with culture or histochemical tests to determine causative agents. Histopathology is most helpful in resolving causes of interstitial pneumonic processes because washings can frequently be productive in the alveolar diseases.

88.3.4

Aspiration Pneumonia

Aspiration of different materials can result in chemical pneumonitis, anaerobic abscesses, or classic bacterial pneumonia.⁶⁸ Inflammation in the lung that follows aspiration of gastric contents is more appropriately termed chemical pneumonitis. Fever, dyspnea, alveolar exudation, and pulmonary interstitial or alveolar infiltration are observed clinically. Bacteria are not always a feature of this syndrome because acidic gastric contents have low bacterial content. Inflammatory changes generally subside after 24 to 36 hours; however, if gastric pH has been increased by antacids or H₂-receptor antagonists, or if small intestinal obstruction or bacterial overgrowth exists, then bacterial loads can be increased. If oral cavity contents are inhaled, then the term aspiration is better referred to as anaerobic pneumonitis because the oropharyngeal microflora is composed of a large number of microaerophilic and anaerobic organisms, which may lead to pulmonary abscesses.⁶⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

88.3.5 Pulmonary Abscess

Pulmonary abscesses—necrotic areas of lung parenchyma containing purulent material usually produced by pyogenic infection—are uncommon in dogs and cats. Most of these abscesses arise from aspiration of oropharyngeal or gastric contents and are termed primary lung abscess. Secondary lung abscess results from a primary underlying process such as bronchial obstruction, septic or heartworm thromboembolism, airway parasite, foreign body, bullous emphysema, tuberculous cavity, or neoplasia. Obligate anaerobic bacteria are identified more frequently than aerobic bacteria are, but mixed infections are common. *Mycoplasma* spp. have also been recovered in cats.

The clinical signs in pulmonary abscess formation depend on the cause but closely resemble those of chronic bacterial pneumonia. Clinical findings include weight loss, chronic fever, cough, and hemoptysis. Hematologic findings include leukocytosis with a left shift, anemia, and rarely hypoproteinemia. An abscess will usually appear on a thoracic radiograph as an ill-defined pulmonary nodule or mass with or without cavitation. Radiographically, abscesses are often indistinguishable from granulomas, traumatic bullae, tumors, and pneumatocysts. If the lesion is close to the chest wall, ultrasound can be used to visualize the abscess, which will appear fluid filled. Cytologic examination of brushings or lavage fluid is consistent with a septic or nonseptic purulent exudate. Ultrasound-guided, fine-needle aspiration is not recommended for lesions suspicious for an abscess because of the risk of spreading the infection to the pleural cavity.

88.3.6 Therapy of Lower Airway Infections

Compared with treatment of upper airway infections, lower respiratory tract infections must be treated more aggressively. Systemically effective antimicrobials must be used. Drug penetration into consolidated lung tissues is more effective systemically than it is by topical (i.e., aerosol) means.

88.3.6.1 Antibiotics

Drug dosages for airway infections are summarized in [Table 88-8](#). Specific information on each drug is available in the Drug Formulary, [Appendix 8](#). Oral or parenteral antibacterials are the principal therapies for lower respiratory tract bacterial infections. Expecting any single antibacterial to be routinely effective against the wide variety of organisms causing bacterial pneumonia is unrealistic. The most important criterion for selection of an antibacterial is identification of the bacterial organism. Substantially more patients recover if antibacterial therapy is administered according to culture results and in vitro susceptibility testing than not.¹³² Morphologic characteristics of bacteria on a Gram-stained slide can aid in antibiotic choice until the results of bacterial culture and susceptibility have become available.¹⁰⁸ Cocci are usually staphylococci or streptococci. Rods are usually members of the family Enterobacteriaceae, which are most unpredictable with respect to antibacterial agents ([Table 88-9](#)).

Penetration of antimicrobial drugs into airway secretions and pulmonary tissues is favored by high lipophilicity and low molecular weight. Drugs enter normal bronchial secretions at a fraction of their serum concentrations. Trimethoprim, clindamycin, fluoroquinolone, erythromycin, and doxycycline enter in highest proportions. Penicillins have the lowest penetration; cephalosporins and aminoglycosides have intermediate distribution. With inflammation, penetrance is increased, but antibiotic distribution through the airway may be impaired in exudates.

Infectious Diseases of the Dog and Cat, 3rd Edition

The aminopenicillanic derivatives have a broader spectrum than penicillin, including activity against gram-positive, many gram-negative, and some anaerobic bacteria. *E. coli*, *Proteus*, *Klebsiella*, and *Pasteurella* are usually susceptible. Resistance is often present in *Enterobacter*, *Serratia*, and *Pseudomonas*. Resistance can be overcome in some instances by using a β -lactamase inhibitor such as clavulanate or sulbactam. Fluoroquinolones or aminoglycosides are recommended if resistant gram-negative infections are suspected. If cytologic information is not available, initial treatment with amoxicillin-clavulanate is recommended. Later therapy should be based on the susceptibility spectrum indicated by cultural results.

With severe clinical signs, respiratory distress, or evidence of bacteremia, intravenous therapy is recommended until the patient stabilizes. Levels of antibacterials in airway secretions after oral or parenteral administration are much lower than serum levels. Systemic antibacterials therefore should be administered in high doses for long periods so that maximum concentrations are reached in lung tissues and airway secretions.

For usually self-limiting tracheobronchitis, antibiotics are not usually indicated unless clinical signs persist for longer than 2 weeks, the dogs have a concurrent respiratory disease (e.g., collapsing trachea), or systemic signs of illness become evident. Of antibiotics administered for *B. pertussis*, high percentages of isolates are resistant to ampicillin and the first- and third-generation cephalosporins, with intermediate resistance to amoxicillin-clavulanate.⁴⁰ Macrolides (e.g., erythromycin, clarithromycin, azithromycin), fluoroquinolones, tetracyclines, chloramphenicol, and sulfonamides reach concentrations in airway tissues and secretions and should be considered as drugs of choice based on susceptibility testing.⁷⁰ For lower respiratory tract infections, treatment is generally recommended for at least 1 week beyond resolution of clinical illness or at least a 2-week minimum. With chronic bronchitis, or with bronchiectasis, treatment may be longer, or repeated cycles of antibiotic therapy may be indicated when a clinical relapse occurs.

877

Particularly severe or resistant gram-negative or anaerobic bacterial pneumonia must be treated parenterally with drugs such as the extended-spectrum penicillin, ticarcillin, combined with clavulanate. The combination is effective against gram-negative bacteria and anaerobes, as are imipenem-cilastatin or second- or third-generation cephalosporins. Aminoglycosides are effective against gram-negative organisms. Pneumonia secondary to bacteremia is often caused by gram-negative sepsis in immunocompromised people or animals. If clinical improvement occurs and blood culture results are negative after 4 days, parenteral therapy can be discontinued and oral therapy begun. Antibiotic therapy should be continued at least 1 week past the resolution of all clinical and radiographic signs of pneumonia.

878

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 88-8 Recommended Dosages of Antibacterial Drugs for Respiratory Disease

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOUR)
Amikacin	B	5.0–7.5 mg/kg	IV, IM, SC	12
	B	15 mg/kg	IV, IM, SC	24

Tobramycin ^f	B	2 mg/kg	IV, IM, SC	8
Trimethoprim-sulfonamide ^B	B	15 mg/kg	PO, SC	12

B, Dog and cat; D, dog; C, cat; IV, intravenous; IM, intramuscular; SC, subcutaneous; PO, by mouth.

- a For more information on all drugs, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval. Duration is for at least 1 week after clinical response is noted. Responses should be noted within 3 to 5 days, and therapy should continue for at least 14 days.
- c Also can substitute minocycline.
- d Also can substitute ciprofloxacin.
- e Highest levels for treating *Pseudomonas*.
- f Potentially nephrotoxic. Must monitor urine sediment and serum urea concentration.

Damage to the lung with aspiration pneumonia is not always caused by the development of bacterial pneumonia; damage from gastric acid can cause a chemical pneumonia, and inhaled food can lead to inflammation and airway obstruction. Compromise of local host immune defense mechanisms may

Infectious Diseases of the Dog and Cat, 3rd Edition

predispose the patient to secondary bacterial infections well after the initial noninfectious pneumonia has been initiated. Routine antibiotic use is therefore controversial. Because of the concern of developing bacterial resistance with indiscriminant antibiotic use, antimicrobials should ideally be delayed until secondary bacterial infection can be documented or until the animal fails to respond appropriately to other therapy for this condition (see later discussion). When infection plays a role in aspiration pneumonia, a multiplicity of aerobic and anaerobic organisms can be involved and combination antibiotic therapy may be required. Culture and susceptibility results should guide selection of the antibiotic. Prevention of aspiration pneumonia involves identifying predisposing risk factors and addressing them directly (e.g., megaesophagus, prolonged anesthesia, neurologic deficits). Aspiration can be avoided by keeping the patient's body positioned in sternal recumbency or by keeping the cranial part elevated and minimizing gastric volume by frequent feedings or keeping feeding tubes in the small bowel (i.e., jejunostomy tubes) rather than the stomach or esophagus. To prevent aspiration and infection during anesthesia, aspiration of oropharyngeal secretions, maintenance of a cuffed endotracheal tube, close monitoring during anesthetic recovery, and avoidance of cross-contamination between patients by using sterilized equipment are recommended.

Mycoplasmas	Doxycycline, chloramphenicol, gentamicin, fluoroquinolones, tylosin, clindamycin

a Consult Drug Formulary, [Appendix 8](#), for appropriate dosages and further information on each drug.

b Despite in vitro efficacy, metronidazole does poorly in treatment of anaerobic pulmonary infections because of the high oxygen tension in these tissues.

Pulmonary abscesses are seen with airway obstruction from severe infection, certain bacteria, such as *Actinomyces* or *Nocardia*, or from foreign material. Lung abscesses are usually initially treated without drainage but with long-term antibacterial therapy. Choice of antibacterials should be based on culture and susceptibility findings. Response to antimicrobial therapy may be temporary or incomplete, and relapse of fever and coughing can occur once treatment is discontinued, even after months of such treatment. Furthermore, evidence of a persistent pattern of alveolar consolidation may be apparent in thoracic radiographs. Bronchoscopy can be used to localize affected lobes and, if performed early, can be used to remove foreign material such as plant awns. With long-standing occlusion, scarring, and abscess formation, thoracotomy and lobectomy are indicated. Lobectomy is most effective in resolving pneumonias, and postoperative complications are least in pneumonias that are localized to individual lobes.⁹¹

Infectious Diseases of the Dog and Cat, 3rd Edition

88.3.6.2 Systemic Hydration

Maintenance of normal systemic hydration is an important therapeutic objective in patients with bacterial pneumonia. Dehydration hinders mucociliary clearance and secretion mobilization because normal respiratory secretions are more than 90% water.

Fig 88-10 Nebulization of antimicrobials for a dog with pneumonia. Note protective mask during therapy. (Courtesy University of Georgia, Athens, Ga.)

88.3.6.3 Airway Hydration

Airway hydration can be directly addressed using aerosol therapy to mobilize secretions by adding water to the mucociliary blanket. A nebulizer that produces particles between 0.5 and 3.0 μm ensures that water is deposited in the lower airways. Water vaporizers or humidifiers are inadequate because the water particulate size is larger and droplets are generally deposited in the nasal cavity. For nebulization, the animal is placed in an enclosed chamber, and a bland aerosol (normal saline) is nebulized into the chamber. Physiotherapy should always be performed immediately after aerosolization to enhance secretion clearance. Methods include increased cough frequency by chest wall coupage or tracheal manipulation, mild forced exercise, and postural drainage. The animal should be nebulized two or three times daily for 20 minutes per treatment. Because bronchoconstriction may develop, pretreatment with bronchodilators can be considered.

Antibiotics can also be administered by nebulization for dogs with infectious tracheobronchitis (Fig. 88-10). A recent study showed gentamicin at an average dose of 6.9 mg/kg diluted 1:2 with sterile saline given via an aerosol significantly decreased cough.⁸⁶ Routine intratracheal or aerosol administration of antibacterials is not recommended in pneumonia. With severe alveolar consolidation in pneumonia, airway penetration of antimicrobials is inferior to systemic administration. Furthermore, people performing the procedure must

Infectious Diseases of the Dog and Cat, 3rd Edition

take precautions to avoid inhaling the aerosolized drugs or avoid contact of the aerosols with their exposed mucous membranes.

88.3.6.4

Supportive Therapy

Animals with severe tachypnea, dyspnea, or marked hypoxemia (arterial oxygen tension under 60 mm Hg) require oxygen therapy. The early period of highest mortality with bacterial pneumonia corresponds to the period of greatest hypoxemia. The oxygen should be humidified to prevent drying of respiratory membranes. Oxygen can be administered in a cage, by intratracheal cannula or nasal catheter, or in intubated patients (with or without a mechanical ventilator). Drugs such as antitussives, diuretics, and antihistamines that inhibit mucokinesis and exudate removal from the respiratory tract are contraindicated with bacterial pneumonia. The use of systemic bronchodilators such as theophylline in animals with evidence of bronchoconstriction must be done with caution if chloramphenicol or fluoroquinolones are being used concurrently because these drugs increase the serum theophylline concentration. Terbutaline can be given at 0.01 mg/kg subcutaneously for emergency treatment of bronchospasm and acute respiratory distress. Cyproheptadine (2 mg, given orally, twice daily) has been administered in cats with bronchoconstriction that do not tolerate terbutaline.¹⁰³

a Fungi such as *Aspergillus*, *Blastomyces*, *Candida*, and *Cryptococcus* have been isolated from canine and feline pyothorax; however, no data are available.

88.4 PLEURAL INFECTIONS

Purulent pleuritis, pyothorax, and thoracic empyema describe septic processes of the pleural cavity resulting in exudate accumulation.

88.4.1 Etiology

Pleural infections are almost always polymicrobial in nature, a factor evident when comparing the cytologic findings and culture results. A high incidence exists of obligate anaerobic bacteria as sole pathogens or in combination with aerobic-facultative and other anaerobic bacteria. Obligate anaerobic bacteria and

Infectious Diseases of the Dog and Cat, 3rd Edition

gram-positive filamentous organisms such as *Nocardia* and *Actinomyces* are most commonly isolated from dogs with pyothorax (see [Chapter 49](#)). Isolation of *Actinomyces* has commonly been associated with grass-awn, foreign-body migration. *Actinomyces* and *Nocardia* have a filamentous appearance; however, these may be confused with *Filifactor villosus*, an anaerobic rod isolated from pyothorax in dogs and cats.^{78,140} The most common aerobic organism isolated in feline pyothorax is *Pasteurella*, although anaerobes are frequently cultured as well.^{139,140} Other bacterial, fungal, and yeast organisms isolated from pleural exudate of the dog and cat are summarized in [Table 88-10](#). Sources of bacterial pleural infections are not identified in most cases but include penetrating thoracic wounds (e.g., bite wounds); migrating foreign bodies (grass awns); esophageal perforation; hematogenous spread; lung parasites; extension from cervical, lumbar, mediastinal, or pulmonary infections; and iatrogenic causes.¹³⁹ Grass awns enter the oral cavity when animals are breathing hard during field training. The awns are barbed so that only antegrade movement is possible. They migrate down the bronchial tree carrying commensal microflora from the oropharyngeal cavity into the lung parenchyma. The awns exit the visceral pleura and enter the pleural cavity where they can cause pyothorax or migrate up the diaphragmatic crura to the sublumbar vertebrae.

88.4.2 Clinical Findings

Pyothorax most commonly occurs in young adult medium- to large-breed dogs, especially of working and sporting breeds.³⁴ The link with these breeds is thought to be associated with grass-awn inhalation during vigorous exercise. Risk factors for cats include young age and being part of a multiple-cat household but not male gender or indoor or outdoor status, as was previously reported.¹³⁹ Clinical signs result from restrictive respiratory disease, including increased respiratory rate, shallow respirations, dyspnea, and orthopnea. Other signs include depression, exercise intolerance, cough, lethargy, anorexia, weight loss, and fever. Physical examination reveals muffled heart sounds, decreased breath sounds, and hyperresonant (dull) percussion sounds, especially over the ventral portions of the thorax. Chronic or severe infections may result in a dehydrated, debilitated, collapsed, or hypothermic patient. Approximately one third of cats with pyothorax may develop signs of sepsis or systemic inflammatory response syndrome (SIRS) (see [Chapter 38](#)). Signs in cats with SIRS include rectal temperature above 39.7° C (103.5° F) or below 37.8° C (100.0° F); heart rate above 225 beats/minute or below 140 beats/minute; respiratory rate above 40 breaths/minute; and white blood cell count over 19,500/μl or below 5000/μl, or band neutrophils above 5%.¹³⁹ In cats, hypersalivation and bradycardia are associated with a worse clinical outcome.¹³⁹

88.4.3 Diagnosis

A diagnosis of pyothorax is confirmed by hematology, thoracic radiography, and thoracocentesis with cytologic evaluation and culture of pleural fluid. Neutrophilic leukocytosis with or without a left shift is the most common hematologic finding; however, in one report, only 56% of affected dogs and 36% of cats had this abnormality.³⁴ Leukogram results do not correlate with the severity of the underlying infection, however, and leukocyte counts within or lower than the reference range are found with some frequency. Biochemical abnormalities in some animals can include hypoalbuminemia, hyperglobulinemia, elevated hepatic enzyme activities, hyperglycemia or hypoglycemia, and azotemia.³⁴ Radiographic signs of free pleural fluid include increased hazy density of the lung fields (ventral portions of lung fields on lateral view), which obscures the cardiac silhouette; retraction of the lobar borders from the chest wall; visibility of the interlobar fissures; and rounding or filling of the costophrenic angles.

880

881

Infectious Diseases of the Dog and Cat, 3rd Edition

Cytologic evaluation of pleural fluid is usually consistent with septic or nonseptic exudates (Table 88-11). Degenerate neutrophils and mixed populations of bacteria are often observed. Cytomorphology of the neutrophil is most helpful for determination of whether pleural fluid should be cultured and for interpretation of the results of culture. Aerobic and anaerobic cultures of pleural fluid should be made, if available, regardless of whether bacteria are seen cytologically. Neutrophil degeneration may be observed in severe cases; however, the level of the neutrophil concentration can vary and does not always correlate with the severity of infection.

88.4.4 Therapy

Treatment of pyothorax should be prompt and aggressive. Initial goals include relief of respiratory embarrassment via thoracocentesis, appropriate fluid therapy, supportive care, and systemic antibacterials. If the animal dies during therapy, this often happens in the initial 48-hour management period of drainage and stabilization.³⁴ Drainage of pleural exudates and lavage are essential, as is the case for any accumulation of pus. Disadvantages of delay in pleural lavage are incomplete resolution of signs and formation of loculated abscesses and fibroses, which will necessitate later thoracotomy. Pleural drainage and lavage are achieved by tube thoracostomy. Advantages of closed chest drainage and lavage include avoiding frequent needle thoracocentesis, facilitating pleural fluid sampling to monitor therapeutic response, and allowing direct instillation of isotonic lavage fluid (+/- additives) into the pleural space (see later discussion). Disadvantages include maintaining drain placement and patency and risking pneumothorax and chest wall infection. Mortality appears to be higher in patients treated with multiple thoracocentesis and antibacterials than it is in those treated with tube thoracostomy alone. The average length of chest tube drainage is 3 to 7 days.

For tube placement, the patient is first given fluid therapy, and specimens for cytologic and microbiologic examination can be withdrawn for analysis by needle aspiration. After sedation with local anesthetic infusion or general anesthesia, a tube is placed in the intercostal space by tunneling under the skin a few interspaces and penetrating the pleura with the tube by hemostat or stylet. After fluid removal, radiographs should be taken to assess whether drainage is complete, especially on the contralateral side. If removal is incomplete, another tube may be required. The tubes are clamped and wrapped to prevent inadvertent air leakage into the pleural space. When available or practical, one-way continuous suction or intermittent suction every 2 hours may be applied. Fluid is infused through the tip of an intravenous administration set wedged firmly into the lumen of the tube's orifice. The clamp is used to control infusion rate. Fluid volumes for infusion are usually 100 ml for small dogs and cats, 500 ml for intermediate-sized dogs, and 1000 ml for large dogs. Lavage is continued for up to 7 days or until the removed fluid is clear of pus. This time interval can be as long as 21 days.³⁴ Cytologic improvement is exhibited by decreasing cell count, with loss of degenerative changes in neutrophils, and absence of bacteria.

Table 88-11 Characteristics of Pleural Fluid from Pyothorax

PARAMETER	REFERENCE CHARACTERISTICS	PYOTHORAX
Physical characteristics	Color: clear, transparent	Color: variable yellow to reddish-brown, opaque, flocculent; sometimes granules can be odorous
Cells	<500/ml	>7000/ml
Protein	<1.5 g/dl	>3 g/dl
Specific gravity	<1.017	≥1.025
Biochemistry of fluid	LDH activity and glucose concentration in reference blood range	LDH activity increased; glucose concentration decreased compared with blood ^a

^aLDH, Lactic dehydrogenase.

Infectious Diseases of the Dog and Cat, 3rd Edition

a These changes have been presently been documented in cats and people.

Although no scientific studies in dogs or cats evaluating the effect of saline lavage (with or without heparin or streptokinase) have been done, empirical data in dogs and cats and studies in the human literature suggest that under some circumstances, lavage may facilitate removal of accumulated pus and bacteria and break down clots and fibrin bands. Heparin levels within the infusate have not been studied, and in all likelihood, it is rapidly absorbed in the systemic circulation giving only temporary anticoagulation. Therefore subcutaneous administration (100 IU/kg) given every 8 hours may provide a more sustained and constant effect during the course of lavage treatment. Instilling proteolytic enzymes such as streptokinase to infusate when treating dogs has been associated with increases in body temperature,⁶⁰ presumably as a reaction to the foreign protein. The benefit of such enzymes has not been substantiated, and the cost is significant; therefore they are not recommended. The intermittent approach involves at least twice-daily instillation of intravenous saline into the pleural space with mild coughage followed by immediate removal of whatever fluid can be obtained (Table 88-12). Addition of antimicrobial agents to the lavage fluid is controversial, as is the case for most absorbable antimicrobials; this is just another means of parenteral administration. In one report, the mean lavage time of lavage was 6.3 days (range of 2 to 21 days) without added antimicrobials to a mean of 4.8 days (range of 4 to 6 days) with them added.³⁴ Ampicillin (5 mg/kg) or amoxicillin-clavulanate (7 mg/kg) or metronidazole (4 mg/kg), alone or in combination, were used as intrapleural drugs.

Systemic antimicrobial therapy can be considered concurrently, but it is *ineffective* without lavage or drainage of the infected pleural cavity (see Table 88-8). No single antibacterial agent will inhibit the wide variety of facultative and obligate anaerobic bacteria associated with pyothorax.¹⁴⁰ Penicillin or penicillin derivatives are often given because they are effective against obligate anaerobic, *Pasteurella*, and *Actinomyces* infections.

881

882

Table 88-12 Comparison of Methods of Managing Pyothorax

METHOD	ADVANTAGES	DISADVANTAGES
Systemic antimicrobial therapy	Inexpensive and noninvasive	Does not allow for drainage of fluid or necrotic debris. Reduced efficacy of resolving intrapleural infection caused by poor antimicrobial penetration into exudates.
Repeated thoracentesis, without lavage	Inexpensive, available to most practices	Higher risk of pulmonary trauma from repeated puncture, causing hemorrhage or pneumothorax. Does not flush out loculated material, and may leave nidus.
Periodic lavage via indwelling tubes	Less monitoring, more convenient for practice. Can instill lavage solutions and reach loculated areas. Easier to monitor appearance of chest fluid by repeated sampling.	May develop thoracic wall infection or fistula. Animal must be collared or drain wrapped (or both) to prevent its removal.
Continuous suction via indwelling tubes	Less daily lavage needed once therapy has been initiated.	High expense of continuous-suction apparatus. Same problems as for Periodic Lavage above, and continuous suction does not reduce time period for lavage treatments. Requires constant 24-hour monitoring of suction equipment.

Systemic antibacterial therapy should be continued for at least 4 to 6 weeks. Regardless of the anaerobic or facultative anaerobic bacteria that are cultured, the regimen should always contain drugs effective against anaerobes. Lack of significant improvement in fluid consistency during lavage, formation of lung abscesses,

Infectious Diseases of the Dog and Cat, 3rd Edition

repeated blockage of drainage tubes, recurrent pneumothorax, mediastinal masses, or radiographic evidence of fluid encapsulation are indications for surgical exploration or lobectomy. Surgical exploration allows for detection of foreign bodies, which are often incriminated as causing pulmonary infections and are often involved in persistent pulmonary abscesses that rupture, leading to pyothorax. Although surgical exploration is expensive, reports suggest that dogs having surgical exploration and Débridement have a better outcome following treatment compared with pleural lavage alone.¹¹⁶

Radiographic monitoring is essential during treatment and followup of pleural infections. Radiography has limitations in evaluating the type and extent of lung lesions in the presence of fluid. When finances are not limited, CT or mirror resonance may be more valuable in initially assessing the need for early surgical intervention. Ideally, radiographic reevaluation should be performed after the fluid is initially removed, when the chest tube is removed, immediately before discontinuing antibiotics, and 1 to 2 weeks after discontinuing antibiotics to monitor for subclinical recurrence of disease.

89 CHAPTER 89 Gastrointestinal and Intraabdominal Infections

Craig E. Greene

This chapter discusses bacterial and fungal infections of the GI tract, which cause alterations in native microflora. For specific infections regarding enteropathogenic viral, bacterial, fungal, or protozoal pathogens, see the respective chapters in this book.

89.1 ORAL CAVITY

89.1.1 Oral Microflora

The resident microbial flora of the canine and feline oral cavity are composed of a wide variety of aerobic bacteria and facultative and obligate anaerobic bacteria (Tables 89-1 and 89-2). In most studies, *Streptococcus* and *Actinomyces* are the most frequently reported bacteria that are not obligate anaerobes. The frequency with which individual species are isolated depends on culture methods, sampling sites, and breed and individual differences. From a clinical standpoint, bacterial culture of specimens from the oropharyngeal region is meaningless because of the diversity of commensal organisms and the lack of accurate quantitative methods. However, antimicrobial agents used in treating oral infections such as gingivitis and stomatitis should be chosen with the composition of the resident microflora in mind. Organisms found in bite-inflicted and soft-tissue wound infections (see Chapter 53), pleural (see Chapter 88), and peritoneal infections (see Intraabdominal Infections later) reflect the composition of the oral microflora.

89.1.2 Gingivitis and Periodontitis

Inflammation and recession of perialveolar gum margins are common findings in dogs and cats.²⁰³ They are initially caused by excessive accumulation of dental plaque resulting from deposition of by-products from breakdown of food and saliva by normal resident microflora. Plaque is an organic matrix of salivary glycoproteins and polysaccharides adhering to the tooth surface that provides sites for oral bacteria to proliferate. Microflora involved with supragingival and subgingival plaque in healthy mucosal sites in dogs are resident streptococci and *Actinomyces* species.^{119,120} At first, these gram-positive, nonmotile aerobic cocci and bacilli predominate. These bacteria produce a glycopolysaccharide referred to as a *glycocalyx*, which facilitates the attachment of other bacteria. This biofilm is further consolidated into a film, or plaque. Plaque accumulation results in inflammation of the gums. Plaque can become mineralized, resulting in calculus (tartar). As periodontal inflammation progresses with associated calculus formation, gram-negative motile, obligate anaerobic rods and spirochetes proliferate (Fig. 89-1).^{213,346} Pups have very few *Porphyromonas* species in their dental plaque; however, their numbers increase as the pup matures and inevitable periodontal disease develops.¹⁴¹ Early bacterial damage occurs in the gingival epithelial tissues with penetration of the interdental retes. Proliferating spirochetes may disrupt the intercellular junctions, creating a portal of entry for other bacteria.²¹³ Periodontal pathogens destroy the integrity of the dentition and oral mucosae and can also cause bacteremia or distant tissue embolization. Many of these bacteria possess proteolytic enzymes that allow them to colonize and invade periodontal tissues. Unfortunately, periodontal disease is irreversible, and damaged gum tissue cannot be restored to health. In people, periodontitis, which results from bacterial proliferation in the gingival sulcus, has been associated with an increased population of *Porphyromonas (Bacteroides) gingivalis*.⁹⁸ In comparison, microflora from anaerobic plaque and gingival crevices of dogs with periodontal disease are *P.*

Infectious Diseases of the Dog and Cat, 3rd Edition

gingivalis; *Porphyromonas* species isolates; *Prevotella* and *Wolinella* species that are pigmented, gram-negative rods; *Actinobacillus actinomycetemcomitans*; and *Clostridium* and *Fusobacterium* species. Reduced numbers of streptococci, enterococci, and staphylococci are found compared with normal flora (Table 89-3).^{140,141} In cats, differences in the microflora between clinically healthy animals and those with gingivitis have not been appreciated (see Table 89-2). *P. gingivalis* is the most likely periodontal pathogen associated with progressive periodontal disease in cats.²²⁴⁻²²⁷ Salivary microflora, which differs from plaque microflora, remain relatively constant in the presence of periodontal disease.

Calculus is mineralized dental plaque that adheres to tooth surfaces, facilitating additional plaque formation and periodontal inflammation. Complete removal of all supragingival and subgingival calculi is essential in control of periodontal disease. Long-term intermittent periodontal care for dogs is highly recommended because it slows the progression of gingival recession and depth of periodontal crevices that develop in dogs not receiving dental hygiene.¹³⁷ Gingival hypertrophy and alveolar abscess formation are sequelae of calculus formation. The type of microflora present, the diet, and the animal's chewing habits may be important in the formation of calculus.³³⁷ Advancing age is a predisposing factor in dogs.¹²⁶ Leukopenia and bacteremia occasionally develop as secondary effects.¹⁸⁹

Although bacterial pathogens are important in periodontitis, antimicrobial therapy alone does not eliminate progression of disease. Proinflammatory cytokines, such as tumor necrosis factor (TNF) and interleukin-1 (IL-1), have been important in the progression of periodontal disease in experimental animals.^{56,91} Cats with more severe periodontal disease have greater serum antibody titers to *Prophyromonas salivosa* and *P. gingivalis* than those with less severe periodontal disease.^{193,223,227,228} Inhibition of IL-1 and TNF with specific blockers has been beneficial in inhibiting inflammation and preserving bone in the periodontal tissues. Other antiinflammatory drugs such as metalloproteinase matrix (e.g., tetracyclines) and prostaglandin inhibitors such as nonsteroidal antiinflammatory drugs (NSAIDs) have been beneficial in this regard. These findings support the concept that periodontal tissue loss is caused by an exaggerated host response to certain species of bacteria with the ability to grow on the tooth surface and in periodontal structures and a triggering of an inflammatory cascade.

Adjunctive management methods such as providing hard diets, regular tooth brushing, and oral hygiene chews have been shown to reduce the incidence of calculus accumulation.^{88-90,137,251} Treatment includes the extraction of severely affected teeth, debriding necrotic or proliferative gum margins, and scaling calculi from the remaining involved dental surfaces.

Systemic antimicrobials such as tetracycline, metronidazole, and tinidazole and topical chlorhexidine have been evaluated for treatment of periodontitis in experimentally affected dogs.²⁵³ Clindamycin treatment for 5 days after dental prophylaxis reduced subsequent oral odor and dental plaque formation when dogs were monitored for up to 70 days.³³⁵ Treatment of clinically healthy beagle dogs with clindamycin for 14 days reduced the amount of gingival crevicular fluid, dental plaque, and gingivitis.³⁶⁶ (For drug dosages, see [Table 89-4](#) and the Drug Formulary, [Appendix 8](#).) Tetracycline and metronidazole have been beneficial in reducing dental calculus

Infectious Diseases of the Dog and Cat, 3rd Edition

or preventing its reformation when they have been given with or without mechanical cleansing. After 1 year of tetracycline therapy, dogs with periodontal disease had less alveolar bone resorption than untreated controls.³⁵⁹

Fig 89-1 Accumulation of dental tartar and resulting perialveolar gingivitis in cat. (Courtesy University of Georgia, Athens, Ga.)

Perioceutics are pharmaceutical formulations that are placed into periodontal pockets to allow for sustained antimicrobial activity against periodontal pathogens. They are used as an adjunct to scaling and cleaning the dental surfaces. These perioceutics, consisting of tetracyclines and having antibacterial and anticollagenase activity, are delivered into the periodontal pocket via a blunt cannula. Once there, the polymer gels coagulate, allowing for sustained release of the drug for up to 13 weeks.^{42,165} Dogs with periodontal disease, having dental cleaning followed by doxycycline polymer applied to their gingival crevice, had less periodontal disease than untreated animals after 12 weeks of monitoring.^{115,122,367} In addition to a reduction in the depth of alveolar pockets, a reduction in aerobic microaerophilic and anaerobic bacterial microflora and proteolytic enzymes, such as collagenase, have been observed.³⁶⁷ Topically applied polymers containing doxycycline (Heska, Fort Collins, Colo.; Pharmacia Animal Health, Piscataway, N.J.) or minocycline (Sunstar Inc., Takatsuki, Japan) are available for treatment and control of periodontal disease in dogs. Metronidazole therapy has had similar beneficial effects.²²⁹ Tinidazole had good efficacy against *P. gingivalis*-like bacteria, which are periodontal pathogens.²⁷⁶ Flushing dental surfaces once daily with 0.1% to 0.2% chlorhexidine¹⁰⁶ or alternate-day brushing²⁸¹ may delay accumulation of calculi. Unfortunately, chlorhexidine may stain teeth light blue, but a commercial product formulated especially for dental purposes (Nolvadent, Fort Dodge Labs, Fort Dodge, Iowa) does not stain. Monoperoxyphthalic acid applied before chlorhexidine was used resulted in less dental staining.⁴⁰ Daily application of chlorhexidine gel was effective in reducing reoccurrence of dental plaque in dogs.¹¹⁸ With twice-daily applications, nisin, an antimicrobial peptide, was as effective as chlorhexidine in preventing calculus in dogs.¹³⁴ Numerous cleansers and brushes have been developed for daily brushing of dogs' teeth, and they warrant consideration when a dog has a tendency to form calculi. Special diets are also available that may help to reduce calculus formation. Daily feeding of a commercial dental food significantly reduced plaque and gingivitis by 39% and 36%, respectively, compared with daily feeding of a control dry food diet.¹⁸⁵

D, Dog; C, cat; B, dog and cat; IL, intralesional; PO, by mouth; IV, intravenous; SC, subcutaneous.

- For additional information, see Drug Formulary, [Appendix 8](#).
- Dose per administration at specified interval.
- Metronidazole and spiramycin are available in combination (Stomorgyl) outside the United States for treatment of oral infections.
- Only given once just before or during anesthesia for dental procedures. In general, the desired spectrum is used to treat anaerobic bacteria. For gram-negative facultative anaerobes in severe pyorrhea, combine whatever drug is chosen with the aminoglycoside (gentamicin) or fluoroquinolone (enrofloxacin).

In cats with naturally occurring periodontal disease, clindamycin, doxycycline, or spiramycin-metronidazole, but not amoxicillin-clavulanate, reduced the numbers of *P. gingivalis*.²²⁶ Furthermore, improvement was observed in the degree of periodontal inflammation. This occurred despite the fact that all isolated organisms showed susceptibility to all the tested drugs. These drugs should probably be selected for adjunctive treatment along with mechanical debridement in cats. The use of special diets supplemented with dental chews may be effective in reducing calculus formation on cat teeth.^{135,138} Cats were fed either a dry diet only or a dry diet supplemented with dental chews. A two-period, crossover design was used, and the test phase lasted 4 weeks. Results indicated that the daily addition of dental chews to a dry diet was effective in reducing plaque and calculus accumulation and the severity of gingivitis. Dental brushing has also been helpful in the prevention of periodontal disease in cats.^{135,138} Daily application of zinc ascorbate gel has also been effective in decreasing bacterial growth, plaque formation, and gingivitis in cats when it was used following dental prophylaxis.⁴¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Systemic complications of periodontal disease, including cerebral and myocardial infarction and early mortality, have been linked in people. Similar relationships to heart, liver, and kidney disease have been made in dogs.⁵² Ophthalmic manifestations can occur from dental disease because of the close proximity of the caudal maxillary teeth and the orbit (Table 89-5).

89.1.2.1 Gingivitis in Kittens

A syndrome of gingival hypertrophy and associated plaque formation has been observed in Abyssinian and Persian kittens around the time of eruption of their adult teeth.³⁵⁵ It may be caused by inborn immunodeficiency with secondary proliferation of gingival and plaque-forming bacteria. Treatment involves gingival tissue debridement, plaque removal, and frequent dental prophylaxis. Systemic antibacterial therapy may temporarily halt the progression, but it cannot be used indefinitely. Fortunately, most cats have a reduction in the severity of proliferation as they mature.

89.1.3 Bacteremia and Dental Disease

Bacteremia associated with dental manipulations may be clinically nonsymptomatic, cause acute septicemia, or subsequently result in bacterial endocarditis or localized embolic tissue infections (see Chapter 87).²⁵⁴ The severity of bacteremia frequently correlates with the degree of periodontitis present. In people, use of antibiotic prophylaxis during dental procedures in patients predisposed to infective endocarditis is widely accepted.¹⁰³ In cats with periodontitis undergoing dental scaling and extraction, 36% had positive blood culture results at the time of the dental procedures.¹⁰⁹ Bacteria most commonly isolated were *Propionibacterium acnes*, *Pasteurella multocida*, and *Staphylococcus epidermidis*. None of the cats became ill after the dental procedures. Positive blood culture results of resident microflora have also been found in up to 40% of dogs with periodontal disease undergoing dental scaling and tooth extraction, and none showed clinical evidence of bacteremia.¹⁰⁸ Dental procedures should not be performed at the same time as other surgical procedures, because surgical wounds have been infected by bacteria released when simultaneous dentistry is performed. Oral microflora may establish themselves in tissue injured or devitalized by routine surgical procedures, sutures, or foreign implants. When dentistry is performed, prophylactic administration of antimicrobial drugs has been recommended (see Table 89-4). Routine use of antimicrobials for dental procedures should be mandatory in immunocompromised animals. Amoxicillin is the drug of choice for people undergoing dental cleaning; because of the risk of infection with viridans group streptococci, intravenous (IV) administration of aqueous penicillin during ultrasonic dentistry in dogs did not alter the prevalence of bacteremia before or after dental manipulation.²⁷ In dogs and cats, pretreatment with clindamycin at 5.5 mg/kg for 5 days decreased plaque and reduced aerosolization of bacteria during ultrasonic teeth cleaning.³⁶⁹ Ampicillin (amoxicillin) has been recommended empirically beginning 1 hour before dental procedures.¹²⁸ On the basis of in vitro susceptibility testing, chloramphenicol, cephalosporin, erythromycin, or gentamicin have also been recommended. With the exception of erythromycin, all can be given parenterally while the animal is anesthetized. Gentamicin should never be administered alone because it is relatively ineffective against anaerobic bacteria. For these reasons, ampicillin (amoxicillin), chloramphenicol, clindamycin, metronidazole, or cephalosporin with or without gentamicin or fluoroquinolone (although rarely) is recommended for dental prophylaxis. Prerinsing the oral cavity with chlorhexidine solutions can also be performed just before the sealing and cleaning procedure. Appendix 8 and Table 89-4 should be consulted for drug information and appropriate dosages. Therapy should begin no earlier than 4 hours before the dental procedure and preferably should be continued throughout the procedure by IV infusion. The most critical period is during the procedure. Drug administration should be terminated no longer

886

887

Infectious Diseases of the Dog and Cat, 3rd Edition

than 12 hours after the procedure because no additional benefits are gained, and the risk for antibiotic-resistant bacteria causing infections increases.

Table 89-5 Ophthalmic Manifestations of Dental Infections

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 89-2 Diffuse necrotizing ulcerative gingivostomatitis in dog. (Courtesy D.W. Scott, Cornell University, Ithaca, N.Y.)

Because of the large numbers of bacteria in the mouth and especially the gingival crevices, public health considerations are important. Face masks and ocular shields should always be worn by people who clean animals' teeth. In addition, biofilms that form on the inside surface of water lines of ultrasonic scalers may harbor *Legionella* species, which might produce acute pneumonia in susceptible individuals.³⁵⁸

89.1.4 Gingivostomatitis and Pharyngitis

In people, *necrotizing ulcerative gingivostomatitis* (NUG), or “trench mouth,” is a syndrome with multiple causes, is characterized by oral ulcerations and secondary infections, and may be observed in dogs or cats (Fig. 89-2). NUG may be a manifestation of systemic or immunosuppressive illness. Opportunistic overgrowth of oral microflora occurs in many diseases when immune defenses are impaired or oral ulcerations develop.^{264,316} Similar to periodontitis, motile (predominantly anaerobic) bacteria, including spirochetes, often proliferate and may invade tissues before the development of necrotic lesions.²⁵⁹ The causes of NUG in dogs and cats are equally diverse and include many acquired immunosuppressive conditions, such as diabetes mellitus, persistent neutropenia, feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) infections, and canine Cushing's disease. Exogenous glucocorticoid administration in dogs also increases their susceptibility to NUG.²¹³ The condition is common in Maltese terriers.¹¹⁴ A virus antigenically related to feline calicivirus (FCV) was found to cause transient gingivitis and glossitis in a dog.⁶⁹ FCV appears to be especially prevalent in affected cats. As in people, psychologic and physical stresses may be involved in some animals. Bristles of plant awns can induce a similar syndrome when they become embedded in gingival tissues.²¹⁰ Fungal stomatitis can result from infection with *Candida* species. Candidiasis can be associated with diffuse oral inflammation, especially on the tongue and at mucocutaneous junctions. (See Chapter 65 for additional information concerning its diagnosis and treatment.)

887

888

Infectious Diseases of the Dog and Cat, 3rd Edition

Cats subclinically infected with FCV and feline herpesvirus (FHV-1) may develop oral ulceration with or without respiratory signs after stress or immunosuppression, such as with concurrent FIV infection. Stress also appears to reduce the amount of fibronectin, a receptor protein, on epithelial cells for gram-positive organisms. Thus overgrowth with gram-negative bacteria may develop. Hard, dry cat food also appears to have a role in exacerbating palatine ulceration in cats with acute FCV infection.¹⁵⁷ Proliferative stomatitis (see following discussion of feline lymphocytic plasmacytic gingivostomatitis) has been associated with persistent FCV infection, occasionally as a result of concurrent FIV infection.^{167,320,344} The prevalence of FeLV infection in affected cats with stomatitis is lower than that of FIV. As a common but poorly understood syndrome with diverse causes, NUG often has uniform histopathologic features of lymphoplasmacytic infiltration.³⁴⁴

Table 89-6 Comparison of Ulcerative Lesions in Oral Cavities of Dogs and Cats

CAUSE	SPECIES	LESION LOCATION	THERAPY
Excessive licking (eosinophilic ulcer)	C	Upper incisor or carnassial area of lip, near philtrum, roof of mouth (hard palate) ^a	Intralesional or systemic glucocorticoids
Autoimmune diseases, bullous pemphigoid	D	Roof of mouth, lips, cheeks—often symmetric; other mucocutaneous regions, footpads	Systemic glucocorticoids
Irritants, uremia	B	Tip of tongue	Systemic antibacterials, amputation
Viral (parvoviral, see Chapters 8 and 10), rickettsial (Rocky Mountain spotted fever, see Chapter 29)	D	Multifocal lingual	Systemic antibacterials, antirickettsials
Maltese terrier stomatitis	D	Ulcerative lesions, lateral tongue and buccal mucosae	Systemic antibacterials
Dental tartar, periodontal disease	B	Periodontal regions (gingival margins), fusospirochetal proliferation	Systemic antibacterials, tartar removal, tooth extraction, chlorhexidine rinses, hard food diets
Herpesvirus (see Chapter 16)	C	Tongue, palate, multifocal	Systemic antibacterials
Calicivirus (see Chapter 16)	C	<i>Acute:</i> tongue, palate, multifocal <i>Chronic:</i> fauces (glossopharyngeal reflection, upper last molar region; occasionally extends rostrally; occasionally roof of mouth [hard palate]) ^b	Systemic antibacterials, soft food diets, intralesional or systemic glucocorticoids, occasional molar extraction
Immunosuppression, hyperadrenocorticism, leukopenia, feline leukemia virus, feline immunodeficiency virus (see Chapters 13 and 14), Abyssinians, Persians	B	Periodontal region, may spread to gums and cheeks ^c	Systemic antibacterials, low-dose oral interferon, oral lactoferrin

C, Cat; D, dog; B, dog and cat.

^a Eosinophilic infiltration on biopsy.

Infectious Diseases of the Dog and Cat, 3rd Edition

- b Lymphocytic-plasmacytic infiltration on biopsy and polyclonal hyperglobulinemia are typical. Feline immunodeficiency virus coinfection can exacerbate.
- c May be observed as an idiopathic syndrome in young cats. See text discussion of gingivitis in kittens. Retroviral infections are occasionally associated with a rapidly spreading gingival necrosis.

The pattern of oral ulceration may be helpful in determining its underlying cause (Table 89-6). Regardless of its cause, oral ulceration has a particular clinical syndrome characterized by reluctance to eat, hypersalivation, halitosis, and evidence of pain on opening the mouth. Hemorrhage may occur spontaneously or after oral manipulation. Although rare, systemic signs may include fever, lymphadenomegaly, and depression. Ulcers may be distributed throughout the oral cavity but are usually concentrated on the dental, labial, and gingival surfaces. Ulcers may be covered by a pseudomembranous exudate. White pseudomembranous plaques can be found in cases of candidal stomatitis. In many neutropenic cats infected with FeLV, the ulcers characteristically have minimal exudation; some can progress rapidly, with sloughing of large portions of the caudal oropharynx or larynx.

89.1.4.1 Diagnosis

Diagnosis of persistent stomatitis-pharyngitis in animals first involves examination for excessive accumulation of dental tartar. Systemic or underlying diseases are usually apparent from the results of urinalysis and routine hematology, biochemistry, and FeLV and FIV testing. Neutropenia or neutrophil function defects are a common underlying cause of oral ulceration. Results of bacterial culture and susceptibility testing are useless because most isolated organisms are merely commensals proliferating in already damaged tissues. Clinical features should be correlated with cytologic and histologic findings. Lymphoplasmacytic infiltration may be present in chronic inflammation from many different causes but has been most commonly associated with chronic stomatitis in cats. 888

Underlying disease processes and other causes of NUG should be eliminated or treated when they are encountered. Plant awns or foreign material embedded in the gums can be scraped away with a scalpel when the gum margins are debrided. Symptomatic therapy of stomatitis includes changing the diet to soft or bland foods to encourage eating and lessen the mechanical irritation of ulcers. With chronic, nonhealing ulcers, it is often beneficial to remove dental tartar and normal or diseased teeth in affected regions of the mouth.¹⁹ Some lesions that arise adjacent to or later involve the tonsillar crypt may originate as or later develop into squamous cell carcinomas. 889

89.1.4.2 Therapy

Topical therapy such as swabbing and flushing of teeth, gums, and lesions throughout the oral cavity with 1% hydrogen peroxide has been recommended for gingivitis and stomatitis; however, excessive use of peroxide may cause vomiting. Astringents or disinfectants have also been advocated but can be irritating and distasteful. Cauterization with silver nitrate or dilute acid solutions also has been recommended but may interfere with healing and epithelization. Administration of vitamins B and C has been recommended on an empiric basis without adequate documentation of efficacy.

Systemic therapies for stomatitis are summarized in Tables 89-4 and 89-7. Topical or systemic antimicrobial therapy appears to hasten the resolution of NUG significantly, perhaps by inhibiting the overgrowth of anaerobic and spirochetal bacteria that colonize and impair healing of ulcerated lesions in the oral cavity. Oral administration of lactoferrin, an iron-chelating agent, was effective in treating intractable stomatitis in

Infectious Diseases of the Dog and Cat, 3rd Edition

cats with and without FIV infections. (For dosages and other information, see [Table 98-7](#) and Drug Formulary, [Appendix 8](#).²⁸⁰) Improvement was presumably a result of its antibacterial effects. Candidal stomatitis is best treated by topical application of antifungal drugs, such as clotrimazole and nystatin (see also [Table 57-3](#)), or with systemic ketoconazole. Historically, tetracycline, chloramphenicol, ampicillin, and penicillin solutions have been applied topically for bacterial stomatitis, although the first two drugs may cause anorexia in cats. Systemic antibiotic therapy directed primarily against anaerobic bacteria appears to be more efficacious in treating stomatitis. Relapses may occur in some cases after termination of antimicrobial therapy, and a repeated course of therapy may be required.

Table 89-7 Adjunctive Drug Therapy for Feline Ulcerative Gingivostomatitis

DRUG ^a	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Prednisone, prednisolone	0.5–2 mg/kg	PO	12 hours	7–14 days
Triamcinolone	4 mg total	PO	24–48 hours	28 days
Methylprednisolone acetate	2 mg/kg	IM	7–30 days	3–12 months
	0.5–1 mg/kg	IL ^c	Once	28 days
Triamcinolone acetonide	0.1–0.2 mg/kg	IL ^c	Once	28 days
Aurothioglucose	1 mg/kg	IM	7 days ^d	Prn
Thalidomide	50 mg	PO	24 hours	330 days ^e
Cyclosporin	7.5 mg	PO	12 hours	28 days ^f
Lactoferrin powder	200 mg	Topical	24 hours	330 days ^g

PO, By mouth; IM, intramuscular; IL, intralesional.

- a See Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c Injection under anesthesia as a last resort.
- d Give every 7 days until improvement, then once every 14 to 35 days as needed.
- e Dose reduced to every other day after this time and then gradually discontinued.
- f After this time and clinical resolution, therapy should be tapered to the lowest dose and frequency that is effective in maintaining remission.
- g Drug given for 4 consecutive days of each week after this time.¹

Glucocorticoid therapy may be needed if an autoimmune disease such as pemphigus is suspected; however, the immunosuppression induced by glucocorticoids can itself cause or exacerbate some cases of NUG.

89.1.4.3 Feline Lymphocytic Plasmacytic Gingivostomatitis

Fauces is characterized by vesicular, ulcerative, and later, proliferative lesions in the mucosa, usually accompanied by lymphoplasmacytic or eosinophilic infiltrations in the tissue of the caudal pharynx at the glossopharyngeal arch (fauces).^{154,320} Fauces frequently appears among a number of cats within a household and tends to be recurrent after the initial treatment or is unresponsive to treatment. In chronic stages, proliferation of granulation tissue forms large masses in the caudal pharynx ([Fig. 89-3](#)). FCV has been isolated in a high percentage of cats with this syndrome compared with clinically healthy cats or those with oral ulcers at other locations. Cessation of FCV shedding was associated with resolution of chronic

Infectious Diseases of the Dog and Cat, 3rd Edition

gingivostomatitis in one cat.¹ It is likely a hypersensitivity phenomenon to persistent FCV infection. Coinfections with FIV or FeLV result in the most severe lesions. CD8 cells, representing cytotoxic and suppressor T cells, have been in the high reference range for all cats. In one study, cats with chronic gingivostomatitis were more likely to shed FCV and FHV-1 together than either virus alone.¹⁸⁸ Compared with nondiseased cats, affected cats showed a significant increase in the relative mRNA expression of IL-2, IL-4, IL-6, IL-10, IL-12 (p35 and p40), and IFN- γ . These results suggest the normal feline oral mucosa is biased towards a predominantly (Th)/type 1 profile of cytokine expression and that during the development of lesions seen in feline chronic gingivostomatitis, a shift in the cytokine profile from a type 1 to a mixed type 1 and type 2 response occurs.¹¹¹ Hyperproteinemia and polyclonal hyperglobulinemia are often present in cats affected with chronic stomatitis (faucitis) and lymphoplasmacytic infiltration. Monoclonal gammopathy may occur in some cats.¹⁹⁵ Cats with chronic gingivostomatitis have higher serum concentrations of IgG, IgM and IgA, likely reflective of chronic antigenic stimulation.¹¹⁰ The release of high concentrations of serum immunoglobulins may facilitate local inflammation in the tissues. Lower salivary IgA may be caused by destruction by bacterial proteases or suppressed secretion. The lower concentration may predispose these cats to persistent oral bacterial infections. Specimens for FCV isolation can be taken by rubbing sterile swabs on the gums, soft palate, and oropharynx (especially palatine tonsillar region) and placing them directly into viral transport or culture media (see [Chapter 1](#)). 889 890

Fig 89-3 Necrotic ulcerative and proliferative gingivostomatitis in cat. (Courtesy University of Georgia, Athens, Ga.)

Although dentistry may reduce pain and discomfort, it is not by itself sufficient in controlling faucitis in many cats.³⁴⁴ Similarly, antibiotic therapy results in improvement; however, the response is temporary. In some cats, removal and biopsy with histologic examination of chronic proliferative lesions may be required. Topical application of an astringent paste containing choline salicylate and cetalkonium chloride (Bonjela Gel, Reckett and Coleman Pharmaceuticals, United Kingdom) has been used as adjunctive therapy to reduce the proliferative lesions.¹⁹⁹ A cat that had recovered was treated with thalidomide, lactoferrin powder, and an additive-free diet containing fat-soluble vitamins.¹ However, clearing of the viral carrier state in this cat may have been coincidental. Treatment of periodontal disease, such as scaling, polishing, and extracting of

Infectious Diseases of the Dog and Cat, 3rd Edition

teeth in areas of severe inflammation, is beneficial. Because faucitis is likely a hypersensitivity phenomenon related to FCV, immunosuppression, rather than immunostimulation, is the most beneficial.

Administration of antiinflammatory and immunosuppressive drugs has provided the most relief (see [Table 89-7](#)). Prednisone or other glucocorticoids may be administered when antimicrobial therapy is being discontinued in an attempt to break the cycle of recurrent chronic stomatitis or faucitis in cats. Reduction in serum immunoglobulin concentration has been observed in cats that were treated for at least 3 months with 0.5 mg/kg methylprednisolone.¹¹⁰ Another systemic treatment with variable success has been parenteral administration of gold salts (aurothioglucose). In cats with refractory faucitis, therapy with hypoallergenic diets, progesterones, or intralesional injections of repositol (water-insoluble) glucocorticoids using general anesthesia may be attempted as a last resort.

Fig 89-4 Bilateral tonsillar enlargement in dog caused by suppurative tonsillitis. (Courtesy University of Georgia, Athens, Ga.)

Cyclosporin has been effective in treating cats with faucitis. Over time the dosage is tapered to the lowest level that is clinically beneficial. Within 2 weeks of initiating treatment, reduction in gingival and buccal erythema subsides, and a reduction in ulcers, granulation tissue, and faucitis occurs. Appetites improve, and hypersalivation subsides.

89.1.5 Tonsillitis

Chronic tonsillar inflammation is most commonly recognized in dogs and is usually accompanied by pharyngeal irritation initiated by foreign bodies, chronic gingivitis or periodontitis, chronic coughing, persistent vomiting or gastroesophageal reflux of acid, and licking of infected sites, such as lesions caused by anal sacculitis. Dogs may have inappetence, hypersalivation, or sneezing and oculonasal discharge; they may scratch at their ears or repeatedly shake the head. Fever and malaise do not usually accompany tonsillitis unless it is secondary to underlying systemic infection or neoplasia.

Infectious Diseases of the Dog and Cat, 3rd Edition

Diagnosis is based on a thorough oral examination, which usually requires sedation. The pharyngeal mucosa is reddened, and tonsils are enlarged and frequently protrude from the crypts as the tongue is pulled rostrally (Fig. 89-4). Organisms cultured from inflamed tonsils have been *E. coli* and *Staphylococcus*, *Streptococcus*, *Pseudomonas*, *Pasteurella*, and *Enterococcus* species. However, these same organisms are also resident microflora, making diagnosis of primary bacterial tonsillitis questionable. Canine tonsillitis also has been associated with *Listeria monocytogenes* infection in two dogs.¹⁷³ Whether this organism can colonize the tonsils nonsymptomatically is uncertain. In general, culture of tonsils is unnecessary, and antibacterial therapy with amoxicillin, tetracycline, or trimethoprim-sulfonamide is recommended. Low antiinflammatory dosages of glucocorticoids have temporarily reduced the severity of clinical signs in conjunction with antimicrobial therapy.³⁶ Surgical removal of the tonsils, followed by histologic examination, is usually the best course of action when antibacterial therapy has been ineffective or transiently curative. Chronic tonsillar enlargement, if not corrected by surgery, usually serves as a nidus for continual infection and occasionally for chronic bronchitis (see also Tonsillitis and Pharyngitis, Chapter 88).

890

89.2 ESOPHAGUS AND STOMACH

891

The oral cavity and ingested material are the primary sources of microorganisms that colonize the proximal portions of the gastrointestinal (GI) tract (Fig. 89-5). The esophagus and stomach contain a transient population of organisms after saliva or food is swallowed. Once the stomach has been emptied of food, the low pH usually destroys most of the bacteria that remain. Those that persist during the fasting period are strains adapted to survival at low pH (Table 89-8). Esophagitis in dogs and cats is usually the result of trauma from ingestion of foreign bodies, irritation from ingested chemicals or drugs such as doxycycline, or from recurrent reflux of gastric acid from the stomach.¹⁰⁷ The oral cavity, esophagus, stomach, and proximal small intestine are colonized primarily by gram-positive aerobic and anaerobic bacteria, which are usually susceptible to penicillin or its derivatives. This susceptibility is the rationale for the clinical use of such drugs in treating ulcerations and perforations and for antimicrobial prophylaxis involving surgery of these portions of the GI tract.

Exudates from abscesses or cellulitis that develop after perforating lesions of the oral cavity or upper GI tract should be collected with sterile syringes that are capped or sealed immediately after collection. The latter method increases the chances of detecting anaerobic bacteria, although cultures must be performed soon after specimen collection (see Chapters 33 and 41). Various organisms, including gram-positive and gram-negative rods and cocci, yeasts, and spirochetes, have been found in the stomach of most normal dogs.³³⁴ Nontoxigenic *Clostridium perfringens* was found in the gastric contents of normal dogs and those with acute gastric dilation. The type and prevalence of organisms in clinically healthy dogs did not differ from those in dogs with acute gastric dilation.

Bacteremia from bacterial translocation was studied in dogs with naturally occurring gastric dilation.³⁶⁰ Approximately 40% had positive jugular venous blood culture results; however, they were comparable to those of clinically healthy dogs. Gram-negative rods were the most frequently cultured organisms. Culture of abdominal organs including the liver, mesenteric lymph node, and stomach also yielded a low rate but comparable degree of isolates. These results indicate that bacterial proliferation or dissemination is not an important feature of gastric dilation-volvulus. Because the stomach has a highly acidic environment and relatively low concentrations of resident microflora relative to other portions of the GI tract, bacterial gastritis is less frequent. However, numerous factors can allow for proliferation of gastric helicobacters and associated gastritis (Fig. 89-6). (For a discussion of Gastric *Helicobacter* Infections, see Chapter 39.)

891

892

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 89-5 Relative concentrations of microorganisms throughout the intestinal tract are depicted in a cat. Highest concentrations are found in the oral cavity and colon. Lowest concentrations are in the stomach from the influence of high acidity. (Courtesy University of Georgia, Athens, Ga.)

h *Bacteroides*, *Fusobacterium*, and *Veillonella*.

89.3 SMALL INTESTINE

89.3.1 Microflora

Concentrations of bacteria in the proximal small bowel are relatively low because of the influence of gastric acid and bile, but they gradually increase toward the ileocecal region (see Table 89-8 and Fig. 89-5). Numbers of microorganisms in the distal small bowel or the large bowel are not affected by feeding and remain relatively constant after meals. Increased numbers of resident organisms may be found in the stomach and upper small intestine, or pathogenic organisms may proliferate when normal bowel defenses are impaired. Excessive use of antacids, obstruction or stasis of intestinal or bile flow, or decreased mucosal or IgA secretions can result in bacterial overgrowth in the small intestine.

Infectious Diseases of the Dog and Cat, 3rd Edition

The normal microflora of the small intestine plays an important role in preventing colonization by pathogenic bacteria by competing for available nutrients, maintaining oxygen levels, and producing antibacterial substances. In addition, the normal intestinal microflora assist the body in metabolizing bile acids and drugs and have a role in synthesizing volatile fatty acids and vitamins. Puppies and kittens lacking normal microflora at birth derive their microflora from exposure to their dam and littermates or from their environment by 2 to 3 weeks of life.¹³⁹ The organisms become established beginning on the first day of life and gradually shift from a predominance of aerotolerant forms to anaerobic species.³³ Organisms that initially colonize the intestinal tract (which may vary between individuals) permanently colonize the intestinal tract and have a somewhat stable composition throughout the life of the individual. Changes in diet, nutritional status, and physiologic state of the host may influence the proportions of residing bacteria. High-meat diets ingested by most carnivores result in a predominance of streptococci and *C. perfringens* and a suppression of *Lactobacillus* species. Upper intestinal bacterial concentrations in carnivores such as the dog and cat are much higher than those in people, presumably relating to dietary differences in these species. Lactose in the diet of nursing animals contributes to acidification of the colonic contents, with a resultant increase in *Enterobacter* organisms and a decrease in *E. coli* and *Bacteroides* species.

892

893

Fig 89-6 Endoscopic appearance of gastric mucosal swelling in dog with *Helicobacter*-induced gastritis. (Courtesy University of Georgia, Athens, Ga.)

Greater knowledge of the composition of the intestinal microflora of dogs and cats has been gained because of improved techniques for culture of anaerobic bacteria. Anaerobes are known to make up a majority of the

Infectious Diseases of the Dog and Cat, 3rd Edition

intestinal microflora, greatly outnumbering aerobes (see [Tables 89-8](#) and [89-9](#)). The duodenum and upper jejunum primarily harbor gram-positive bacteria, including streptococci and lactobacilli. Anaerobes and gram-negative organisms predominate in the distal portions of the small bowel and colon. The maximum numbers of microorganisms are found in the cecum, colon, and feces.

Research studies using molecular-based methods for determining bacterial profiles in the Labrador retriever gut have exposed the limitations of traditional culture methods.⁹⁶ The classical cultural approach failed to reflect the diversity present in dog feces, and many of the isolates remained unclassified. Furthermore, agars designed for anaerobic isolation have poor recovery efficiencies. Thus future studies using molecular methods may help to better characterize resident enteric microflora and its alterations in disease.

Quantifying organism numbers is important in determining whether bacterial overgrowth may be occurring. In contrast to cats with GI illness, clinically healthy cats have much higher concentrations of bacteria in the duodenal or proximal jejunal region ([Table 89-10](#)).^{158,161} The most common anaerobes in cats were *Bacteroides*, *Eubacterium*, and *Fusobacterium*, whereas *Pasteurella* species were the most common among aerobic flora. In another study on cats,²³³ in which similar numbers of bacteria were found, the most common anaerobes were *Clostridium*, *Fusobacterium*, and *Bacteroides* species. The most common aerobes were gram-negative rods, streptococci, enterococci, and staphylococci. In studies on healthy dogs, results of quantifying proximal small intestinal bacteria have varied, with some showing numbers of $<10^5$ per ml³⁴² and others having populations comparable to those in cats.^{21,50,289}

ND, Not determined.

a Data from direct aspiration of contents without dilutional flush.

The composition and distribution of the normal fecal flora can be altered by disease, such as diarrhea.¹³⁹ Decreased transit time of intestinal contents and evacuation of fluid feces result in decreased numbers of lactobacilli with concomitant increased numbers of *Bacteroides* organisms and members of the Enterobacteriaceae. Organisms such as *Enterobacter* species, which normally reside in the small intestine, may appear in the feces of dogs with diarrhea. The concentration of many anaerobes is reduced in the feces during diarrhea because these organisms normally require intestinal stasis and low oxygen tension for growth.

89.3.1.1

Intestinal Immunity

The GI tract is lined by a one cell layer of absorptive epithelium. Cells migrate up the villus to be shed in the intestinal epithelium. Lymphoid cells can be found as single cells in the lamina propria or as intraepithelial lymphocytes. Lymphoid follicles are located throughout the intestine as Peyer's patches. Mucosal lymphoid B cells produce secretory IgA.

893

From Johnston KL, Swift NC, Forster-van Hijfte M, et al. 2001. Comparison of the bacterial flora of the duodenum in healthy cats and cats with signs of gastrointestinal tract disease. *J Am Vet Med Assoc* 218:48–51.

a Samples were collected via endoscopy.

b Cats had signs of chronic weight loss, diarrhea, or vomiting. Ill cats had significantly lower numbers of *Pasteurella* spp., *Bacteroides* spp., and *Lactobacillus* spp. than healthy cats.

89.3.1.2

Probiotics

Microorganisms added to the food for their beneficial effects are called *probiotics*. Enterococci, lactobacilli, and bifidobacteria—normal colonic inhabitants—have often been administered after antimicrobial treatment, intestinal infections, weaning, stress, or dietary changes in an attempt to reestablish enteric microbial flora. Many of these microorganisms become transient constituents of the enteric microflora. In people, these bacteria have been administered in the form of yogurt, cheese, and milk products, and efforts have been made to include these in canine and feline diets. Theoretical benefits of probiotic food additives are antagonism of enteropathogens, reestablishment of enteric microflora flora after antimicrobial treatment, and the decrease in host reactivity to food antigens. In dogs, *Enterococcus faecium* SF68 has shown to provide the most benefit in enteric immunostimulation, and it is free of virulence factors and transferable antimicrobial resistance factors. Dogs fed *E. faecium* SF68 had stimulation of the mucosal immune system with production of polyclonal IgA secretion.²⁰ Furthermore, young pups fed a dry food supplemented with *E. faecium* SF68 also had a greater immune response to canine distemper vaccine than those not supplemented.²⁰ Probiotics have had some effects in inhibiting gastric helicobacters as an alternative or adjunctive treatment with antimicrobials.⁷⁴ Probiotics appear to be helpful in the prevention and treatment of antimicrobial-associated diarrhea in people²⁴¹ and in experimental colitis in animals.²⁸³ In dogs receiving certain diets, feeding of *E. faecium* SF68 or *Lactobacillus acidophilus* resulted in a decrease of *C. perfringens* concentration in the stool.^{20,307,309} These findings suggest that probiotics can be used to help reduce the anaerobic population of bacteria in the colon in lieu of antimicrobial therapy. This modality might be beneficial in treatment of inflammatory bowel disease (IBD), small intestinal bacterial overgrowth (SIBO), or dietary hypersensitivities. Commercial pet foods that claim to contain bacterial species had very low numbers of organisms and often did not contain the species noted on the label.³³⁹ Not only may these misrepresented products be ineffective, but enteric flora is reestablished spontaneously and immediately after antimicrobial agents are discontinued. Furthermore, use of supplemental yeast in an attempt to reestablish the intestinal microflora may have caused intestinal colonization by these fungi in a dog with chronic diarrhea.²¹⁴ Intestinal flora may have an important role in the pathogenesis of IBDs. Probiotic supplementation, containing organisms such as lactobacilli and bifidobacteria, has been the most beneficial

Infectious Diseases of the Dog and Cat, 3rd Edition

in clinical trials in people.¹⁰⁵ Lactobacilli may be best adapted to pet food because they can ferment starch.¹⁶⁶ Probiotics containing *L. acidophilus* have been incorporated into dry dog food and have survived intestinal transit in dogs to eventually reside in the colon.⁹ Additional studies are needed to determine whether these supplements are effective in people and animals.

89.3.1.3

Prebiotics

Prebiotics are undigested foods that alter the replication of specific enteric bacteria in an attempt to alter fecal consistency or digestive function. Fructooligosaccharides (FOSs) are polymers of glucose that have been added to commercial diets as a source of soluble fiber. They occur naturally in plants or are synthesized from fermentation. Other natural sources rich in soluble fiber are oat bran or wheat pulp. FOSs are not digested by the mammalian small intestine, and they reach the colon intact. There they are fermented by anaerobic bacteria such as *Bifidobacterium* spp. or lactobacilli into short-chain fatty acids such as acetate, propionate, and butyrate. These organisms proliferate and inhibit growth of other potentially pathogenic microbes such as *Clostridium* species and *E. coli*. The effects of prebiotics on the intestinal microflora and immune parameters of dogs and cats are reviewed in [Table 89-11](#) and other sources.³⁰⁶

89.3.1.4

Bacterial Translocation

The GI tract is a known reservoir of microorganisms, which under certain circumstances can spread by portal blood vessels or intestinal lymphatics to extraintestinal sites, including the mesenteric lymph nodes, liver, spleen, pancreas, and to other organs by systemic circulation. The inability to culture bacteria in the blood of affected animals may be explained by the fact that many organisms or their toxins first interact with immune cells in the gut-associated lymphoid tissue and then the mesenteric nodes, rather than immediately entering the systemic circulation. Rather than the bacteria entering the circulation, it may be their cytokines or toxins that enter the lymphatic or systemic circulation, leading to multisystemic inflammatory responses. Furthermore, mesenteric nodes drain into the thoracic duct, which can bypass the mononuclear phagocyte system or Kupffer cells in the liver and allow bacteria or their by-products to go directly to the lungs and systemic circulation. This can result in more virulent systemic inflammatory response syndrome or multiple organ dysfunction syndrome. (See endotoxemia, [Chapter 38](#), for an additional discussion of diagnosis and treatment of these syndromes.) [Table 89-12](#) summarizes the bacterial species isolated from mesenteric lymph nodes of 26 of 50 clinically healthy bitches having ovariohysterectomies.⁴⁹ Corresponding peripheral venous and portal venous blood cultures yielded a gram-positive coccus and a coagulase-negative *Staphylococcus* species from the peripheral blood of one dog. Mesenteric lymph node culture needs additional evaluation in ill dogs before conclusions can be drawn about its clinical usefulness.

896

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 89-11 Summary of Prebiotic Use in Diets of Dogs and Cats and Effects on Intestinal Microflora and Immune Parameters

PREBIOTIC	SUBJECTS AND/OR DIETS	EFFECT ON MICROFLORA OR IMMUNITY
Lactosucrose ³¹⁸	Adult dogs; 1.5 g/day for 14 days	Fecal bifidobacteria increased and clostridia decreased from baseline
Short-chain fructooligosaccharides (scFOS) ³⁵³	IgA-deficient German shepherd	Decreased aerobic and anaerobic bacteria in tissue and aerobic bacteria in duodenal/jejunal fluid samples compared with controls
Mannanoligosaccharides (MOS) ²²⁹ as	Adult beagle dogs; control diet (no MOS) or 1, 2, or 4 g MOS/kg	No difference in plasma protein or IgG
	Border collie pups; control diet (no MOS) vs. 2 g/kg MOS and vaccinated	Increased neutrophil activity
scFOS and inulin ²⁶⁵	Dogs; either soy or soy and scFOS	Decreased fecal clostridia and increased bifidobacteria
Different fiber sources ¹³²	Beet pulp, scFOS, cellulose, or fiber blend	Supplemented with scFOS: greater number of aerobes in distal colon but not other regions
Oligofructose (OF), MOS, xylooligosaccharides (XOS) ³⁰³	Ileal cannulated healthy adult dogs	Decreased fecal <i>Clostridium perfringens</i> in dogs fed MOS
scFOS ³⁵¹	Healthy beagle dogs	Ineffective in altering fecal flora, although disparity of fecal flora makes benefit difficult
OF ²²	Adult dogs; diet with or without 1% OF	Increased total fecal anaerobes, aerobes, lactobacilli, streptococci, clostridia, bifidobacteria
ScFOS, <i>Lactobacillus acidophilus</i> (LAC), or both ³⁰⁷	Adult dog groups; sucrose plus cellulose, FOS plus cellulose, sucrose plus LAC, FOS plus LAC	FOS: lower <i>C. perfringens</i> ; LAC: more effective in combination with FOS than alone
scFOS, MOS, or both ³⁰⁸	Adult dog groups; control, scFOS, MOS, FOS plus MOS	MOS vs. control dogs: MOS dogs—lower fecal aerobes, greater <i>Lactobacillus</i> , greater concentration of plasma lymphocytes, and serum IgA; scFOS plus MOS dogs—higher ileal IgA
MOS and scFOS ³⁰⁹	Adult dogs; MOS plus scFOS vs. sucrose placebo	Increased fecal aerobes, bifidobacteria, and <i>Lactobacillus</i> ; increased ileal <i>Lactobacillus</i> concentrations; no effect on ileal IgA
MOS, transgalactosylated oligosaccharides (TOS), lactose, lactulose ³⁶⁵	Dogs; MOS and other carbohydrates	MOS: decreased fecal pH and ammonia excretion but decreased nutrient digestibility
scFOS ⁷⁷	Adult dogs; ileal cannulated with four doses scFOS	ScFOS: increased ileal aerobes and decreased <i>C. perfringens</i> concentrations
Chicory, MOS, or both ⁹⁷	Geriatric dog groups; control, chicory, MOS, chicory and MOS	Either chicory or MOS alone: increased fecal bifidobacteria concentrations, and MOS alone decreased fecal <i>Escherichia coli</i> concentrations; some changes in neutrophils and lymphocyte subtypes

Infectious Diseases of the Dog and Cat, 3rd Edition

Lactosucrose ³¹⁷	Cats; lactosucrose for 14 days, checked feces at 7 and 14 days	Decreased fecal ammonia and decreased lecithinase-positive clostridia, fusobacteria, lecithinase-negative clostridia, staphylococci, and Enterobacteriaceae and increased lactobacilli, with all bacterial concentrations returning back to baseline 7 days after diet no longer fed
Fructooligosaccharides (FOS) ²⁹⁷	Control diet for 8 weeks followed by FOS for 12 weeks	No decline in duodenal bacterial numbers, although marked variations in microflora; increased fecal lactobacilli and <i>Bacteroides</i> and decreased <i>E. coli</i> and <i>C. perfringens</i>
Chicory ²³⁴	Control diet for 15 days followed by various chicory concentrations for 15 more days	Increased fecal bifidobacteria and lactobacilli when fed higher chicory concentrations

<i>Propionibacterium acnes</i>	1
Data from Dahlinger J, Marks SL, Hirsh DC. 1997. Prevalence and identity of translocating bacteria in healthy dogs. <i>J Vet Intern Med</i> 11:319–322.	

Bacterial overgrowth in the bowel can contribute to bacterial translocation. Use of antacids in certain patients may cause proximal gut colonization because of the reduction in gastric acid normally entering the small intestine. Conditions of reduced perfusion of splanchnic ischemia that can result from systemic hypotension or hemorrhagic shock can cause mucosal breakdown and gastric or intestinal compromise or ulceration. Bacterial translocation occurs in conditions associated with decreased peristalsis such as intestinal ileus or obstruction, blind loop syndromes, or hyperosmolar enteral or low-fiber diets. Administration of vasopressors, glucocorticoids, or NSAIDs can result in reduction in GI mucus production, a normal protective defense of the bowel against bacteria. Antimicrobial therapy that inhibits anaerobic GI microflora can lead to proliferation of more virulent gram-negative enteric bacteria. Conditions associated with bacterial translocation migration are intestinal resection, abdominal trauma, burns, abdominal radiation therapy, and obstructed biliary disease.²³ In humans, laparoscopic pneumoperitoneum, used for diagnosis of peritonitis, did not cause hematogenous translocation of enteric bacteria.⁴³ (For an additional discussion of this problem relative to abdominal surgical intervention, see [Chapter 55](#).)

Clinical manifestations of bacterial translocation can be melena or vomiting of blood or severe ileus, decreased mentation, cardiac arrhythmias, systemic hypotension, cyanosis, reduced urinary output, tachycardia (often bradycardia in cats), and hypothermia. Laboratory abnormalities can include leukopenia

Infectious Diseases of the Dog and Cat, 3rd Edition

or leukocytosis, elevated serum bilirubin or alanine transaminase (ALT) activity, azotemia and hypercreatinemia, thrombocytopenia, prolonged coagulation times, and low PaO₂(arterial oxygen pressure) and elevated PCO₂(carbon dioxide pressure) values.

Treatment involves increasing perfusion of the bowel and systemic circulation through the use of crystalloids or colloids. Oxygenation is accomplished by increasing inspired oxygen through nasal or cage oxygen. Infusion of whole blood, packed erythrocytes, or polymerized hemoglobin solutions can be used to increase the oxygen-carrying capacity. Blood pressure and tissue perfusion can be increased by infusion of sympathomimetic drugs such as dobutamine or dopamine. (For additional information and dosages, see [Chapter 38](#).)

Prevention of bacterial translocation involves antimicrobial prophylaxis. For the GI tract, antimicrobials should be considered during manipulative procedures in which intraabdominal contamination is expected or occurs. In animals with anorexia or that are fasting for more than 3 days, enterocyte and villous atrophy can occur, resulting in altered absorption, secretion, and permeability. Forced or premature enteral intake can be associated with complications related to ileus such as diarrhea and bowel distention. Parenteral feeding can help maintain an animal's nutritional status; however, it is expensive and may cause thromboembolism.

When initiating feeding, solid rather than liquid diets may help prevent bacterial translocation.¹⁸ Insoluble fibers and nondigestible carbohydrates are also important in this regard. Glutamine has been considered an important nutrient in the integrity and replication of lymphoid and gut epithelial cells. It is an essential amino acid that has reduced mucosal inflammation when it is applied topically. Glutamine-enriched enteral diets or solutions have been beneficial in rodents but not in methotrexate-treated cats.²⁰² Additional studies are needed to determine whether this therapy is beneficial.

Oxidation is an important inflammatory mechanism and contributes to IBD through the production of free radicals. Supplementation with dietary oxidants is recommended, although specific documentation of efficacy does not exist. Fat restriction helps to prevent inflammatory responses in the bowel. Assimilation of dietary fat is a difficult digestive process and it should be restricted to no more than 20% calories. This is especially important when lymphangiectasia develops during IBD as a result of intestinal lymphadenitis. The addition of dietary n-3 polyunsaturated fatty acids (PUFAs) provides potential antiinflammatory activity by interfering with the arachidonic acid pathway. Concurrent antioxidant treatment helps to inhibit any oxidation of the PUFAs.

89.3.2 Pathophysiologic Mechanisms of Infectious Diarrhea

Enteropathogenic organisms, unlike resident and nonpathogenic transient microflora, have acquired means of overcoming the host defense mechanisms and the inhibitory properties of the normal microflora. Adherence factors (e.g., somatic pili) that permit intestinal pathogens to establish infection also allow them to attach to, multiply on, and colonize the intestinal mucosa. Some pathogenic bacteria that cause diarrhea remain on the mucosal surface and produce potent enterotoxins that disrupt fluid flux across the intestinal mucosa. Others are able to penetrate intact epithelial cells, producing inflammatory damage in the underlying mucosa. Enteric viruses damage the intestine by replicating within and destroying selected populations of epithelial cells. Various mechanisms by which microorganisms produce intestinal injury are covered in the following sections.

Infectious Diseases of the Dog and Cat, 3rd Edition

89.3.2.1 Normal Function of Intestinal Villi

Intestinal epithelial cells are produced by germinal epithelium located in the intestinal crypts (Fig. 89-7). Younger, undifferentiated, and primarily secretory epithelial cells, produced by the germinal epithelium of the intestinal glands (crypts), migrate up the intestinal villus as the older, differentiated, absorptive cells at the tip eventually slough into the intestinal lumen. Most of the absorptive process is confined to the differentiated cells at the villous tip, which also produce locally active intestinal enzymes that aid in the digestive process. The preponderance of intestinal secretion is confined to specialized goblet cells and undifferentiated cells that line the sides and depths of the crypts.

896

897

Fig 89-8 Pathogenesis of infectious diarrhea. A, Noninvasive enterotoxigenic bacteria (e.g., vibrios, staphylococci, and clostridia) primarily stimulate cyclic adenosine monophosphate (AMP). **B,** villous atrophy results from selective infection of apical epithelial cells with certain viruses (e.g., coronaviruses and rotaviruses). **C,** Intestinal gland degeneration and mucosal collapse occur when viruses (e.g., parvoviruses) damage germinal intestinal gland epithelium. (Courtesy University of Georgia, Athens, Ga.)

89.3.2.2 Noninvasive Enterotoxigenic Organisms

After attachment to the intact epithelial surface, noninvasive organisms produce powerful heat-labile exotoxins that bind to surface receptors on the small intestinal epithelial cells. Toxin acts at the cellular level to stimulate adenyl cyclase and other unknown mechanisms to increase intracellular cyclic adenosine monophosphate (AMP) (Fig. 89-8, A). The net effect of cyclic AMP is to increase secretion of chloride and to decrease absorption of sodium by intestinal epithelium, resulting in loss of large quantities of water and electrolytes in feces in the absence of morphologic injury to intestinal mucosa.

Many bacterial species that infect dogs and cats not only produce enterotoxin-induced diarrhea after initial colonization but also produce mucosal invasion (Table 89-13; see Chapters 37 and 39). Strains of some species, such as *E. coli*, can produce diarrhea by either mechanism. Several enterotoxin-producing strains of bacteria such as *Staphylococcus* species, *C. perfringens*, and *E. coli*, which commonly cause food-borne diarrhea and acute gastroenteritis, are harbored in the colons of clinically normal dogs and cats.⁹³ Presumably, the bacteria and toxin cause clinical illness only after being ingested or during bacterial overgrowth or intestinal stasis, when they proliferate in the small intestine. Enterotoxigenic *E. coli* have been recovered from dogs with acute diarrhea, but their importance as a primary cause of illness has been

Infectious Diseases of the Dog and Cat, 3rd Edition

uncertain (see [Chapter 37](#)). Similar isolation of enteropathogenic strains has been made from cats.²⁴²
Clostridium difficile, a bacterium associated with diarrhea in people and animals, produces an enterotoxin and a cytotoxin, which induces diarrhea and frequently mucosal ulceration and hemorrhage.

897

Table 89-13 Mechanism and Site of Enteropathogenic Microorganisms^a

MECHANISM AND ORGANISM	SITE OF ACTION ^b
Enterotoxin Production	
<i>Vibrio cholerae</i> (people)	Small intestine

Infectious Diseases of the Dog and Cat, 3rd Edition

- a Host species affinities, where cited, appear in parentheses.
- b Site depends on species. See relevant chapter for evidence of pathogenicity for dogs and cats.

898

89.3.2.3 Enteroadherent Organisms

899

Some organisms, notably adherent streptococci classified as enterococci, have been reported to be present on the intestinal epithelial surfaces of dogs and cats with diarrhea (see [Table 89-13](#); see also Enterococcal Infections, [Chapter 35](#), and the respective chapters for other organisms). Microscopically, diffuse colonization of intestinal enterocytes with mild inflammatory changes has been observed.^{44,152} Bacterial attachment has not usually been seen in the upper small intestine.

89.3.2.4 Mucosal-Invasive Organisms

After invasion of the mucosa, some bacteria produce hemorrhagic (dysenteric) stools (see [Table 89-13](#)). Two bacterial genera that classically produce dysentery are *Salmonella*, which usually has an affinity for the ileum, and *Shigella*, which has an affinity for the ileum and the colon. After they penetrate submucosal tissue, both produce a marked inflammatory response characterized by the influx of neutrophils. *Shigella* species and many strains of *Salmonella* are phagocytized and killed, although some may persist, causing a chronic carrier state (see [Chapter 39](#)).

89.3.2.5 Submucosal-Invasive Organisms

The same organisms that invade mucosally can penetrate deeper into submucosal tissues (see [Table 89-13](#)). Host defenses are usually impaired, and systemic spread may occur. Submucosal invasion is characterized by hemorrhagic diarrhea, increased fecal leukocytes, leukopenia, leukocytosis, or leukopenia with a left shift and positive blood culture results. Clinical evidence of bacteremia is manifest by fever, hemorrhagic diarrhea, and shock. Fungal or protozoal pathogens or opportunists may also invade the submucosal layers, producing chronic granulomatous enterocolitis.

89.3.2.6 Villous Atrophy

The well-differentiated apical absorptive cells of the intestinal villus are responsible for producing digestive enzymes that act locally at the intestinal brush border. Reoviruses, rotaviruses, and coronaviruses have a selective affinity for replication within and destruction of these cells, resulting in villous atrophy ([Fig. 89-8, B](#)). Impaired absorption and digestion are characteristic of this type of diarrhea. A relative increase in intestinal secretion is usually associated with terminal villous atrophy because of continued replication of the undifferentiated germinal crypt epithelial cells, which have more secretory than absorptive functions.

89.3.2.7 Intestinal Crypt Degeneration

Because canine and feline parvoviruses require rapidly dividing cells for replication, they selectively damage mitotically active intestinal gland epithelium so that absorptive cells at the tips of the villi are not replaced, which leads to intestinal gland degeneration and eventual mucosal collapse ([Fig. 89-8, C](#)). The primary defect is in absorption; however, secretory processes are also inactivated. Damage to the mucosal barrier in most cases also results in an influx of inflammatory cells and increase in vascular permeability, with the eventual exudation of serum proteins.

Infectious Diseases of the Dog and Cat, 3rd Edition

89.3.3 Diagnosis of Acute Infectious Gastroenteritis

Collection of fecal samples for culture of aerobic bacteria is easier when commercially prepared, sterile, cotton-tipped applicators are used. These are supplied with transport media or enrichment broth in which the swab is placed immediately following specimen collection (see [Chapter 33](#)). Additional care can be taken to clean the anus with 70% alcohol or dilute organic iodine solution before inserting the cotton-tipped applicator. When organisms such as *Salmonella*, *Shigella*, *Helicobacter*, or *Campylobacter* are suspected, the laboratory can be notified because selective media or special cultural conditions may improve yield (see [Diagnosis, Chapter 39](#)).

Cytologic examination of fecal mucus or exudate can be an effective way to determine the integrity of the bowel mucosa. Infectious processes that cause damage to mucosal surfaces result in the appearance of large numbers of neutrophils and macrophages in feces. Diarrhea caused by parvoviruses and invasive bacteria can be distinguished by the presence of these inflammatory cells and erythrocytes.

Like cultures of specimens from the oral cavity, cultures of feces or other intestinal contents yield ambiguous results. Disturbances in the composition of microflora are not detected unless quantitative cultures are performed. Primary pathogens such as *Salmonella* and *Shigella* require selective media if they are to be isolated. Enterotoxigenic strains of bacteria require specific identification techniques that are not routinely available to most veterinarians.²⁴³ Finding a potentially pathogenic organism is not the same as identifying the cause of diarrhea, because the prevalence of subclinical carriers of *Salmonella*, *Campylobacter*, and other enteropathogenic bacteria in dog and cat populations is high (see [Chapters 37](#) and [39](#)). Cultures should always be performed when zoonotic exposure to these pathogens is suspected.

89.3.4 Therapy for Acute Infectious Gastroenteritis

89.3.4.1 Antimicrobials

Antibacterial therapy is indicated in selected instances of intestinal disease, and it is usually combined with supportive care such as dietary modification, fluid therapy, motility modification, and antiemetics. Antimicrobials should be used when episodes of diarrhea or vomiting are accompanied by signs of systemic illness, including fever, depression, and impending shock, and the presence of leukopenia or leukocytosis with a marked left shift. These findings indicate that absorption of microbes or more likely, their toxins, has occurred.²³¹ In some instances, routine use of antimicrobials may be harmful, altering the composition and number of intestinal microorganisms that normally serve to inhibit the growth of pathogenic varieties or the induction of resistant strains. The choice of drugs depends on knowledge of the susceptibilities of the usual pathogens and the normal intestinal flora (see [Drug Formulary, Appendix 8](#)).

89.3.4.2 Antimotility Drugs

Antimotility agents have been routinely used in the treatment of infectious diarrhea. However, slowing intestinal transit may be counterproductive because diarrhea is a defense mechanism that eliminates harmful microorganisms and their toxins. Antimotility drugs have resulted in increased morbidity and persistence of infection in bacterial enteritis (see [Salmonella Therapy, Chapter 39](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

89.3.4.3

Fluid Therapy

Fluid therapy is probably one of the most important treatments of symptoms of the diarrheic animal. Fluids should be given IV when severe shock and hypotension, semicoma, or persistent vomiting or ileus accompanies the diarrheic episode. Less affected animals with these complications should receive subcutaneous (SC) fluids. The majority of animals with acute nonhemorrhagic diarrhea without vomiting can be treated with specific oral fluid preparations.²¹² Oral fluid therapy is based on the observation that glucose is actively absorbed by the normal small bowel and sodium is carried with it in an approximately equimolar ratio. Hypertonic oral antidiarrheal fluid replacement solutions can be prepared that contain sodium and glucose in an equimolar ratio, in addition to bicarbonate and potassium in a composition similar to that of the fluid lost in diarrheic stool (Table 89-14). In most situations, amino acids commercially marketed for veterinary use such as glycine have been added to facilitate absorption. Solutions containing glucose or sodium, either alone or in an imbalanced ratio of a decreased concentration, are *not* effective in reversing fluid and electrolyte flux across the intestinal mucosa. Similarly, polyionic, isotonic fluids such as lactated Ringer's solution, Pedialyte (Ross Laboratories, Columbus, Ohio), and Gatorade (Pepsico, Purchase, N.Y.) are helpful only for oral fluid maintenance or electrolyte supplementation and do little to stop ongoing or existing losses. Oral antidiarrheal solutions are effective only when the integrity of the intestinal mucosa is intact. This can be assessed in practice by looking for gross and microscopic evidence of blood and leukocytes in stools.

Promoted by the World Health Organization (WHO) for treating human cholera, an oral rehydration solution (ORS) called *WHO ORS* can be made by veterinarians or their clients (Table 89-15). The ingredients can be mixed and stored in a powdered state and reconstituted when necessary. Unused portions can be stored in a refrigerator for several days or weeks. Efforts to improve the original solution have resulted in reduced osmolality (e.g., sodium ranges of 60 to 75 mEq/L and glucose ranges of 75 to 90 mmol/L).⁶¹ WHO ORS is voluntarily accepted by most dogs and some cats, although some animals require gavage by syringe or stomach tube. The volume of WHO ORS to be administered depends on the circumstances, but a range of 50 to 100 ml/kg/day according to the fluid losses is usually given until the diarrhea stops. Vomiting, which may occur when use of these hypertonic solutions begins, can usually be obviated by giving small amounts more frequently. Although they facilitate fluid absorption, large volumes of hypertonic fluids may cause a transient increase in stool water volume because of residual unabsorbed electrolytes in the feces. Hypertonic oral fluids can also cause serum hyperosmolality and hyperosmolar coma when adequate volumes of water or isotonic fluids are not provided orally. Parenteral isotonic fluid therapy may have to be given concurrently with hypertonic fluids in small or young animals.

Table 89-15 Composition of World Health Organization Oral Rehydration Solution (WHO ORS)

DRY INGREDIENTS ^a	AMOUNT IN GRAMS (TEASPOONS)	SUBSTITUTES
Sodium chloride (table salt)	3.5 (0.64)	None
Sodium bicarbonate (baking soda)	2.5 (0.55)	None
Glucose powder (dextrose)	20.0 (6.0)	Sucrose (table sugar): 40.0 g (8 tsps) or equivalent amount of honey or corn syrup
Potassium chloride	1.5 (0.31)	Apple juice: 0.47 liter (1 U.S. pint)
Data modified from World Health Organization: Treatment and Prevention of Dehydration in Diarrheal Diseases, Geneva, WHO, 1976; Gangarosa EJ. 1977 Recent developments in diarrheal diseases, <i>Postgrad Med</i> 62:113–117; and Pierce NF, Hirschhorn N. 1977. Oral fluid—a simple weapon against dehydration in diarrhea. How it works and how to use it. <i>WHO Chron</i> 31:87–93, 1977.		
g, Grams; tsps, teaspoons		

Infectious Diseases of the Dog and Cat, 3rd Edition

a In 1 liter of water (1.05 U.S. quarts).

89.3.4.4 Protectants and Adsorbents

Protectants and adsorbents such as kaolin and pectin are limited because they are relatively ineffective in absorbing toxins produced by enteropathogenic bacteria. Kaolin (hydrated aluminum silicate) is a potent coagulation activator and may be of some benefit in treating diarrhea associated with mucosal disruption and hemorrhage. Pectin is a polymeric carbohydrate that is thought to act as an adsorbent; however, large amounts may produce diarrhea. Kaopectate should be used with caution in cats because it now contains salicylate.

NSAIDs such as aspirin have been shown to be beneficial in the management of infectious diarrhea. Clinical studies in people and experimental studies in dogs and cats have shown that salicylates interfere with the mechanism of enterotoxin-induced intestinal hypersecretion, presumably by blocking production of cyclic AMP and prostaglandin synthesis. Subsalicylate preparations (Pepto Bismol, Norwich Eaton Pharmaceuticals, Norwich, N.Y.) that are commonly provided in the treatment of diarrhea are thought to work in a similar manner. Additional studies have shown that bismuth subsalicylate has antibacterial activity because of the binding and killing of exposed pathogenic bacteria. Administration at a dose of 0.25 ml/kg every 4 to 6 hours early in the course of disease may be helpful in treating diarrhea that results from the mechanism of increased secretion.

89.3.5 Infectious Small Intestinal Disorders

Numerous defined syndromes attributed to alterations in intestinal microflora have been described and are discussed in the following sections. In many instances, the pathophysiologic mechanisms are not completely elucidated.

89.3.5.1 Neonatal Colibacillosis

Neonatal colibacillosis caused by *E. coli* has been described in many species, including dogs^{32,79} and cats²⁴² (see [Chapter 37](#)). Characteristically, puppies are affected within the first week of life and have a high mortality rate. They show acute depression, weakness, hypothermia, cyanosis, and central nervous system signs before death. Older puppies that survive for several weeks may have persistent diarrhea, abdominal discomfort, weight loss, and dehydration. Gross necropsy findings include hemorrhagic lesions on serosal surfaces of all body cavities and throughout the GI mucosa. Septicemia can be confirmed by bacterial culture from the blood or from many organs. Histologic examination reveals gram-negative bacilli in many tissues of septicemic newborns.

The cause of *E. coli* septicemia in newborn puppies may be associated with their immunologic incompetency rather than the virulence of a particular strain of organism. Enterotoxic, attaching, and effacing bacterial strains of *E. coli* exist. Furthermore, intestinal epithelial cells of newborn puppies are highly and nonselectively permeable to various proteins (including bacteria), which are absorbed by pinocytosis. Exposure to *E. coli* before colostrum ingestion or the failure to obtain sufficient colostrum may further predispose newborn puppies to infection. *E. coli* is also able to cross the intestinal epithelial barrier 48 to 72 hours after birth, after which the cells also cease to absorb immunoglobulins. Puppies appear to be completely resistant to intestinal exposure to *E. coli* at 2 weeks of age. Enteropathogenic *E. coli* may cause disease in animals of any age.

901

Klebsiella pneumonia has also been associated with enteritis and septicemia in young dogs²⁶⁰ (see [Chapter 37](#)).

89.3.5.2 Small Intestinal Bacterial Overgrowth

SIBO in people is a syndrome characterized by increased proximal small intestinal bacterial concentrations leading to macrocytic anemia, steatorrhea, and weight loss. Reduced gastric acid, impaired peristaltic motion, and ileocecal valve dysfunction can all lead to increases in the load of small intestinal bacteria. Collection and culturing methods to confirm this disorder are critical to enable cultivation of anaerobes.

Levels of 10^5 colony-forming units/ml of anaerobic bacteria are high in people; however, dogs and especially cats have much higher concentrations. Furthermore, levels of cobalamin and folate in serum are not consistently predictable and can be affected by amounts of these nutrients in the diets or other supplements.

SIBO in animals is a syndrome of bacterial proliferation in the upper intestinal lumen accompanied by chronic or recurrent small bowel diarrhea. It has been most commonly observed in German shepherd dogs.^{13,17} Causes for SIBO in this and other breeds are impaired motility or obstruction of the GI tract, secretory IgA deficiency, and reduced gastric or pancreatic secretion. Dogs with SIBO are typically between 5 months and 2 years of age. They are usually bright and alert but show variable weight loss, which becomes apparent with time, and they consistently pass foul-smelling, watery feces for months. Results of quantitation of bacteria in duodenal secretions from affected animals have revealed increased numbers of *E. coli* and enterococci, typically normal flora of this site, and proliferation of anaerobes such as clostridia, which are unusual inhabitants.¹⁷ Duodenal bacterial overgrowth also occurs in German shepherd dogs with pancreatic exocrine insufficiency (PEI). Furthermore, similar clinical features of PEI and bacterial overgrowth make these syndromes difficult to differentiate. Bacterial overgrowth in the jejunum has developed in dogs after surgical reconstruction of the biliary tract.³⁶³

Although disordered motility and hypochlorhydria are possible causes of SIBO, a secretory IgA immune deficiency is considered most important (see [Chapter 95](#)).^{13,343,353,354} Histochemical analysis suggests that German shepherd dogs have defective synthesis or secretion of IgA despite the presence of IgA-committed plasma cells.¹³ Duodenal biopsies from German shepherd dogs with IBD or SIBO had greater levels of expression of mRNA for inflammatory cytokines, IL-2, IL-5, IL-12p40, TNF- α , and transforming growth factor- β 1 (TGF- β 1) messenger ribonucleic acid (mRNA) expression than control dogs, but no significant differences between dogs with IBD or SIBO were found.⁸⁵ Furthermore, antibiotic treatment in five dogs with SIBO resulted in reduced TNF- α and TGF- β 1 mRNA expression. Such alterations in cytokine mRNA expression suggest heightened immune responses within the duodenal mucosa in German Shepherd dogs with either SIBO or IBD.

Anaerobic bacterial overgrowth in the proximal small intestine leads to increased breath-hydrogen concentration in most dogs and variably increased serum folic acid concentration.³⁵³ Increased serum folate results from increased synthesis of this compound by the large numbers of intestinal bacteria, with greater amounts available for absorption. In addition, reduced serum B₁₂, found in up to 25% of these dogs, is thought to be caused by bacterial binding of the vitamin within the intestine, preventing its absorption. Steatorrhea is usually mild or absent unless concurrent PEI is present. Xylose absorption has been variably reduced in affected dogs, presumably as a result of bacterial use of xylose in the proximal small bowel,

Infectious Diseases of the Dog and Cat, 3rd Edition

thereby decreasing the amount being absorbed. In some cases, abnormal xylose absorption may be corrected by prior administration of antibiotics. Differential sugar absorption testing has been used to confirm the presence of SIBO and monitor the response to treatment.²⁶⁹ Serum trypsinlike immunoreactivity and absorption of bound para-aminobenzoic acid have been within reference ranges unless concurrent PEI is present. Minimal histologic abnormalities have been found in affected dogs, and the activities of some brush border intestinal enzymes have been altered depending on whether anaerobic or aerobic bacteria predominate and whether PEI is present.^{15,16,357} Chronic SIBO may result in protein-losing enteropathy, which can be controlled by antimicrobial therapy.

Although difficult to perform in routine practice, quantitative culture of duodenal or proximal jejunal fluid from dogs with overgrowth shows bacterial counts greater than 10^5 organisms per milliliter.^{50,57} Proliferating organisms in dogs often consist of small intestinal microflora such as *E. coli*, *Enterobacter*, *Enterococcus*, and *Lactobacillus*, but occasionally unusual species for the location, such as clostridia, predominate.

When possible, underlying causes of SIBO should be determined and eliminated. Response to antimicrobial therapy supports the diagnosis (Table 89-16). Oxytetracycline and tylosin are recommended for dogs and metronidazole for cats.³⁵⁶ Because of the development of overgrowth in some dogs with PEI, antimicrobial therapy may be required in those that do not respond to enzyme supplementation alone. In addition, a bland diet, such as boiled rice with cottage cheese or chicken or specialized diets (I/D, Hills Foods, Topeka, Kan.) have often been recommended during the treatment period to obtain more consistent responses. Increased-fiber diets actually reduced transit time and intestinal bacterial populations. Feeding IgA-deficient dogs with SIBO FOSs reduced bacterial populations in their proximal small intestines.³⁵³

89.3.5.3

Inflammatory Bowel Disease

IBD can be attributed to various pathogenic or opportunistic enteric microorganisms (Table 89-17); however, in other cases, specific organisms cannot be incriminated despite chronic inflammatory enteric disease. In this latter idiopathic IBD, resident microflora may become secondarily involved in perpetuating the inflammatory process. IBD is suspected to be caused by an immune hypersensitivity derangement resulting in immunoreactive or autoreactive intestinal injury. In humans, IBD can involve any part of the GI tract (e.g., Crohn's disease) or be regional (e.g., ulcerative colitis). Care must be taken when extrapolating pathogenesis from the human disease. The clinically healthy intestinal tract is exposed to a large variety of foreign dietary and microbial antigens. It develops immunologic tolerance through a complex interaction of the gut-associated lymphoid tissue (GALT). Recognition of antigens outside of this group can trigger an inflammatory response. With dietary proteins, soluble antigens tend to evoke less of a secretory antibody response compared with insoluble ones. Clinical observations and animal models incriminate luminal bacteria or their products in the initiation and perpetuation of the disease. Outside of dietary antigens, the ability to recognize pathogens is genetically conserved and is based on Toll-like receptors (TLRs) in the intestinal cell membrane. In the healthy intestine, TLR expression is low. Should microbial antigens such as lipopolysaccharide, lipoteichoic acid, or peptidoglycan be detected, a sequence of inflammatory cascades occurs. Transcription factor (NF- κ B) induces gene transcription of inflammatory cytokines such as IL-1, IL-6, IL-8, IL-12, and CD80/CD86. A key factor in the pathogenesis of IBD is disruption of the mucosal barrier and associated chronic inflammation. The production of antibodies against self-antigens in immune cells such as granulocytes and mast cells and against cell wall components of bacteria may perpetuate a chronic inflammatory process. Chronic inflammation with or without altered host immunity may lead to invasion by enteric organisms as a secondary complication. Microbial flora in the intestinal tract, including

902

903

Infectious Diseases of the Dog and Cat, 3rd Edition

bacteria and yeasts, are therefore pathogenic elements in the disease progression. To develop, this disease likely involves an interaction between enteric microorganisms in hosts having a particular immunologic and genetic composition. Chronic exposure of GALT to ingested or endogenous microfloral antigens or toxins may be responsible.

Table 89-16 Antimicrobial Therapy for Bacterial Overgrowth, Lymphoplasmacytic Enteritis, and Enteropathogenic Bacteria

DRUG ^a	USE	SPECIES	DOSE (mg/kg) ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Tylosin	SIBO, LPE, EPB	B	10–15	PO	12	7–14
Tetracycline ^c	SIBO	B	20	PO	8	28
Metronidazole	SIBO, LPE	D	15	PO	12	7–14
		D	10	PO	8	7–14
		C	30	PO	24	7–14
Sulfasalazine ^d	LPE	D	12.5	PO	6	21–28
		D	10–30	PO	8	21–28
		C	250 mg total	PO	24	14–21
		C	20	PO	24	14–21
Prednisolone	LPE	B	0.5–2	PO	12	14–21
Azathioprine	LPE	D	1–2.5 ^e	PO	24	14–21
		C	0.3	PO	48	14–21
Erythromycin	EPB	D	10	PO	8	7–14
Enrofloxacin	EPB	D	5	PO	12	7–14
		C	5	PO	24	7–14
Gentamicin	EPB	B	5	IV, IM, SC	24	7
Trimethoprim-sulfonamide	EPB	B	15	PO, SC	12	7–14

SIBO, Small intestinal bacterial overgrowth; LPE, lymphoplasmacytic enteritis; EPB, enteropathogenic bacteria (see Chapter 39); B, dog and cat; D, dog; C, cat; PO, by mouth; IV, intravenous; IM, intramuscular; SC, subcutaneous.

- b Dose per administration at specified interval.
- c Or oxytetracycline.
- d Azulfidine.
- e Dose also expressed as 40 mg/m² based on body surface area.

Immunohistochemical studies suggest that IgG is the major antibody in the immune response in the lamina propria of affected dogs.²⁰⁶ A disordered imbalance of cytokines in IBD also exists. Increased numbers of B and T cells are found in the intestinal wall of dogs with IBD, indicating a chronic cellular immune reaction.³⁰² Immunohistochemical studies of the intestinal mucosa from dogs with various diarrheal disorders and control dogs have indicated alterations of immune elements.⁸⁴ Compared with controls, dogs with antibiotic-responsive diarrhea had increased numbers of lamina propria IgA⁺ plasma cells and CD4⁺ cells. More marked alterations were noted in dogs with IBD, with significant increases in lamina propria IgG⁺ plasma cells, T cells (CD3⁺), CD4⁺ cells, macrophages, and neutrophils but reduced mast cell numbers. Compared with controls, dogs with IBD had increased intraepithelial CD3⁺ T cells. However, when compared with controls, dogs with adverse food-induced diarrhea had unchanged lamina propria and epithelial populations. The altered mucosal immune cell populations observed in dogs with antibiotic-responsive diarrhea or IBD may reflect an underlying immunologic pathogenesis in these disorders.

Infectious Diseases of the Dog and Cat, 3rd Edition

Numerous nutritional derangements occur in IBD that result in metabolic abnormalities. Hypomagnesemia develops through a combination of anorexia, fluid diuresis, and malabsorption. Cobalamin deficiency develops, especially in older cats with various GI diseases and pancreatic insufficiency.²⁹⁰ These cats, which can develop villus atrophy or megaloblastic anemia, may benefit from parenteral cobalamin administration.²⁸⁸ Microcytic hypochromic anemia can also be observed, as a sign of chronic blood loss or inflammatory sequestration of iron.²⁵⁸ Anemia and malabsorption, especially in cats, may also result from the B₁₂ deficiency associated with IBD and other malabsorptive enteric and pancreatic diseases.²⁹⁰ Thrombocytopenia has also been documented.²⁵⁵ Before evidence of hypoalbuminemia, fecal α -1 proteinase inhibitor (α -1PI) was increased in the stool of dogs with histopathologic changes in their enteric mucosa, a fact that may be helpful in early detection of protein-losing enteropathy.²¹⁷

Idiopathic *IBD*, previously termed “lymphocytic-plasmacytic enteritis,” is a frequent cause of GI illness in dogs^{268,313} and cats.* It is characterized by diffuse mucosal infiltration of lymphocytes, plasma cells, eosinophils, and neutrophils.⁴⁷ Variants of IBD are eosinophilic and granulomatous infiltrations. IBD may or may not involve the stomach and colon. In cats, it has been observed in association with cholangiohepatitis and pancreatitis.³⁴⁰

In contrast to SIBO, no dog breed is predisposed to this syndrome, and affected animals are usually older than 2 years. The disease generally affects older purebred cats. Chronic or intermittent intractable diarrhea with occasional vomiting is noted in dogs. Stools may vary in consistency, but gross evidence of hemorrhage is often lacking in dogs with small bowel inflammation. With long-standing and severe disease, weight loss develops. Dogs with lower bowel involvement have the greatest prevalence of increased frequency of defecation and hematochezia and mucus in their stool.⁴⁷ In contrast, vomiting and weight loss are major signs in affected cats; vomiting is often unrelated to eating and may occur in sporadic episodes.³⁶¹ Diarrhea is less common and variable and can have a small- or large-bowel origin. Some cats have colonic localization with signs of large-bowel diarrhea with hematochezia.⁵⁸ Appetite may be reduced, corresponding to the episodic nature of vomiting and diarrhea. Some dogs and cats with significant weight loss have voracious appetites similar to those in PEI. Thickening or discomfort may be found on palpation of the intestine. Hepatomegaly has been observed in some cats. Edema, hydrothorax, or ascites may be found in animals with severe hypoproteinemia.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 89-17 Microorganisms Causing Chronic Inflammatory Bowel Diseases in Dogs and Cats

TYPE OF BOWEL DISEASE	MICROORGANISMS
Suppurative	
Bacterial	<i>Salmonella</i> spp. (see Chapter 39), toxigenic <i>Escherichia coli</i> (see Chapter 37), <i>Yersinia</i> spp. (see Chapter 39)
Lymphoplasmacytic	
Viral	FCV-associated gingivostomatitis (see Chapter 16), immunosuppression induced by FIV (see Chapter 14) or FeLV (see Chapter 13)
Bacterial	<i>Helicobacter</i> spp. (see Chapter 39), <i>Campylobacter</i> spp. (see Chapter 39), <i>Clostridium perfringens</i> (see Chapter 39), resident microflora (overgrowth, SIBO)
Protozoal	<i>Cryptosporidium</i> spp. (see Chapter 82)
Granulomatous	
Viral	Feline coronavirus (see Chapter 11)
Bacterial	<i>Mycobacterium</i> spp. (see Chapter 50)
Fungal	<i>Histoplasma</i> spp. (see Chapter 60), <i>Cryptococcus</i> spp. (see Chapter 61), <i>Zygomycetes</i> spp. (see Chapter 67), <i>Pythium</i> spp. (see Chapter 67)
Algal	<i>Prototheca</i> spp. (see Chapter 68)
Protozoal	<i>Leishmania</i> spp. (see Chapter 73), <i>Toxoplasma</i> spp. (see Chapter 80)
FCV, Feline calicivirus; FIV, feline immunodeficiency virus; FeLV, feline leukemia virus; SIBO, small intestinal bacterial overgrowth.	

Neutrophilia, occasionally with a left shift, or a stress leukogram and hypoproteinemia are seen in dogs with moderate to severe disease. Cats may have high serum activities of ALT and alkaline phosphatase (ALP).¹¹² Clinical laboratory evaluation for malabsorption or maldigestion is generally within reference ranges. Measurement of nonspecific markers of inflammation has been used in human medicine to determine whether chronic bowel inflammation is occurring. Blood parameters such as acute phase reactants, C-reactive protein (CRP), and erythrocyte sediment rates are increased. Similarly, CRP was increased in affected dogs, which paralleled the laboratory and histologic severity of illness.^{148,153} As another measure of bowel inflammation, high concentrations of IgG and nitrates can be detected in colonic lavage analytes.¹⁰¹ In dogs with IBD, serum antibody reactivity to perinuclear cytoplasm of neutrophils (pANCA) and *Saccharomyces cerevisiae* (ASCA) has been more prevalent than in clinically healthy dogs and those with other types of acute diarrhea or chronic non-IBD-associated diarrhea.⁴ The ASCA result was more inconsistent, perhaps because of the dietary differences among dogs, whereas that for pANCA had a low level of sensitivity, making it less valuable as a screening blood test. In addition, tests for absorption of inert sugars show altered values in dogs with IBD.²⁹⁴ Contrast radiographic findings vary and have low yields. Intestinal biopsy by endoscopy or exploratory laparotomy is the *only* means of definitive diagnosis. Biopsies of mesenteric lymph nodes should be taken if the nodes are enlarged.

Caution should be taken when interpreting biopsy reports of mild lymphoplasmacytic infiltrations in the intestinal mucosae. Pathologists may vary in their interpretations of mild infiltrates, which may be found in intestinal biopsy specimens of clinically healthy animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

In cats, lymphoplasmacytic infiltrates, crypt distortion, villous blunting and fusion, and fibrosis have been most commonly seen in cats with moderate or severe IBD.⁸ Clinicopathologic findings of some cats have included anemia, leukocytosis or leukopenia, hypocholesterolemia, and hyperproteinemia or hypoproteinemia. Abnormalities are not apparent on abdominal radiography; however, contrast studies using barium can reveal radiographic abnormalities in a few cats. Ultrasonographic abnormalities, which are present in a majority of cats, include poor intestinal wall layer definition, focal thickening, and large mesenteric lymph nodes with hypoechoic changes consistent with IBD. Endoscopic observation can reveal gross findings (e.g., erythema, plaques, mucosal friability) consistent with bowel inflammation in only about half of the cases.

Therapy for IBD is very similar to that for chronic colitis. Bacterial overgrowth may be involved, especially in long-standing cases, and should be addressed in some treatments. Hypersensitivity to enteric organisms or food ingredients may be associated with the pathogenesis, and hypoallergenic diets are recommended for initial treatment. Elimination diets, in which offending foods can be identified, are helpful in many dogs and cats affected with IBD having regional involvement and lymphoplasmacytic, eosinophilic, or mixed cellular infiltrates.³⁹ Theoretically, protein hydrolysate diets provide less antigenic stimulation to the intestinal immune system and have offered empiric improvement in animals with IBD. Presumably, less antigenic stimulation reduces intestinal inflammation, resulting in improved mucosal integrity.

Increased fiber may benefit animals with IBD. Fermentable fibers affect intestinal flora by causing increases in favorable microflora species. Probiotics are microbial preparations that colonize the host and alter the composition of intestinal microflora.

904

Because immune-mediated and infectious causes may be involved, antimicrobial (metronidazole, tylosin, sulfasalazine) and antiinflammatory or immunosuppressive (glucocorticoid or azathioprine) therapies are recommended if dietary management fails or cannot be implemented (see [Table 89-16](#)). When the diagnosis is uncertain, antimicrobial therapy should be instituted first because of potential complications of immunosuppression of dogs with bacterial overgrowth. Protein and energy malnutrition may result from decreased absorption. Iron and B₁₂ deficiency can develop in dogs and cats.³⁹ Doses of B₁₂ for both species are 500 µg SC daily for 4 to 5 weeks. Some discomfort can result because of local irritation. Vitamin K supplementation may be needed, especially in cats with a coagulopathy. Administration of other parenteral water-soluble vitamins and fat-soluble vitamins is also indicated for patients that have poor body condition. Low serum magnesium levels have also been identified in some dogs and cats with primary intestinal disease.^{204,323} Response to therapy varies and is unpredictable. Although some animals show improvement after therapy is instituted and have prolonged remissions, others relapse or do not respond at all.

905

Hypoalbuminemia at the time of diagnosis has been associated with a poor response to therapy.⁴⁷

89.3.5.4

Hemorrhagic Gastroenteritis

Hemorrhagic gastroenteritis (HGE), a syndrome characterized by the sudden onset of vomiting and production of profuse, mucoid, bloody diarrhea, was primarily described in small house dogs between 2 and 4 years of age.³⁴ The syndrome is also marked by hematologic findings that include relative polycythemia, with a normal or low plasma protein concentration, and coagulation test results suggestive of disseminated intravascular coagulation (DIC) and occasionally, acute oliguric renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

The pathogenesis of the syndrome of acute HGE is unknown, but many clinical and laboratory findings are similar to those produced in dogs by experimental administration of bacterial endotoxin or enterotoxins with resultant DIC (see [Chapters 37 and 38](#)). Whether a cause or an effect, DIC may explain many of the clinical features that have been observed in dogs. Allergic, hereditary, autoimmune, and infectious causes for HGE have been proposed. This syndrome has features that are very similar to those produced in bacterial translocation. The high prevalence of HGE in certain breeds, such as schnauzers and miniature poodles, has been explained by their hereditary predisposition to such causative factors. Dogs have been reported to develop hemolytic-uremic syndrome as well, which may be related to enterotoxigenic bacteria.¹²⁷ The influence on microbial flora of the highly digestible meat-based protein diets commonly fed to well-cared for house dogs should be examined. Diagnosis of the syndrome of HGE is based on historical, clinical, and laboratory findings. Treatment is essentially similar to that for endotoxemia (see [Chapter 38](#)). Rehydration and diuresis with polyionic isotonic fluids are the most important components of treatment. Antimicrobial therapy for enteropathogens is recommended because of the damaged mucosal integrity (see [Table 89-16](#)). Some enteropathogenic bacteria, including members of the genera *Clostridium*, *Escherichia*, and *Salmonella*, can also cause similar appearing, acute hemorrhagic diarrhea (see [Chapters 37 and 39](#)).^{7,325}

89.4 LARGE INTESTINE

89.4.1 Microflora

The cecum and colon are the richest sources of intestinal microflora, and a single gram of feces contains up to 10^{11} organisms,⁴⁴ approximately 100 times the human population of the world. Organisms that inhabit the lower bowel are primarily gram-negative aerobes and spore-forming and non-spore-forming anaerobes (see [Table 89-8](#) and [Table 89-18](#)). Anaerobic bacteria, which usually comprise more than 90% of the colonic microflora, include clostridia, lactobacilli, and *Bifidobacterium* and *Bacteroides* organisms. Aerobic or microaerophilic bacteria primarily consist of streptococci, members of the Enterobacteriaceae, and spirochetes. In cats that were older than 9 years, fecal *C. perfringens* concentrations were higher and bifidobacteria and lactobacilli concentrations were lower.²³⁵ Cats fed high-protein cat food had a significantly higher fecal *C. perfringens* concentration than those fed dry cat food.²³⁶

89.4.2 Acute Colitis

Numerous acute inflammatory diseases of the colon have been described in dogs and cats. Colitis, whether acute or chronic, usually involves the microflora as a secondary phenomenon. As with stomatitis, many cases of acute colitis in dogs and cats can be associated with the stressful circumstances or immunosuppressive diseases. Acute colitis has been reported in cats experimentally infected with panleukopenia virus, although the colonic lesions were milder than those in the small intestine.²⁸⁶ One case of mycotic colitis in a cat was assumed to be a sequela to panleukopenia virus infection.²⁸ Acute ulcerative colitis of undetermined cause has also been recognized in young cats.^{68,179,329}

905

89.4.2.1 Antimicrobial Drug–Associated Pseudomembranous Colitis

906

Antimicrobial drug-associated pseudomembranous colitis syndrome can be caused by species of *Clostridium* (especially *C. difficile*) and staphylococci in people. Suppression of normal flora by antimicrobial agents, immunosuppression, or nosocomial acquisition is a possible predisposition. Although this syndrome has been well documented in people and horses, especially those given macrolides, it is not well recognized in dogs and cats. Carriage of *C. difficile* with a proportion of toxigenic strains has been documented in cats housed in a veterinary teaching hospital.¹⁹⁷ Cats with toxigenic strains had at least one risk factor, and half of the cats had diarrhea. Treatment for this disease in people involves vancomycin or metronidazole. (For an additional discussion of clostridial colitis, see [Chapter 39](#).) Antibiotic-associated colitis caused by an imbalance in colonic microflora (presumably, proliferation of streptococci and *Pseudomonas* organisms) was suspected in a dog treated with enrofloxacin and ampicillin.³⁵⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

89.4.2.2 *Spirochetal*(*Brachyspira pilosicoli*) *Diarrhea*

Spirochetes have been recognized in the colonic crypts and feces of clinically healthy dogs for decades. In addition, numerous reports have been made of spirochetes causing diarrhea in dogs and cats.⁹² Their role in disease has been debatable, and several reasons explain this discrepancy. A diverse group of related spirochetes are known to be a part of the normal microflora throughout the GI tract of dogs and cats, with the greatest numbers in the oral cavity, cecum, and colon. Because spirochetes are not demonstrable by hematoxylin-eosin (H and E) staining, they have been overlooked in biopsy specimens by pathologists. Historically, confusion is also associated with histologic examination of spiral helicobacters (see [Chapter 39](#)). Scanning or transmission electron microscopy (EM) and special staining procedures can help to confirm the presence of spirochetes, which are usually attached to the intestinal epithelia at the base of crypts. Intestinal spirochetosis caused by *Brachyspira* (*Serpulina*) *pilosicoli* has been documented in people as an enteric disease with potential zoonotic implications.⁶⁴ This organism was a resident spirochete in the large intestine and feces of nonhuman primates, dogs, pigs, and birds. Dogs might be one of several animal reservoirs for these infections in people. Clinical illness has also been produced in swine with *S. pilosicoli*, and it may be responsible for illness in other immunocompromised animals.²⁹³ In addition, a second spirochete, *Serpulina canis*, has been identified as a nonpathogenic commensal because it has primarily been isolated from clinically healthy dogs.⁶⁴

Because of intestinal adherence, spirochetes are not shed in formed feces of dogs and cats. During large-bowel diarrheal episodes, especially in pups, they dislodge from the epithelia and appear in large numbers in feces. Spirochetes in stool cannot be incriminated as the cause of diarrhea, despite their close relationship with *Serpulina* (*Treponema*) *hyodysenteriae*—the cause of swine dysentery⁶³—and spirochetes from people with diarrhea.^{176,178} An specific-pathogen-free beagle pup with a history of chronic diarrhea and concurrent giardiasis had suspected colonic spirochetosis.^{62,63} Spirochetes were attached to the lamina propria in areas of superficial mucosal erosions, similar to those in swine and human intestinal spirochetosis. Treatment recommended for intestinal spirochete infections has often centered around tylosin; however, studies have shown increasing genetic resistance of canine intestinal spirochetes to this antimicrobial agent.²⁴⁴

89.4.2.3 *Anaerobiospirillum Species Ileocolitis*

Ileocolitis caused by *Anaerobiospirillum* species was found in six cats. Acute diarrhea, with or without vomiting, was found in two cats; in addition, one cat had chronic diarrhea, another had anorexia and lethargy, and two cats did not have signs of GI illness.⁵³ The presence of an *Anaerobiospirillum* species was demonstrated on the basis of ultrastructural morphology of spiral bacteria associated with intestinal lesions and polymerase chain reaction (PCR) amplification of a genus-specific 16S ribonucleic acid (rRNA) gene from affected tissues from each cat. The colons of three clinically healthy cats without lesions and one cat with mild colitis not associated with spiral bacteria were negative for *Anaerobiospirillum* species in the same assay. (For additional information on enteric spiral bacterial infections in dogs, see *Anaerobiospirillum* Infections, [Chapter 39](#).)

Infectious Diseases of the Dog and Cat, 3rd Edition

89.4.3 Histocytic Colitis

The colitis that occurs in boxers, French bulldogs, and occasionally in other breeds (e.g., one time in a Mastiff, an Alaskan malamute, an English bulldog, and a Doberman pinscher) and begins at a young age is characterized by large-bowel diarrhea including hematochezia, increased frequency of defecation, and tenesmus.^{131,301,315}

One report of the disease in a cat has also been made.³²⁸ The lesions are typically granulomatous and associated with infiltrates of periodic acid-schiff (PAS)-positive histiocytes. It may be a secondary result of chronic ulceration and a reaction to intestinal microflora. Immunohistochemical studies have described increased numbers of CD3+ T cells, IgG3+ and IgG4+ plasma cells, major histocompatibility complex class II+ cells, L1+ macrophages, and neutrophils, as well as decreased numbers of goblet cells in the colonic lesions.⁸⁴

Although organisms have not been confirmed in lesions and are difficult to visualize by light microscopy, EM and other observations have suggested that organisms such as enteroadherent bacteria, cell-wall deficient mycobacteria, or *Mycoplasma*, *Chlamydia*, or *Bartonella* species have been involved. This situation is reminiscent of one related to Whipple disease in people, in which a new actinomycete bacillus—*Tropheryma whipplei*—related to other soil bacteria was finally discovered. In Whipple disease, macrophages containing PAS-positive granules, presumably from staining of bacilli and their remnants, are found within the lamina propria of the small intestine.⁷⁵ Empirically, histiocytic colitis has been successfully treated with a combination of clavamox, metronidazole, spiramycin, and enrofloxacin. However, enrofloxacin has also been used as the only antimicrobial to control this disease,^{51,131} indicating that a yet-to-be-identified quinolone-susceptible microorganism is likely responsible for the disease (Table 89-19). Remarkably, histologic abnormalities of cellular infiltration resolved in dogs beginning the first week of treatment, and diarrhea usually resolves within 12 days of instituting treatment. The duration of treatment has ranged from 1 to 21 months, and the length can only be established by stopping therapy to determine whether clinical signs recur. Treated and recovered dogs have been off therapy for up to 14 months without relapse of signs even though PAS-positive macrophages persisted in their colonic biopsy specimens.¹³¹ This response to the quinolone administration suggests that an undetermined microorganism may be responsible for this syndrome, or quinolones may have an unknown immunomodulatory effect on this condition. Granulomatous inflammation of the bowel can also develop in animals with feline infectious peritonitis, protothecosis, mycobacteriosis, and zygomycosis and pythiosis (see Chapters 11, 50, and 67, respectively).

89.4.4 Chronic Colitis

Chronic idiopathic colitis is a common syndrome recognized in dogs, characterized by intermittent diarrhea with hematochezia and tenesmus, weight loss, occasional vomiting, and abdominal pain. As a syndrome, it does not appear to be as important as it is in cats. Fever is not a consistent finding with large-bowel inflammation.

Chronic ulcerative colitis does not appear to be associated with primary bacterial pathogens but probably results from stress, debilitation, or immunosuppression in conjunction with an immune imbalance. Comparison of cell populations among dog groups indicated that IgA- and IgG-containing cells and CD3+ T cells were significantly more numerous in the colonic mucosa of dogs with lymphocytic-plasmacytic colitis (LPC).¹⁴⁹

Chronic colitis has also been identified in dogs with perianal fistulas.¹⁴³ Semiquantitative reverse transcriptase PCR (RT-PCR) was performed using specific primers on RNA isolated from the colonic mucosa of healthy dogs, dogs with clinical signs of large intestinal disease but normal histopathologic signs in the colon, and dogs with LPC.²⁵⁷ In comparison with healthy colonic mucosa and the mucosa of dogs with large intestinal diarrhea but normal histopathologic signs, canine LPC was associated with overexpression of IL-2. Higher levels of TNF- α mRNA were also seen in the mucosa of dogs with LPC than those with healthy mucosa. These results

Infectious Diseases of the Dog and Cat, 3rd Edition

suggest that LPC is associated with activation of CD4+ T-helper lymphocytes and increased production of T-helper-1-type cytokines. That the lesions are invaded by intestinal microflora after mucosal disruption may explain the apparent beneficial effect of antibiotics and the occasional deleterious effect of glucocorticoids in treating this disease.

a See Drug Formulary, [Appendix 8](#) for additional information on each drug.

b Dose per administration at specified interval.

c Most cats get one fourth of a 250-mg tablet per day.

d Recommended for histiocytic ulcerative colitis of boxers and other dogs.

e 75,000 units/kg in equivalent dosage.

f Librax, Roche Products Inc., Marrati, P.R.

Older cats appear to be affected by a chronic ulcerative colitis similar to that of dogs.³⁴⁸ Cats infected with FeLV or FIV can develop chronic ulcerative colitis, presumably as an immunosuppressive phenomenon. LPC, a chronic IBD, has been described in cats with chronic large-bowel diarrhea.²²⁰

Acute or chronic colitis should be suspected in any animal with large-bowel diarrhea. A stained fecal smear and rectal scraping and a parasite examination are helpful in eliminating parasitism, neoplasia, and algal and fungal

Infectious Diseases of the Dog and Cat, 3rd Edition

disorders as causes of the diarrhea and in many cases, they help to confirm a diagnosis. A presumptive diagnosis of colitis should be confirmed by colonoscopy and biopsy (Fig. 89-9).

Increased fiber may benefit animals with colonic inflammatory diseases as a result of enhanced motility, increased fluid and electrolyte absorption, or dilution of luminal toxins. Either fermentable (soluble) or nonfermentable (insoluble) fiber can be considered. Soluble fiber, such as that found in oat bran, is fermented into short-chain fatty acids (acetate, butyrate, propionate) that facilitate the colonic mucosae and reduce pathogenic microbial growth.⁸⁰ Diets containing insoluble fiber from wheat bran or other cellulose are often beneficial because they solidify the stool and absorb free water. FOS-containing diets have been used in cats to increase fecal numbers of lactobacilli and *Bacteroides* and decrease numbers of *E. coli* and clostridia.²⁹⁷ Their overall benefit for clinical use in colonic inflammatory diseases has not been evaluated.

The antibiotics that have been useful in treating canine and feline ulcerative colitis are primarily those that are effective against anaerobic bacteria (see Table 89-19). Metronidazole, tylosin, and sulfasalazine have been most commonly used (see Drug Formulary, Appendix 8). Without antimicrobial and adjunctive therapy, lesions usually do not resolve spontaneously. Additional measures include dietary management, which is often attempted first in dogs and cats. Food should be withheld for 24 to 48 hours, and the animal should start on a bland diet, receiving multiple, small feedings. A nonallergenic, low-fat diet, such as boiled rice, meat, and

907

908

potatoes, is satisfactory.²⁵⁶ For dogs, prescription diets (I/D or D/D, Hills, Topeka, Kan.) are indicated. Drugs that have been most effective in dogs and cats include oral sulfasalazine, oral chloramphenicol, and oral metronidazole. In addition to its antibacterial effect, sulfasalazine inhibits intestinal hypersecretion by interfering with leukotriene and prostaglandin synthesis. After several weeks of therapy, the dosage should be reduced, and in animals requiring long-term therapy, the minimum effective dose should be determined. Cats with LPC have responded to sulfasalazine with or without concurrent metronidazole and glucocorticoid therapy or to dietary management of lamb and rice or a prescription diet (c/d DIET, Hills, Topeka, Kan.).²²⁰ Omega-3 fatty acids have been added to commercial diets for IBD because of their antiinflammatory effects. Glucocorticoids should be provided at antiinflammatory doses with caution and only if relapses have occurred after clinical improvement has been noted with antimicrobial therapy. When stress is suspected to be a problem or diarrhea is incessant, clidinium and chlordiazepoxide, diphenoxylate, loperamide, or diazepam may be added to the regimen. Because colonic motility is already depressed in dogs with colitis, there is no need for routine anticholinergic or opiate drugs unless given for relief of acute straining. Antispasmodic drugs, such as diphenoxylate and loperamide, must be used with caution in invasive bacterial infections of the bowel because of the increased risk of sepsis or toxemia. In acute experimental colitis in dogs, drugs such as desferrioxamine, verapamil, and disulfiram, which are oxygen free-radical scavengers, were effective in preventing mucosal ulceration.¹⁶⁸

Fig 89-9 Colonic mucosal swelling and hemorrhage in dog with ulcerative colitis. (Courtesy University of Georgia, Athens, Ga.)

89.5 INTRAABDOMINAL INFECTIONS

89.5.1 Pancreatitis

Pancreatic infection with bacteria develops in less than 10% of humans with acute pancreatitis but in up to 40% of those with severe pancreatitis. Bacterial contamination may arise from hematogenous spread from the systemic circulation, duodenal reflux up the pancreatic duct, contamination from the biliary tree, or bacterial translocation from the lower bowel via the portal circulation. With necrotizing pancreatitis, structural and functional hemodynamic alterations in the bowel cause bacterial translocation from the intestine to the diseased pancreatic tissue. The goal of antibiotic prophylaxis is to reduce mortality by decreasing or delaying pancreatic colonization and systemic circulation of translocated bacteria.²⁹¹ Common enteric organisms are usually involved, causing secondary infection of acutely inflamed or necrotic pancreatic tissue (Fig. 89-10). People with severe acute necrotic pancreatitis who receive prophylactic antibiotics IV have a lower mortality rate than those who do not.¹²³ Routine broad-spectrum prophylactic antibiotic use has altered the colonizing organisms from predominantly gram-negative coliforms to gram-positive organisms without altering the rate of β -lactam resistance or fungal infection.¹³³ Even though pancreatic infections cannot be eliminated, treatment with a broad-spectrum antibacterial agent with adequate pancreatic tissue penetration reduces the morbidity and mortality of people with necrotizing pancreatitis.²⁸⁵ Although similar associations between bacterial infection

Infectious Diseases of the Dog and Cat, 3rd Edition

have not been determined for a majority of pancreatic infections in dogs and cats, veterinarians commonly use antibacterial drugs when treating this disease. In this event, similar recommendations might be considered for treating dogs and cats, especially those with severe pancreatic necrosis. Unfortunately, no pathognomonic features have been observed that distinguish acute necrotizing from chronic nonsuppurative pancreatitis in cats.⁷⁶ In cats, experimental inoculation of pancreatic ducts with *E. coli* resulted in infection with concurrent pancreatitis, whereas bacteria were cleared in cats with healthy pancreatic tissue.³⁴⁵ Antimicrobial therapy with cefotaxime (50 to 100 mg/kg, given intramuscularly (IM) every 8 hours) was started 12 hours after inoculation. Infection developed in 73% of animals receiving no antibiotics and in none of the cats receiving antibiotics. In one report of natural infection, *Enterococcus hirae* enteropathy was associated with ascending cholangitis and pancreatitis in a kitten.¹⁷⁵

Fig 89-10 Pancreatic abscess from dog. (Courtesy University of Georgia, Athens, Ga.)

In dogs with intestinal colonization by genetically labeled *E. coli*, organisms had spread to the pancreas and mesenteric lymph nodes after experimentally induced pancreatitis.¹⁶⁴ Secondary ischemic damage to jejunal and ileal mucosa was noted in affected dogs and was probably responsible for portal venous bacteremia. In dogs with acute experimental pancreatitis, significant differences in bioactive levels were found between antibiotics in pancreatic tissue.³²⁴ Ampicillin, gentamicin, and cefazolin reached therapeutic levels in blood but not in normal or inflamed pancreatic tissue. Of other drugs tested, clindamycin, metronidazole, and chloramphenicol achieved penetrance in normal and inflamed pancreas. Cefotaxime has been shown to reach effective therapeutic levels in feline pancreatic tissue.³⁴⁵ From these results, lipid-soluble drugs appear to have the best penetration in pancreatic tissue. Other drugs or combinations used in people are imipenem-cilastatin, quinolone combined with metronidazole, and an extended-spectrum penicillin (see [Table 89-20](#) and the Drug Formulary, [Appendix 8](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

89.5.2 Peritonitis and Intraabdominal Abscesses

89.5.2.1 Etiology and Clinical Findings

Peritonitis and intraabdominal abscess formation are frequent complications of intestinal perforation caused by postsurgical wound dehiscence of the GI tract, foreign bodies ([Fig. 89-11](#)), severe ulcerative enteritis, penetrating abdominal wounds, and rupture of abscesses of intraabdominal organs.^{129,130,321} Anaerobes are the predominant organisms in the generation of adhesions or abscesses or pyoabdomen. Infection of ascitic fluid may occur from hematogenous, lymphogenous, and transmural migration from the GI or genitourinary tract. Animals with peritonitis may become depressed, weak, and hypotensive after a GI illness or abdominal wounds. Fever and abdominal distention and pain are variable findings. Anaerobic bacteremia is a frequent complication.

89.5.2.2 Diagnosis

Peritonitis should be suspected when a severe, inappropriate left shift in the leukogram is found. Hypoproteinemia and hypoalbuminemia (2.5 g/dl) correlate with an increased risk of leakage after intestinal anastomosis and resultant peritonitis.²⁴⁷ Radiography may be misleading in early or localized disease. Confirmation of intraabdominal sepsis is best achieved through abdominal paracentesis. Radiographs should always precede paracentesis because pneumoperitoneum that may result can be confused with that caused by bowel perforation. Ultrasound may also be helpful before diagnostic paracentesis because it can detect small pockets of abdominal fluid for collection. In addition, it is very helpful in detecting ingested and perforating wooden foreign bodies that appear hyperechoic with shadowing.²³⁷ Focal bowel ischemia and associated localized peritonitis have been also detected with ultrasound.³³²

89.5.2.3 Abdominal Paracentesis and Diagnostic Peritoneal Lavage

For abdominal paracentesis and diagnostic peritoneal lavage (DPL), the animal is placed in lateral recumbency. The skin of the midline ventral abdomen is clipped free of hair and prepared as for surgery from the umbilicus to the inguinal region. An 18-gauge, 1-inch needle fitted to a 20-ml syringe can be used to make the tap. The needle is inserted at the level of the umbilicus. The needle is first inserted without a syringe attached to determine whether fluid flows freely. The needle can be rotated on its long axis to free any tissue that may have occluded the tip. If no fluid is obtained, a 3- to 6-ml syringe is attached, and gentle suction is applied. Plastic IV catheters or metal teat cannulas are less likely than metal needles to penetrate intraabdominal structures accidentally, and they allow sampling at greater depths. Over-the-needle catheters, into which several side ports have been incised, may increase the likelihood of fluid collection.³³³ The use of needles and IV catheters is frequently unrewarding because of occlusion, too small a volume of abdominal fluid being recovered, and localization of the inflammatory process. Multiple collection attempts in each of the four abdominal quadrants are recommended. DPL should be attempted if no material can be aspirated.^{25,26} For this procedure, peritoneal dialysis catheters or cutting fenestrated openings in flexible Teflon vascular catheters facilitates administration and withdrawal of fluid. Animals often require additional sedation for this procedure. DPL is performed by inserting the large catheter through the caudal ventral abdominal wall in the direction of the pelvic canal. A negative aspiration is followed by rapid (2- to 5-minute) infusion of warmed isotonic saline through an IV drip set at a volume of 20 ml/kg. After the animal has been gently rotated, the fluid can be removed by placing the still-connected fluid bottle on the floor to allow gravity drainage. Caution should be exercised in interpreting specimens obtained by DPL because they are diluted by the infused fluid. A portion of the fluid that runs back into the bottle should be analyzed for protein concentration and examined cytologically. If an inflammatory exudate is detected, an aliquot should be submitted for culture. The presence of degenerative neutrophils with nucleated cell counts greater than 9000 cells/ μ l, intracellular bacteria, or organic debris indicates bacterial peritonitis. In bile peritonitis, mucinous material may be found in the abdominal fluid.²³⁰ A portion of the fluid should be kept in a sealed syringe to preserve anaerobes during transport to the laboratory. Immediate inoculation of an

Infectious Diseases of the Dog and Cat, 3rd Edition

aliquot of fluid into a blood culture bottle improves the isolation rate of aerobic bacteria, even compared with centrifugation-lysis methods.²⁸⁷ Rare complications of paracentesis include introduction of contaminants, spread of infection from an abscess, laceration of a hollow viscus, or intraperitoneal bleeding.

Fig 89-11 Intestinal foreign body removal from dog via enterotomy can result in contamination of surgical site and intraabdominal infection. (Courtesy University of Georgia, Athens, Ga.)

Although cytologic examination is most helpful in determining whether septic peritonitis is present, toxic neutrophils or intracellular bacteria are not always consistently found. Simultaneous measurement of pH, bicarbonate, lactate and glucose concentrations in peritoneal fluid and blood has been evaluated as means of distinguishing septic peritonitis.²⁹ A glucose concentration difference of 20 mg/dl between blood (higher) and peritoneal fluid (lower) was a reliable means of differentiating septic from nonseptic effusions. In some of the dogs a blood-to-fluid lactate difference was evaluated, and a difference of 2.0 mmol/L was helpful. In additional studies, dogs with septic abdominal effusions had absolute peritoneal fluid concentrations greater than 2.5 mmol/L and a peritoneal fluid lactate concentration higher than that of blood.¹⁸⁰ However, this same method was not accurate in detecting septic peritoneal effusions of cats. DPL was also helpful in identification of blastomycosis in a dog with peritoneal involvement.²²¹

89.5.2.4

Therapy

Antibiotic therapy is important in the management of intraabdominal infections (Table 89-21).¹¹ Mixed infections caused by indigenous flora are associated with GI leakage. With gastric leakage, lower concentrations of bacteria result in lower prevalence of infection, unless microbial overgrowth develops from decreased gastric acid output and gastric motility or from gastric ulcers or malignancies.²²² With biliary leakage, contamination rates are intermediate. With lower small intestinal and colonic leakage, infection is certain. Organisms in all cases are a mixture of facultative anaerobic bacteria, usually Enterobacteriaceae, and obligate anaerobes.

Infectious Diseases of the Dog and Cat, 3rd Edition

A combination of surgical drainage and antimicrobial therapy is required for treating most cases of intraabdominal infections. The use of either primary closure or open peritoneal drainage for treatment of septic peritonitis appears to be equivocal with survival rates that have ranged between approximately 50% and 70%.^{299,174} Dogs with open drainage were more likely to require plasma transfusions and placement of a jejunostomy tube because of protein loss than those treated with primary closure. Closed-suction drainage has been beneficial in treating animals for which primary closure is used.²¹⁶ Therapy to treat facultative enteric gram-negative bacteria (e.g., *E. coli*) and anaerobes (e.g., *Bacteroides fragilis*) is essential when leakage occurs from the small intestine, cecum, or colon. Aerobes (e.g., *E. coli*) are important in producing bacteremia and early mortality in intraabdominal infections, whereas the obligate anaerobes, which outnumber them, are instrumental in leading to adhesions, abscess formation, and pyoabdomen. Drugs such as aminoglycosides have been recommended because of their effect on gram-negative bacteria.^{124,155} In animals with experimentally induced intraabdominal sepsis, the administration of aminoglycosides alone greatly reduces the mortality associated with gram-negative sepsis, although the prevalence of postoperative adhesions and abscess formation are unaffected. Under similar experimental circumstances, the use of drugs effective against anaerobic bacteria such as clindamycin resulted in death from gram-negative septicemia, even though the prevalence of intraabdominal abscesses was reduced. This finding indicates that antimicrobial drugs or combinations used in treating intraabdominal sepsis must be effective against aerobic and anaerobic intestinal flora to decrease mortality and abscess formation after peritonitis. Animals with severe bacterial peritonitis may be sensitive to the nephrotoxicity associated with aminoglycosides. Regimens in which a third-generation cephalosporin such as cefotaxime is substituted for the aminoglycoside or metronidazole is substituted for clindamycin give similarly favorable results. Combinations in which a parenteral quinolone is substituted for an aminoglycoside are also possible for dogs. Parenteral amoxicillin-clavulanate offers an effective combination in available areas outside the United States. In humans for whom cost is not a factor, single-agent regimens include a β -lactam and β -lactamase inhibitor combination (e.g., ampicillin-sulbactam, ticarcillin-clavulanate, or piperacillin-tazobactam), or a carbapenem (ertapenem, meropenem, or imipenem-cilastatin).²⁹² The combination regimens recommended for use in humans include a second- or third-generation cephalosporin (cefazolin or cefuroxime) plus metronidazole, a quinolone plus metronidazole, or aztreonam plus metronidazole.²⁹² Based on expense and the risk of inducing resistant bacterial strains that might transfer from animals to people, these combinations should be restricted in animal use. A summary of antimicrobial drug combinations recommended for abdominal sepsis in dogs and cats is presented in [Table 89-21](#).

89.5.2.5

Antimicrobial Prophylaxis

To reduce postoperative complications, antimicrobial agents can be administered to animals without established infections when they undergo abdominal surgery in which spillage of ingesta is anticipated. Preoperative and intraoperative administration of cephalosporins or penicillin derivatives combined with aminoglycosides has been effective in reducing the complications of intestinal leakage and peritoneal contamination in people. However, total sterilization of the bowel before surgery is impossible in a conventional environment. Bowel sterilization has been achieved only experimentally in dogs that have been kept in a germ-free environment, fed sterilized food, and given combination therapy with large dosages of nonabsorbable antibiotics.³³¹ Even with these elaborate procedures, decontamination was incomplete, and the microflora was reestablished within 1 week after termination of therapy. Administration of prophylactic antimicrobial therapy for GI surgery should begin 12 to 24 hours before the operation and terminate on the day of surgery if the bowel contents are not spilled. One week of therapy is indicated if contamination occurs during the surgical procedure.

Infectious Diseases of the Dog and Cat, 3rd Edition

Granulocytic colony-stimulating factor (G-CSF) has been administered before experimental peritonitis in mice.³³⁰ Compared with antibiotics alone, antibiotics in combination with G-CSF improved survival, decreased splenic bacterial colony-forming units, and increased IL-10.

89.5.2.6

Management of Surgical Contamination

Postoperative peritonitis can have a higher risk of complications than naturally acquired forms of peritoneal inflammation.²⁶¹ An advantage is that spillage can be anticipated, and a knowledge of the normal enteric flora can assist in appropriate choice of prophylaxis to use. Spillage of intestinal contents during

910

experimental surgery in dogs has been best controlled by rinsing the peritoneal cavity with an irrigation solution of neomycin (500 mg), polymyxin (500,000 U), and bacitracin (50,000 U) mixed in 1 L of saline.^{246,331} Similar broad-spectrum antimicrobial activity can be achieved by rinsing the peritoneal cavity with organic iodine solutions diluted 1:10 to 1:20 with physiologic saline. Intraabdominal instillation of

911

povidone-iodine solutions can cause peritonitis and hepatotoxicity in dogs.²¹⁸ Dosages of 3.5 ml/kg of a 10% solution caused neutrophilic leukocytosis, increased hepatic enzyme activity, icterus, and death. Lower dosages (2 ml/kg) had fewer side effects. Although beneficial when given with antimicrobial therapy or drainage, saline alone to rinse the abdominal cavity has been less successful in preventing infection, despite its diluting effect on the spilled material (see Halogens, [Chapter 94](#)).

- a See Drug Formulary, [Appendix 8](#) for additional information on these drugs.
- b Dose per administration at specified interval.
- c Oral route recommended for pancreatitis and only in intraabdominal sepsis when animals are not vomiting.
- d Or other third-generation cephalosporin.
- e Or other fluoroquinolone.
- f Must be diluted 10-fold before IV administration, and then given very slowly over 10 minutes.
- g Extrapolation of human dose with limited studies in dogs and cats.

89.5.2.7 Management of Established Peritonitis

Antimicrobial therapy is essential for animals with acute septic peritonitis. Broad-spectrum antimicrobial therapy is less important than lavage in the management of established peritonitis. This procedure involves the placement of intraabdominal tubes and daily infusion and removal of isotonic saline solutions. Antimicrobial agents can be placed in the infusion fluid to reach higher concentrations than when they are

Infectious Diseases of the Dog and Cat, 3rd Edition

given orally or parenterally. Only small amounts of many systemically administered antibiotics reach the peritoneal cavity, whereas most of the drug introduced into the abdominal cavity enters the systemic circulation.

Open peritoneal drainage has usually been successful for treatment of established generalized peritonitis in dogs and cats.^{48,94} The technique involves exploratory laparotomy, surgical correction of the cause, lavage of the abdominal cavity, and incomplete closure of the ventral midline incision with supportive wraps. The abdominal cavity is treated like one large abscess that can drain through the open incision. When the bandage is changed, additional lavage is performed. Complications are loss of fluids, proteins, and electrolytes. Absorbent abdominal pads are applied under a supportive wrap to draw fluid away from the incision. This method is reserved for advanced cases of septic peritonitis in which all the tissues cannot be debrided and sepsis is expected from residual intraabdominal inflammation. Closure of the peritoneal cavity was usually done 3 to 4 days after surgery. Antimicrobial therapy was continued until the time of final closure.

Aminoglycosides, such as gentamicin given IM, and cephalosporins given orally or IM result in minimal peritoneal concentrations. Higher concentrations, should they be desired, might be added in restricted therapeutic doses to the peritoneal lavage fluid. When given orally, metronidazole, a relatively effective drug for anaerobic infections, reaches a higher concentration than most other antimicrobial agents in peritoneal effusions.⁸¹

90 CHAPTER 90 Hepatobiliary Infections

Sharon A. Center

90.1 ANTIBACTERIAL DEFENSE

Bacteriologic studies of portal vein blood of the mature dog have shown that alimentary flora commonly circulates to the liver.^{22,24} Although unproven, the suspicion is that this activity also occurs in the cat. Enteric organisms delivered to the liver in the healthy animal are extracted by the hepatic Kupffer cells and either killed or excreted in bile. Liver disorders associated with ischemic injury, impaired hepatic artery perfusion, reduced macrophage function, and cholestasis can be complicated by infections derived from this normal enteric flora.¹⁶

90.2 SUSCEPTIBILITY TO INFECTION

Given the dual blood supply and strategic location of the liver, its exposure to substances derived from the splanchnic and systemic circulations is considerable (e.g., gut-derived particulate debris, toxins, microorganisms, immunoreactive substances). The hepatic Kupffer cells (hepatobiliary macrophages) play an essential role in the innate immune response to bacteria and their by-products entering from the portal system. These cells also protect against systemic bacteremia by cleansing blood delivered through the hepatic artery. Hepatoprotection against systemic toxicity and infections can become compromised when the liver is injured in a variety of ways. The integrity of the hepatic reticuloendothelial system (RES), which influences systemic susceptibility to enteric bacterial translocation (i.e., is associated with hemorrhagic and endotoxic shock, trauma, and bowel ischemia), is compromised in chronic liver disease, portal hypertension, portosystemic shunting, and cholestasis.¹²⁰ Consequently, patients with liver disease have increased risk for hepatic infection with or without polysystemic complications. In addition, the expansive sinusoidal endothelium of the liver provides a site for invasion by vasculotropic organisms.

Substantial host-dependent differences exist in hepatic clearance of blood-borne particulates. In dogs, 60% to 90% of hematogenously borne bacteria and particulates are removed by the liver and spleen, giving them an inherent propensity for hepatobiliary infections.^{40,180} Comparatively, the cat appears to target pulmonary macrophages preferentially. Failure of hepatic Kupffer cells to function properly can shift the burden of RES function to other organs, such as the spleen, lungs, and lymph nodes, as has been shown in dogs with chronic liver disease associated with acquired portosystemic shunting and in dogs with congenital portosystemic vascular anomalies (PSVA).^{78,95} Humans with cirrhosis have an increased incidence of bacterial infections; similar data is unavailable for the dog and cat. Current belief asserts that the predominant perfusion of hepatic sinusoids with portal venous blood, a low-flow low-pressure system, rather than arterial blood, facilitates efficient bacterial removal by the RES because slower flow permits greater opportunity for phagocytosis.^{85,140} Given that hepatic arterial perfusion compensatively increases when portal flow is compromised (for example, chronic liver disease with portal hypertension and portosystemic shunting or PSVA or hepatofugal circulation), change in sinusoidal blood flow may thwart efficient phagocytosis.

913

90.3 ENDOTOXIN

Endotoxin, or lipopolysaccharide (LPS), is derived from enteric microorganisms and is a normal constituent in portal venous blood. These glycolipids represent a portion of the outer bacterial cell membrane of gram-negative

Infectious Diseases of the Dog and Cat, 3rd Edition

bacteria and are largely derived from organisms colonizing the colon.¹⁶² Normally, hepatic Kupffer cells efficiently clear endotoxin such that the liver attenuates systemic exposure. Endotoxin extraction is enabled by high-affinity LPS receptors on Kupffer cells and LPS-binding glycoproteins on hepatocytes that facilitate transfer to Kupffer cell receptors. On exposure to endotoxin, Kupffer cell activation initiates a series of signals eventuating in production of proinflammatory cytokines. Consequently, increased hepatic exposure to endotoxin can exacerbate ongoing liver injury and produce changes in liver enzymes reflecting inflammation.

Certain changes in liver function or perfusion can increase hepatic and systemic exposure to endotoxin. In fact, endotoxemia in the absence of overt sepsis is a common finding in cirrhotic humans. Although higher levels of endotoxemia are associated with hepatic failure, hepatic encephalopathy, and death, it is unclear whether detectable systemic endotoxin levels reflect normal exposure left unchecked by the dysfunctional liver, relevant systemic abnormalities, increased enteric uptake (i.e., enhanced enteric endotoxin translocation), or if they play a causal role in liver disease or merely represent an epiphenomenon. Because enteric bile acids bind and inactivate endotoxin, patients with extrahepatic bile duct occlusion (EHBD) or severe cholestasis having impaired enterohepatic bile acid circulation may experience increased enteric endotoxin uptake and hepatic exposure.¹⁵⁵ Dogs with experimentally induced chronic liver disease (chronic administration of dimethylnitrosamine) with acquired portosystemic shunts develop measurable portal, hepatic, and caudal vena caval venous endotoxemia.⁷⁹ Dogs with PSVA ($n = 10$), medically stable at the time of laparotomy for vascular ligation, also had detectible endotoxemia in portal and peripheral venous samples (mean \pm SD, 28.0 ± 16.9 versus 19.6 ± 7.0 ; median [range], 20 [12 to 40] versus 17 [8 to 30]). In the PSVA dogs, shunt ligation attenuated peripheral endotoxemia at postoperative sampling (at 5 to 13 months).¹³⁵ Small patient numbers precluded achieving significant differences ($p = 0.06$, six dogs studied postoperatively). These observations in clinically relevant conditions suggest that systemic endotoxemia is a real phenomenon in dogs and, by inference, suggest increased systemic exposure to enteric microbes and their by-products in the circumstance of hepatofugal circulation. However, systemic response to endotoxemia, the presence of bacteremia, or evidence of altered oxygen utilization in portal blood have not been shown in dogs with PSVA.¹⁶⁹

90.4 ROLE OF KUPFFER CELLS

Hepatic Kupffer cells comprise the largest compartment of tissue macrophages in the body, representing 80% to 90% of the total fixed macrophages and approximately 35% of the nonparenchymal liver cells.⁷⁰ Residing mainly within the lumen of the hepatic sinusoids and adherent to endothelial cells by long cytoplasmic processes, Kupffer cells are most numerous in the periportal area where they offer first-line defense against bacteria, endotoxin, and microbial debris entering from the alimentary canal.⁵⁷ Kupffer cells possess both F_C and C_3 receptors and phagocytize a wide variety of opsonized and nonopsonized particulates.¹⁰⁰ Similar to other mononuclear phagocytes, Kupffer cells also have the capacity to function as antigen-presenting cells, for induction of T lymphocytes, and on activation, can release superoxide radicals, hydrogen peroxide, nitric oxide, hydrolytic enzymes, and eicosanoids (prostaglandins and leukotrienes), which can aid in antigen destruction. They also release a large number of different immunoregulatory and inflammatory cytokines, including interleukin (IL)-1, IL-6, tumor necrosis factor (TNF)- α , platelet-activating factor, transforming growth factor- β (TGF- β), and interferon (IFN)- γ . A heterogeneous population of Kupffer cells resides in different lobular zones. Cells associated with the portal triad (zone 1) are larger, more phagocytic, and generate greater amounts of TNF- α , IL-1, prostaglandin E, and lysosomal enzymes. Smaller cells are associated with zone 3 where more nitric oxide and superoxide are produced; these exhibit greater cytotoxic activity to certain stimuli and are more easily activated.⁵² Nitric oxide released by Kupffer cells mediates a wide variety of physiologic events, including (but not restricted to) vasodilation, neutrophil chemotaxis, and adhesion of neutrophils to vascular endothelium in response to

Infectious Diseases of the Dog and Cat, 3rd Edition

bacteria or endotoxin.⁷⁰ As potent inducers of inflammatory cytokines, Kupffer cells are implicated in the pathologic events leading to liver injury.¹⁶² Inflammatory mediator release from Kupffer cells is enhanced after *priming* by endotoxin exposure in *reactive* hepatobiliary processes. Later, during the course of infection, other cells including hepatocytes, T lymphocytes, and immigrating phagocytes (monocytes and neutrophils) contribute cytokines to the inflammatory process. Certain bacteria undergo initial physical attachment to Kupffer cell surface receptors (macrophage scavenger receptors) and are subsequently cleared from the sinusoidal circulation. These receptors have a high affinity for a broad range of polyanionic ligands, including lipoteichoic acid, a component of gram-positive bacteria.^{52,131} However, some organisms are not efficiently cleared by Kupffer cells (e.g., *Pseudomonas aeruginosa*, *Morganella morganii*, and *Serratia marcescens*) caused by cell surface composition or increased hydrophobicity, or both.⁶⁹

90.5 ROLE OF NEUTROPHILS

Routine, uneventful removal of bacteria, endotoxin, and particulate and antigenic debris acquired from the portal venous circulation occurs in part in collaboration with infiltrating neutrophils. Immigrating neutrophils contribute an early bactericidal influence important for bacterial pathogen clearance.⁶⁹ While providing this ancillary defensive role, neutrophil participation also may impart self-injury. Neutrophil accumulation in hepatic sinusoids, a distinguishing feature of endotoxemia and sepsis, fosters the production, release, and accumulation of toxic metabolic products and degradative enzymes (reactive oxygen intermediates and proteolytic enzymes) from themselves, as well as from neighboring Kupffer cells. This involvement of neutrophils in response to endotoxin exposure confuses histologic interpretation of hepatobiliary lesions, erroneously suggesting in some cases the actual presence of an infectious organism. This response may contribute to the lesion characterized as *reactive hepatitis*, commonly described in liver biopsies from veterinary patients with inflammatory bowel disease (IBD). Neutrophil associated tissue injury is normally limited by neutrophil apoptosis and phagocytosis by hepatic Kupffer cells on infection control or toxin elimination. Dysregulation of these mechanisms can propagate chronic liver injury and inflammation.

913

914

90.6 BILE: PROTECTION FROM INFECTION

Hepatobiliary production of bile and IgA contribute importantly to the health of the biliary and gastrointestinal (GI) systems. Secretory IgA (S-IgA) is the major immunoglobulin in bile; IgG and IgM are present in much smaller amounts. IgA binds to a secretory component, made in the liver, forming an S-IgA complex, which assists in maintaining mucosal integrity by binding infectious agents (e.g., bacteria, viruses). Bile and IgA both influence enteric bacterial populations (type, number of organisms, and enterocyte adherence). Normal physiologic choleresis (bile flow) routinely cleanses biliary pathways. The normal biliary-entero-bacterial cycle permits rapid elimination of bacteria achieving entrance to the biliary tree, and local IgA production protects against epithelial invasion.^{20,154} Bile salts contribute an antibacterial influence synergistic with IgA binding, limiting enteric and biliary bacterial translocation. Normally, tight junctions between hepatocytes resist bacterial entry into canalicular bile. Along with the high competence of the extrahepatic biliary structures, normal pressure differentials in the biliary system limit retrograde access of enteric organisms to the hepatobiliary system. However, development of EHBDO or substantial cholestasis of any cause can interrupt these mechanisms, increasing host susceptibility to infection.¹⁵⁴

Infectious Diseases of the Dog and Cat, 3rd Edition

90.7 BACTERIAL FLORA OF THE HEPATOBILIARY SYSTEM

The sterility of the portal venous circulation, hepatic tissue, and bile in health has been investigated for more than 50 years. Although older studies suggest that liver tissue is commonly contaminated, especially with *Clostridium* spp., more recent work is contradictory.^{38,49} In the absence of biliary tree obstruction or choleliths, gallbladder and bile are now thought to be normally sterile.¹⁵⁵ Improved methods of collecting samples (reducing cross-contamination) has been suggested to explain disparate observations.

Normally, enteric organisms delivered to the liver are extracted and killed by neutrophils and hepatic Kupffer cells. Remaining organisms are thought to be excreted in bile. Clearly, even in normal animals, portal venous translocation of large bacterial inocula result in hepatic sinusoidal bacterial exposure and bacterobilia.¹⁶² In the diseased liver (e.g., perfusion abnormalities, impaired macrophage function, cholestasis), survival of infectious agents may be permissively affected by loss of normal protective mechanisms already discussed.²⁰ Consequently, diseases of the biliary tract and liver may be complicated by the presence of pathogenic bacteria (in bile [bacteriobilia] or liver tissue) as a secondary phenomenon. Positive bacterial culture results from liver tissue and bile from animals with chronic liver disease in the author's hospital supports this contention.

90.8 CIRCUMSTANCES INCREASING THE RISK OF HEPATOBILIARY INFECTION

The liver plays a key role in providing protective responses during gram-negative sepsis. Consequently, a variety of liver diseases place the host at increased risk for infection. Enhanced pathogenicity of gram-negative sepsis has been demonstrated in experimental cirrhosis in animal models.⁷⁷ An important point to acknowledge is that bacterial organisms commonly found in bile, gallbladder, or liver tissue, in disease, are nearly always enteric in origin. Greatest risks for infection and postoperative sepsis exist for EHBDO and chronic liver disease associated with portal hypertension, compromised hepatic perfusion or Kupffer cell function, or both, and conditions promoting enteric bacterial translocation.

Along with reduced mechanical cleansing of the biliary tree, impaired biliary IgA production or delivery, enhanced translocation of gut flora into the splanchnic circulation, impaired Kupffer cell activation and phagocytosis, reduced humoral immunity, compromised neutrophil rolling, migration, or adherence in hypertensive splanchnic vasculature (but not in hepatic sinusoids), disruption of tight junctions between hepatocytes, and increased access to hepatic lymph, each facilitate infection.* Cholestasis also imposes an immunosuppressive effect by reducing in vitro lymphocyte transformation testing. This activity relates to high plasma, tissue, and bile concentrations of dihydroxy bile acids.¹⁵⁵

* References: 47, 88, 133, 138, 139, 141, 143, 165, 167, 172, 174.

90.9 INFLUENCE OF CHOLESTASIS ON HEPATOBILIARY INFECTIONS

Any disorder invoking cholestasis can compromise protective mechanisms normally derived from bile and normal choleresis. EHBDO provokes numerous changes facilitating hepatobiliary and systemic bacterial infection. Animal models of EHBDO, including dogs and cats, convincingly demonstrate that impaired enteric bile flow favors small intestinal bacterial overgrowth (SIBO) and enteric-bacterial translocation.³⁴ Cessation of enteric bile delivery (bile salts and s-IgAs) curtails the normally suppressive influence of bile salts on the endogenous bacterial population and s-IgA on bacterial mucosal adherence. Defective RES function, altered sinusoidal fenestra in the area of the peribiliary plexus (permitting greater access to bacterial organisms), reduced enteric mucosal

Infectious Diseases of the Dog and Cat, 3rd Edition

integrity, and impaired endotoxin clearance or inactivation augment the opportunity for enteric bacterial and endotoxin translocation to mesenteric lymph nodes, liver, and the systemic circulation. Given that the liver is metabolically compromised in cholestasis and the RES dysfunctional, a heightened risk of hepatobiliary infection is achieved. In this circumstance, development of cholangitis by any route (ascending, hematogenous, or lymphatic) is favored.¹⁵⁵ Inadequate RES function and liberalized portal bacteremia increases the risk for systemic bacteremia and endotoxemia.¹²⁸ Although biliary decompression ameliorates jaundice, chronic damage to the biliary tree causing functional changes reverse slowly, and certain functionality is never fully restored. Immune dysfunction in cholestatic liver injury derives from inadequate or inappropriate antigen processing by the RES, cytokine production by Kupffer cells, or abnormal Kupffer-hepatocyte interactions. Chronic down regulation of Kupffer cell vigilance against endotoxin increases risk for endotoxemia during episodes of heightened exposure (e.g., hemorrhagic gastroenteritis). Hepatofugal portal circulation reduces hepatic delivery and extraction of substances in the portal splanchnic vasculature, causing increased systemic exposure to immune complexes, enteric bacteria, and antigens. Impaired bacterial opsonization reduces appropriate macrophage bacterial clearance and heightens risk of infection. Dysregulation of inflammatory cascades, crucial to wound healing, may increase postoperative complications, including wound dehiscence and infections that compromise surgical recovery.¹⁵⁵

a In order from most to least common. Data acquired from case records, 1985–2001, Companion Animal Hospital, College of Veterinary Medicine, Cornell University, Ithaca, N.Y.

Experimental models have clarified the significance of enteric portal bacteremia. Infusion of 10^5 to 10^7 bacteria into the splenic vein of normal cats results in a significant reduction in bile flow and the appearance of bacteria in bile within 30 minutes. However, in the presence of EHBDO, modest bacterial inocula (10^3) cause bacterobilia within the same time frame. Bacteria enter sinusoidal blood where some are phagocytized (Kupffer cells and neutrophils), but ultimately, viable organisms enter bile.¹⁶⁷ Although mechanical obstruction of the biliary tree clearly augments bacteriobilia, also apparent is that any cause of cholestasis may impart this influence. Given that hematogenously dispersed gram-negative organisms impart a cholestatic response in both dogs and cats, this activity likely augments their risk for hepatic infection. This phenomenon may explain why bacterial organisms are unexpectedly cultured from liver tissue and bile in animals with illnesses thought not to be primarily bacterial in origin (Table 90-1).

90.10 TRANSMURAL PASSAGE OF ENTERIC ORGANISMS

The idea that translocation of bacteria and endotoxin from the GI tract may initiate or exacerbate infection has been increasingly accepted as the so-called gut hypothesis of sepsis and multiple organ failure.⁴⁵ Increased vulnerability of the jaundiced host to gut-barrier breakdown and bacterial translocation has been confirmed by many experimental studies and is strongly supported by clinical observations in veterinary patients. Diseases involving the biliary tract especially thwart protective mechanisms, leading to bacteriobilia.¹⁶⁴

Study of dogs undergoing routine ovariohysterectomy proves that enteric bacterial translocation occurs even in normal dogs.³⁷ In this study, bacteria was verified in 52% of 26 dogs by positive results of culture of a single mesenteric lymph node; the number of bacteria cultured varied from 50 to 10^5 organism/g of tissue. Organisms isolated, in decreasing prevalence, were *Escherichia coli* (n = 6), *Bacillus* (n = 5), nonhemolytic *Streptococcus* (n = 4), *Salmonella* (n = 3), coagulase-negative *Staphylococcus* (n = 2), *Enterococcus* (n = 2), and one each with *Staphylococcus intermedius*, *Clostridium sordelli*, *Micrococcus* spp., *Pseudomonas* spp., *Lactobacillus* spp., and *Propionibacterium acnes*. However, no bacteria were isolated from a single portal blood specimen.⁴²

Translocated enteric bacteria and endotoxin invoke Kupffer cytokine secretion, neutrophil chemotaxis, vascular adhesion, and degranulation, as well as proinflammatory changes in sinusoidal endothelial cells and hepatic stellate cells (the source of connective tissue in chronic liver disease), leading to fibrosis. Tissue injury derives from products of activated Kupffer cells and neutrophils, including reactive oxygen species, cytokines, and proteases, along with reactions involving complement and coagulation system activation. Gut-derived bacteria or endotoxin may provoke development of the sepsis syndrome in the absence of clinically proven microbiologic infection. Although compromised gut-barrier function is believed to be relevant to sepsis in the jaundiced patient, correlation of plasma endotoxin concentrations with morbidity and immunosuppression is inconsistent and quite

Infectious Diseases of the Dog and Cat, 3rd Edition

variable as a result of differences in regional blood sample collection, methods employed to detect endotoxin, units of expression, and inconsistent use of endotoxin standards and expression units.^{67,138}

Enteric translocation of bacteria and subsequent hepatobiliary invasion is enhanced in the presence of (1) bowel disease (direct mucosal injury), (2) altered gut flora with gram-negative microbial overgrowth (SIBO), (3) portal hypertension, (4) splanchnic hypoperfusion, (5) hepatofugal portal circulation, proven in dogs with acquired and congenital portal shunting, (6) local or systemic immunosuppression, including impaired macrophage function, (7) altered gut motility (slow transit time documented in cirrhosis), and (8) absence of enteric bile (bile acids, IgA, mechanical cleansing function of bile in the biliary tree). In human and animal models with chronic liver disease, reduced enteric transit rate has been shown to increase the risk of SIBO and enteric bacterial translocation.¹³⁴ Contributing factors include portal hypertension, acquired varices, gastroduodenal vascular ectasia associated with portal hypertensive gastroenteropathy, and oxidative damage in the bowel (with or without coexistent IBD).^{30,151,182} An increased propensity for enteric translocation of bacteria in EHBDO has been proven in dogs and cats.^{29,167} The clinical impact of cholestasis on enteric translocation is exemplified in humans in whom postoperative infectious complications following EHBDO decompression are reduced by preoperative internal biliary drainage.^{106,175}

90.1 BACTERIOBILIA

Bacteriobilia may be clinically silent until biliary obstruction leads to systemic sepsis by biliary-venous reflux. Increased pressure in the biliary system (at least 25 cm water), causing retrograde flow of bile (regurgitation) into hepatic sinusoids is a proven prerequisite for infection. The importance of mechanical disruption of bile flow is well exemplified by the long-term follow-up of humans with choledochoduodenostomy in which retrograde invasion of the biliary tree by bacteria is the rule. These patients do not develop septic cholangitis as long as mechanical obstruction to bile flow is avoided. Furthermore, clinical and experimental evidence suggests that infection is most likely when obstruction is incomplete or intermittent and is seemingly potentiated by the presence of a foreign body such as a cholelith.⁴⁸

Once enteric organisms gain access to bile, they may dehydroxylate and deconjugate bile acids, generating membranocytolytic forms (e.g., chenodeoxycholate yielding lithocholate) capable of provoking cholestasis, oxidant cell injury, immunotargeting of biliary epithelium or hepatocytes, and cell death by cytolytic necrosis or apoptosis. This activity is thought to greatly facilitate tissue injury in cats with cholangiohepatitis.

Unfortunately, the bacterial flora in bile is not accurately represented by detection of systemic bacteremia or urinary tract organisms. Anaerobic bacteria are infrequently found in blood, as compared with bile, and *E. coli* is found far more commonly in bile. Consequently, no easy and practical screening method exists for detecting bacteriobilia. Despite many experimental studies of bacterial translocation that show compelling evidence supporting this infectious pathomechanism, exactly which clinical patients besides those with EHBDO have greatest risk has not been clearly defined in either human or veterinary patients.

Cytologic evaluation of bile with a Wright-Giemsa's stain discloses a rich blue amorphous material. Identification of multilobular nuclear remnants (released from degenerating neutrophils) may be the only evidence of inflammation. However, with sepsis, bacterial organisms are commonly seen, sometimes in the absence of well-defined inflammatory cells.

Infectious Diseases of the Dog and Cat, 3rd Edition

90.12 RISKS INCREASING POSTOPERATIVE SEPSIS

Given that mechanical resolution of EHBDO allows acute mobilization of *sequestered* bacteria, a sudden appearance of bacteria in bile is realized. Failure to provide adequate antibiotic coverage during this transition increases risk of postoperative infection and sepsis in patients with biliary tree infection and EHBDO undergoing surgical investigation and correction. An important point to remember is that surgical trauma augments the risk imposed by reduced gut-barrier function in patients with cholestasis or severe hepatobiliary dysfunction.^{46,132} Presurgical internal drainage of the biliary tree in humans with EHBDO has been shown to reduce postoperative septic complications. Modifying the enteric microbial population with antibiotics (e.g., fluoroquinolones, neomycin, tobramycin) or using certain probiotics (Lactobacilli combined with antioxidants) also has reduced septic complications in humans and animal models with cholestatic liver disease. Treatment of cirrhotic humans with ciprofloxacin reduces spontaneous bacterial infections with enteric organisms.¹⁴² Restoration of biliary-enteric communication improves RES function and restores protective mechanisms lost to cholestasis, reducing the risk of systemic and biliary tree infection.¹⁵⁵

90.13 INNOCENT BYSTANDER EFFECTS ON THE HEPATOBILIARY SYSTEM

Despite the immense potential for exposure of the liver to infectious organisms, increased liver enzyme activity and hepatic dysfunction in infectious disease more commonly reflect secondary effects of systemic infection rather than specific hepatic involvement.^{116,123} Pyrexia, anoxia, nutritional deficits, released toxins, and inflammatory mediators each contribute to clinicopathologic abnormalities. “Innocent bystander” injury from pathologic conditions initiated elsewhere in the body can lead to inappropriate diagnostic emphasis on the hepatobiliary system. Occasionally, a self-perpetuating form of chronic active hepatitis may develop as a complication of infection with bacterial or viral agents. Examples include chronic hepatitis in dogs after infection with leptospirosis or canine adenovirus-1.^{13,64} An emerging role of *Helicobacter* spp. in humans with cholestatic liver disease, cholecystitis, and neoplasia of the biliary tree suggests that a relationship may also exist between this organism and liver disease.^{58,102,121} Isolation of *Helicobacter canis* from a single dog with multifocal necrotizing hepatitis has been reported; organisms were observed using a silver stain at the periphery of necrotizing lesions.⁵⁹ Bacteria were concentrated between adjacent hepatocytes in bile canaliculi and observed in the lumen of bile ducts. Organisms were cultured and phenotypically and molecularly identified as being different from *H. canis*. Detection of *Helicobacter* DNA using polymerase chain reaction (PCR) and amplicon sequencing from archived formalin-fixed liver tissue from 2 out of 29 cats with cholangiohepatitis and a cat with PSVA included in a control group was reported in a scientific abstract.⁷¹ Based on comparisons to published sequence homology, *H. nemestrinae*—*H. pylori* and a combination of *H. nemestrinae*—*H. pylori*, and *H. felis*—*H. cinaedii* in the two cats with cholangiohepatitis and *H. bilis* in the PSVA cat were identified. In no case were organisms identified by silver stains or immunocytochemistry.

90.14 SYSTEMIC INFECTIONS

90.14.1 Sepsis and Endotoxemia

Hepatic dysfunction and cholestatic liver injury have been documented in people and in numerous animal models as a result of systemic bacterial infection and endotoxemia.⁴⁹ Intrahepatic cholestasis induced by severe extrahepatic bacterial infection has been experimentally modeled in dogs and cats and observed clinically in

916

these species.^{167,171} Response of the liver to systemic infection has been studied in dogs experimentally infused with endotoxin or live gram-negative bacteria, or both.^{55,72-74} Acute morphologic changes include dilation and congestion of sinusoids and hepatic veins, central (zone 3) and midzonal (zone 2) hepatocellular necrosis, fatty or vacuolar degeneration (not glycogen associated), acute diffuse influx of inflammatory cells (neutrophils and monocytes), and microabscess formation. Kupffer cell hyperplasia is occasionally described, and canalicular stasis (microscopically evident “bile plugs”) has also been described with chronicity. Considerable hepatocellular dysfunction can cause a shift to anaerobic metabolism, impair gluconeogenesis, and mobilize lipid from adipose stores. In dogs, acutely increased serum triglyceride, nonesterified fatty acids, and cholesterol concentrations reflect a metabolic shift to fatty acid oxidation.⁷² If this activity also occurs in cats, peripheral fat mobilization might augment development of hepatic lipidosis. In fatty liver modeled in the choline-deficient rat, impaired RES function increases host susceptibility to endotoxemia.¹²² Although it is not known if this is also true in cats with hepatic lipidosis, the common occurrence of a more primary disease causing anorexia and subsequently the lipidosis syndrome warrants consideration that IBD or constipation might potentiate endotoxemia in these patients.

Logically, animals with compromised liver function or cholestasis experiencing gastroenteric hemorrhage have an increased risk for endotoxemia, as is shown in humans. These patients should be treated with broad-spectrum antimicrobials appropriate for enteric opportunists. Unfortunately, a risk exists that aggressive antimicrobial treatment for gram-negative organisms may intensify endotoxin release and related clinical signs (as suggested by some in vitro and in vivo work). This risk relates to the type of antibiotic action and whether the microbial cell wall remains intact.^{41,81,83} For β -lactam antibiotics, endotoxin-enhancing properties relate to the affinity of the penicillin-binding proteins (PBP) in the bacterial cell wall. Antibiotics with highest affinity for these proteins (PBP-2) initiate bacterial transformation to rounded spheroplast forms without cell lysis or endotoxin release. Antibiotics with highest affinity for the penicillin-binding proteins (PBP-3) convert bacteria to long-filament forms, with substantial endotoxin release. Antibiotics with high affinity for both receptors have an intermediate effect. In addition to endotoxin-induced hepatic injury, patients with obstructive jaundice, cirrhosis, or following extensive hepatic mass excision have greater susceptibility to endotoxemia caused by impaired Kupffer cell function and hepatic perfusion and greater enteric microbial translocation.

90.14.1.1 Tick-Borne Diseases

Ticks transmit a variety of organisms, including protozoal, bacterial, and rickettsial organisms. The most common agents encountered in dogs that may have clinical evidence of liver involvement (increased liver enzymes and less consistently hyperbilirubinemia) include *Ehrlichia* sp., *Rickettsia rickettsii* and *Borrelia*. Pathomechanisms of rickettsial agents easily explain their apparent hepatic involvement in systemic infection because these organisms may infect either hepatocytes or endothelial cells. Considering the extensive endothelial network in the liver, organisms with endothelial tropism may involve the liver as an innocent bystander. In humans, hepatic involvement in ehrlichial infection occurs in over 80% of patients causing mild transient increases in transaminase activity.⁵¹ Rarely, cholestasis and liver failure may occur, but in most cases, signs of liver injury resolve with appropriate antimicrobial therapy. A similar phenomenon may also occur in dogs. Liver injury is related to proliferation of organisms in hepatocytes and by stimulation of immunologic and nonspecific inflammatory mechanisms. In humans, lesions vary from focal hepatic necrosis to granulomas and cholestatic hepatitis associated with a mixed portal infiltrate, sinusoidal lymphoid cell infiltrate, and reactive Kupffer cells.^{51,118} Vasculotropic *Rickettsia* such as the organism causing Rocky Mountain spotted fever can involve hepatic endothelium, leading to mild or moderate increases in hepatic transaminase activity, hepatocellular apoptosis, and less commonly, cholestasis. In

Infectious Diseases of the Dog and Cat, 3rd Edition

humans, cholestasis often reflects pancreatic infection and vasculitis, leading to common bile duct entrapment.^{178,181} Hemolysis also may contribute to hyperbilirubinemia.¹⁸¹ Similar effects likely occur in dogs but have not been well characterized. Systemic borrelial infections in humans, early in the course of disease, can also be associated with clinical evidence of hepatic infection (high liver enzyme activity). In dogs, this association has also been observed clinically and confirmed by liver biopsy in two ill dogs (several weeks of illness) observed by the author. Histologic lesions were consistent with lobular dissecting hepatitis in one dog and a mixed multifocal inflammatory reaction causing focal pyogranulomas in the other. Experimental work with *Borrelia* suggests that organisms are rapidly extracted by Kupffer cells following systemic dispersal and killed by nonopsonic phagocytosis (in vivo and in vitro).¹⁴⁴ Considering the complicated immunopathogenesis of *Borrelia* infections, aberrant immune response, humoral immune activity, cytokines, and cell-mediated immune events likely invoke liver injury.⁸⁰ Experimental work with the *Borrelia* suggests direct hepatic invasion by the spirochete in conjunction with cellular and humoral immunologic mechanisms.¹⁸¹

90.14.1.2 Leptospirosis

During the last 15 years, retrospective clinical reports of leptospirosis in dogs in North America and additional reports from other continents have been published, owing to increased disease recognition and diagnostic surveillance (see [Chapter 44](#)). A retrospective report of cases managed in the author's hospital documented hepatic involvement in 22 out of 36 (61%) dogs based on increased liver enzyme activity.¹² Approximately 17% became hyperbilirubinemic, although some of these dogs had evidence of microangiopathic anemia as a complicating factor. Increased serum alkaline phosphatase (ALP) activity was most common (60% of dogs with high liver enzymes) and was evident either on initial blood work or developed after initiation of treatment (antimicrobial therapy). High transaminase activity in some dogs reflected muscle injury, substantiated by concurrently high creatine kinase activity. Rise in liver enzyme activities and evidence of cholestasis during the first week of treatment is thought to reflect hepatocellular or vascular injury derived from released bacterial toxins or immunologic responses. An association between infection with *L. pomona* and high liver enzymes has been appreciated. Other retrospective and experimental studies of leptospiral infection in dogs confirm that increased ALP activity is the most common indicator of hepatic involvement.* Evidence of liver injury in the absence of renal involvement seems uncommon but may occur. Hepatic lesions in a small number of necropsied dogs were characterized by marked hepatic venous and sinusoidal congestion, severe perivenous edema, and a predominantly neutrophilic multifocal inflammatory reaction. Association between leptospiral infection and chronic hepatitis also has been recognized.¹³

* References: 12, 76, 86, 89, 137.

90.14.1.3 Clinical Findings of Hepatobiliary Involvement in Infectious Disorders

Hepatomegaly, splenomegaly, fever, icterus, and lethargy are common clinical signs. The hemogram may depict a leukopenia, degenerative left shift, and nonregenerative anemia. Markers of an acute phase response including hyperglobulinemia and hyperfibrinogenemia, a negative acute phase response of hypoalbuminemia, and hypoglycemia may develop rapidly. These changes are accompanied by variable increases in the serum activity of liver enzymes, notably alanine aminotransferase (ALT) and aspartate aminotransferase (AST). In the dog, ALP activity consistently increases after several days, and hyperbilirubinemia occurs in dogs and cats after 36 to 48 hours. Certain bacterial organisms can directly induce jaundice without causing substantial hepatic injury; however, generally, the development of jaundice

Infectious Diseases of the Dog and Cat, 3rd Edition

portends a poorer prognosis. Disseminated intravascular coagulation (DIC), acute renal failure, and myocardial dysfunction may develop in terminal cases.

90.14.1.4 Therapy

The cornerstone of treatment is the provision of adequate fluid therapy, including colloids, parenteral antibiotics effective against involved organisms, glucose supplementation in the event of hypoglycemia caused by the sepsis syndrome or hepatic failure, and identification and correction of associated conditions (see Endotoxemia, [Chapter 38](#)). Widespread interest in and documentation shows that oxidant and peroxidative injury is an important pathomechanism in necroinflammatory. Cholestatic liver disease, as well as in infectious disease, and the recent documentation of antioxidant depletion in companion animals with spontaneous liver diseases warrant provision of adequate nutritional and vitamin support and antioxidant supplementation.²⁸ Maintaining a positive nitrogen balance is important for cell repair and hepatic regeneration. Antioxidant supplementation in the form of thiol donors, that is, nutritionally as cystine, cysteine, or methionine or by supplementation with N-acetylcysteine or S-adenosylmethionine (SAME), along with α -tocopherol (vitamin E) for biomembrane protection, is recommended.²⁸

90.15 SPECIFIC HEPATOBILIARY INFECTIONS

Bacterial infections restricted to the hepatobiliary system are relatively uncommon. These infections may assume the form of multifocal microabscess formation, diffuse suppurative cholangitis-cholangiohepatitis, cholecystitis, choledochitis, ill-defined hepatic inflammation (as is the case in chronic hepatitis), or they may be associated with discrete, focal suppuration, and necrosis involving large abscesses. Conditions predisposing the patient to hepatobiliary infections are summarized in [Table 90-2](#).

90.15.1 Pyogenic Abscess

Unifocal pyogenic hepatic abscesses are rare but may develop consequent to a significant number of disorders (see [Table 90-2](#)).^{*} Most common causes include trauma, extension of sepsis from adjacent viscera or the peritoneal cavity, hematogenous distribution, ascending biliary tract infection, or ischemia associated with liver lobe torsion or a neoplastic mass that has outgrown its blood supply. In humans, dental infection is an important occult cause commonly overlooked; this also may be true in animals. Patients with solitary abscesses may have no discernible underlying or predisposing condition, whereas those with multiple abscesses usually have some other disease in the abdominal cavity or disorder producing bacteremia. Because of the dynamics of the portal circulation delivering splanchnic blood first to the right liver lobes, focal abscess formation is most common on that side in humans. Despite observation that portal blood also first disseminates here in dogs, lateralization to the right side does not appear to occur in this species. Lethal hepatic abscesses derived from omphalogenic infections have been reported in neonates in which *Staphylococcus* appears to be the most common isolate.⁷⁵

Table 90-2 Conditions Predisposing to Hepatobiliary Infections^a

Obstructed Bile Flow

Extrahepatic bile duct occlusion

Disease of the gall bladder:

Dysmotility

Cholelithiasis

Cystic duct occlusion

Cholecystic neoplasia

Parenchymal cholestasis

Destruction of intrahepatic bile ducts: ductopenia (e.g., certain cats with chronic cholangitis, cholangiohepatitis)

Microcholelithiasis (intrahepatic bile ducts)

Pancreatitis

Impaired Hepatic Perfusion +/- Oxidant Injury

Chronic necroinflammatory liver disease: chronic hepatitis, chronic cholangiohepatitis

Cirrhosis

Copper storage hepatopathy

Acquired portosystemic shunting

Congenital portosystemic shunting

Liver lobe torsion

Infectious Diseases of the Dog and Cat, 3rd Edition

Hepatic neoplasia

Primary: development of a necrotic center

Hepatocellular carcinoma, hepatoma

Metastatic:

Lymphosarcoma, adenocarcinoma, malignant histiocytosis

Portal venous thrombosis

Pancreatitis

Trauma: automobile accident, bite wounds, penetrating wounds

Compromised Immunocompetence

Hyperadrenocorticism

Diabetes mellitus

Severe hypothyroidism

FIV, FeLV infection

Treatment with immunomodulatory drugs: glucocorticoids, azathioprine, methotrexate, chemotherapy

Amyloidosis

Increased Translocation of Enteric Organisms

Inflammatory bowel disease

Enteric neoplasia: lymphosarcoma, adenocarcinoma

Chronic liver disease

Extrahepatic bile duct occlusion

Infectious Diseases of the Dog and Cat, 3rd Edition

Reduced bowel motility

Pancreatitis

Neonatal

Omphalitis

Visceral larval migrans

Toxocara

Iatrogenic

Extension from a feeding device

Surgical infection

FIV, Feline immunodeficiency virus; FeLV, feline leukemia virus.

a Disorders in dogs and cats with culture positive hepatobiliary infections.

In most cases, hepatic abscesses are linked to portal bacteremia or extension from biliary tract infections; impaired tissue perfusion increases the risk of infection.^{16,94} Portal thromboembolism related to enteric and mesenteric disease processes, liver lobe or splenic torsion, or necrosis of tumor tissue are likely causes. Immunocompromised patients have the greatest risk. In humans, polymicrobial infections and anaerobic bacteria are isolated from approximately 50% of large solitary abscesses.¹¹² Organisms retrieved from cultures of liver and bile from dogs and cats with suppurative hepatic inflammation and abscesses are given in [Table 90-1](#). Approximately 50% of these organisms were polymicrobial, at least on morphologic (cytologic) evaluation. Infections with gram-negative organisms are complicated by LPS. Some organisms (e.g., *Pseudomonas aeruginosa*) produce exotoxins that induce clinical signs of illness. Purified exotoxin A associated with *P. aeruginosa* is highly lethal for animals, producing shock in dogs. This toxin inhibits hepatic protein synthesis and impairs lymphocyte response to mitogens.¹⁵²

Multifocal microabscess formation also may occur in conjunction with a variety of organisms causing systemic infection; examples include *Listeria*, *Salmonella*, *Brucella*, *E. coli*, *Yersinia pseudotuberculosis*, *Bacillus piliformis*, *Actinobacillus lignieresii*, *Actinomyces*, *Nocardia*, and *Pasteurella*.

90.15.1.1 Clinical Findings

As an isolated focus of infection, hepatic abscess formation may provoke only vague clinical signs, including fever, lethargy, anorexia, vomiting, diarrhea, trembling, weight loss, and rarely, polyuria, and polydipsia. Physical examination usually discloses fever and abdominal tenderness, tachycardia, tachypnea, dehydration, and, less commonly, bleeding tendencies (surface hemorrhages, retinal hemorrhages), hepatomegaly, or a cranial abdominal mass effect, as well as suspicion of abdominal effusion. Early diagnosis may be difficult. Animals with systemic infections usually show signs commensurate with other organ system involvement, with the hepatobiliary system a secondarily and less overtly affected site.

Infectious Diseases of the Dog and Cat, 3rd Edition

* References: 16, 54, 73, 75, 94, 104, 114, 153.

90.15.1.2 Diagnosis

Most patients develop a neutrophilic leukocytosis inconsistently associated with a left shift, toxic neutrophils, and monocytosis. Some patients become thrombocytopenic (severe to mild) and demonstrate a nonregenerative anemia. Increased serum ALT (1.1 to 50 times high normal), AST (1.1 to 18 times high normal), and ALP (1.2 to 21 times high normal) activities and hyperglobulinemia are common. Hyperfibrinogenemia with an associated hyperglobulinemia represents an acute-phase response. Hyperbilirubinemia is inconsistent and usually mild. The sepsis syndrome is exhibited by hypoglycemia and high lactate concentrations.⁵⁵ Studies in dogs confirm that lactic acidosis derives from increased splanchnic lactate production and reduced hepatic lactate extraction.³³ Gram-negative bacterial abscess formation often evokes laboratory features of endotoxemia. Septic peritonitis follows abscess rupture. Blood cultures are more likely to be positive in patients with multiple abscesses and rarely disclose anaerobic organisms.

Ultrasound (US) provides the best chance for early diagnosis of unifocal hepatic abscess formation and is capable of disclosing focal lesions that are 0.5 cm or larger. In humans, US is considered the diagnostic modality of choice because of high utility in both detecting and serially monitoring lesions. US imaging also may disclose evidence of multiple *miliary* abscesses overlooked by more sophisticated imaging modalities (e.g., computerized tomography [CT], contrast-enhanced imaging).¹⁷¹ US appearance of hepatic abscesses is variable and may appear as anechoic masses having irregular margins, as lesions with a well defined rim, or it may contain variable and complex internal echoes (Figs. 90-1 and 90-2, A and B). The presence of a gas-associated anechoic (fluid) compartment highly suggests infection; gas appears echogenic with or without acoustic shadowing depending on its amount and distribution. Overall echogenic patterns associated with hepatic abscesses have been described as (1) *hypoechoic lesions*, consistent with liquefaction necrosis, (2) *heteroechoic lesions*, reflecting an irregular hyperechoic abscess rim surrounding a liquefied hypoechoic center, or (3) *hyperechoic lesions*, representing a highly cellular “cellulitis” or pyogranulomatous reaction, caseation, dystrophic mineralization, or an emphysematous foci.^{82,114} Rarely, a target lesion similar in appearance to hepatic neoplasia (especially carcinoma) may be observed. An important rule-out diagnosis is fluid collection in benign cystic structures; these are comparatively free of internal echoes and are associated with well-defined walls, usually generating excellent sonographic transmission. Unfortunately, US images of hepatobiliary abscesses may be compromised by intestinal ileus in which enteric gas compromises the imaging “window.” Plain radiographs usually have limited value in diagnosing hepatic abscess formation. Exceptionally, radiographs may disclose loculated hepatic gas, free abdominal gas, focal mineralization, mass lesions, or reduced peritoneal detail, reflecting peritonitis or effusion, or both (Fig. 90-3). Miliary abscess formation cannot be distinguished from other multifocal hepatic parenchymal lesions based on US or radiographic imaging. Thoracic radiographs may reveal evidence of pneumonia, reflecting increased pulmonary exposure to infectious organisms. The presence of sternal lymph node enlargement may signal abdominal inflammation or infection because this lymphatic pathway drains the abdominal structures.

Although blood and urine cultures may identify causal organisms, these cultures are unreliable. More direct diagnostic sampling is achieved by lesion aspiration. Cytologic examination of aspirated material should be initially completed using a modified Wright-Giemsa's stain (Diff Quik). Identified microorganisms are subsequently characterized by Gram staining. Although exceedingly useful, diagnostic and therapeutic abscess aspiration is associated with a risk of peritoneal contamination, requiring forethought as to the need for emergency laparotomy. Anaerobic and aerobic cultures of abscess contents should always be submitted. Polymicrobial infections nearly always involve an anaerobic organism; approximately 50% of solitary

919

920

Infectious Diseases of the Dog and Cat, 3rd Edition

hepatic abscesses in dogs appear to be polymicrobial. Because anaerobes are difficult to culture, they should be suspected and treated when cytologic evaluation discloses a polymicrobial population. Furthermore, therapy should continue even if no organisms are cultured or only a few aerobic organisms are grown. When causal factors remain illusive, hepatic biopsy may be indicated in a search for underlying neoplasia or other primary hepatic processes permissive to infection.

Fig 90-1 Ultrasonographic image of a hepatic abscess showing a hyperechoic rim and heterogenous interior echogenicity (*between arrows*). The image reflects solid or complex mass structure associated with hemorrhagic, cellular, or edematous fluid or caseation. The gross appearance of this abscess is shown in Fig. 90-2, **A** and **B**.

Fig 90-2 Gross appearance of the hepatic abscess demonstrated in Fig. 90-1 **A**, Lesion on surface of the liver. **B**, Lesion on cut surface. A polymicrobial infection was proved to involve *Bacteroides*.

Fig 90-3 Radiograph demonstrating pneumoperitoneum associated with emphysematous hepatic abscesses (*arrows*) and pneumoperitoneum from a mature dog. Central necrosis of a large hepatic adenoma was the underlying disease. A clostridial organism was suspected based on Gram stain characteristics and was subsequently confirmed by anaerobic bacterial culture.

90.15.1.3 Therapy

Successful management of multifocal microabscess formation in 60% of treated human cases is accomplished when only intravenous (IV) antibiotics are used.¹¹⁷ Successful outcome usually requires early diagnosis, aggressive abscess drainage (needle-catheter or surgical drainage), lobectomy, or any combination of these, and long-term administration (minimum of 6 to 8 weeks) of an appropriate antibiotic. Needle or catheter drainage procedures have received increased attention as a therapeutic option for successful management of single (or few) abscesses owing to the wide availability and high sensitivity of US imaging.^{36,114,153} Aspiration using an 18-gauge needle (superficial abscess) or 22-gauge spinal needle (deep abscess) or via a drainage catheter placed by guide-wire technique may be performed with the intent of removing all liquefied suppuration (large syringe, three-way valve, and collection reservoir prepared in anticipation). Flushing the abscess cavity with sterile saline is recommended if physically possible after evacuation. Reappraisal for potential peritoneal contamination by US imaging is recommended within 24 to 48 hours. Response to therapy is monitored with serial US images, body temperature, and measurement of

Infectious Diseases of the Dog and Cat, 3rd Edition

liver enzymes. In human medicine, bedside US imaging and abscess drainage (n = 886 cases) by the managing clinician have been proven to be advantageous and safe.³⁶ Aspiration drainage by clinician-operated US technique met or exceeded information and treatments afforded by imaging specialists or alternative imaging modalities (e.g., fluoroscopy, CT imaging).³⁶

US-guided abscess aspiration as a primary mode of abscess treatment has been successfully applied to veterinary patients. This approach is recommended for several reasons: (1) as a method of confirming the diagnosis, (2) to provide time for patient stabilization before surgical exploration for liver lobe resection, and (3) because it is successful as a solitary means of therapy in a subset of patients. Major factors arguing against this technique include unsafe access (i.e., abscess immediately adjacent to large vascular structures in the porta hepatis or main biliary structures) and lesion depth exceeding aspiration needle length. When aspirating a suspected hepatic abscess, the clinician must always anticipate a need for immediate surgical intervention in the event of abscess rupture into the peritoneal cavity. Given that primary hepatic tumors 920
comprise an important underlying cause of hepatic abscess formation in older dogs, these lesions must 921
always be considered. Unfortunately, although these lesions require resection, they may not be diagnosed until tissue is resected and examined histologically.

The duration of antimicrobial treatment remains empirical, being based objectively on perceived patient response. In humans, certain organisms (e.g., *Actinomyces*) are routinely treated for a minimum of 3 months.¹⁵⁶ Because polymicrobial infections involving anaerobes are relatively common, antibiotics effective against both aerobic and anaerobic organisms should be initially administered. Anaerobes may act synergistically with other pathogens, altering the course of infection and the prevalence of other pathogens caused by microniche modification. In this circumstance, infection control and bacterial eradication may become more difficult, requiring a longer course of treatment. Anaerobes can enhance virulence of other bacteria by inhibiting phagocytosis (i.e., impairing opsonization, neutrophil chemotaxis) and by locally interfering with the efficacy of antibacterial therapy.^{102,154,155} *Bacteroides fragilis* is one of the worst offenders, producing β -lactamases, which can overwhelm the function of β -lactamase inhibitors.¹⁰⁶

Good initial therapy for hepatic abscess formation is achieved with a combination of a penicillin and a fluoroquinolone or an aminoglycoside. Metronidazole or clindamycin can be substituted for penicillin to provide an anaerobic spectrum (see Therapy sections and [Tables 90-3, 90-4, and 90-5](#)). Fluoroquinolones provide broader gram-positive coverage compared with aminoglycosides and are thought to have better penetration across an abscess wall. First-generation cephalosporins, potentiated sulfonamides, and aminoglycosides are uniformly ineffective against anaerobes.

NA, Not available; –, not effective; +, slight efficacy; ++, effective; +++, very effective.

- Aminoglycosides require transport enzyme systems to gain entrance to the interior of the bacteria; these are lacking in anaerobes.
- Sulfonamides are usually not effective despite in vitro sensitivity testing results. Tissue necrosis and suppuration commonly associated with anaerobic infections result in competitive inhibition of sulfonamide activity.

Treatment of hepatic microabscesses requires extensive supportive care and long-term administration of a tailored antibiotic regimen specifically targeting involved pathogens along with identification and management of the underlying cause. Disseminated sepsis should initiate a search for an underlying condition compromising immune defense (see Table 90-2).

90.15.2 Granulomatous Hepatitis

Granulomatous hepatic inflammation is an uncommon diagnosis characterized by multiple discrete, sharply defined nodular infiltrates consisting of macrophage aggregates (and sometimes epithelioid cells) surrounded by or intermixed with (or both) lymphocytes and plasma cells. Lesions may be focal, multifocal, or diffuse. Underlying causes include metazoal (e.g., schistosomiasis, dirofilariasis), fungal (e.g., histoplasmosis, paecilomycosis), protozoal (e.g., visceral leishmaniasis, toxoplasmosis), bacterial (e.g., infections with mycobacteria, *Nocardia*, *Bartonella*, *Brucella*, *Borrelia*, *Propionibacterium acnes*), and viral (e.g., feline

921

922

Infectious Diseases of the Dog and Cat, 3rd Edition

coronavirus [feline infectious peritonitis virus] infections; visceral larval migrans (*Toxocara migration*); and noninfectious disorders (drug reactions, lymphangiectasia, histiocytosis or histiocytic neoplasia, lymphosarcoma, and immune-mediated inflammation). These disorders may be associated with a positive antinuclear antibody test.²⁶ Causal factors have remained elusive in at least 50% of cases; however, with increased molecular surveillance for infectious origins, more definitive diagnoses are anticipated.

a *Pseudomonas* may require parenteral third-generation cephalosporins, antipseudomonal penicillins: ticarcillin, carbenicillin, ticarcillin clavulanate, or lastly, a fluoroquinolone.

b Synergistic with aminoglycosides.

c Not used for *Pseudomonas fluorescens* infections.

d Aminoglycosides require transport enzyme systems to gain entrance to the interior of the bacteria; these are lacking in anaerobes.

Infectious Diseases of the Dog and Cat, 3rd Edition

- e Sulfonamides are usually not effective despite in vitro susceptibility testing results. Tissue necrosis and suppuration commonly associated with anaerobic infections result in competitive inhibition of sulfonamide activity.

Clinical signs may remain vague. In patients with diffuse hepatic involvement, signs may involve profound hepatomegaly, causing discomfort, icterus, and (later) ascites. Laboratory features include hyperbilirubinemia, high serum ALP, and more variable transaminase activity. In patients with diffuse severe parenchymal involvement, hepatic failure is indicated by subnormal cholesterol and urea concentrations and prolonged coagulation times. Although hepatomegaly is associated with severe diffuse parenchymal involvement, chronic disease may lead to a reduced liver size. Change in hepatic size is usually evident radiographically. The US image may appear normal or disclose a diffusely or irregularly hyperechoic hepatic parenchyma and regional hypoechogenicity. Splenomegaly and mesenteric lymphadenopathy are common, followed later by peritoneal effusion. Histopathologic lesions vary in zonal distribution, severity, and cell involvement, depending on the underlying cause.³¹

Infectious causes require specific targeted therapy. In idiopathic cases in which an immune-mediated mechanism is surmised, lesions may abate with glucocorticoid or other immunosuppressive therapies (e.g., azathioprine, cyclosporin, methotrexate). However, immunosuppression requires vigilant monitoring for opportunistic pathogenicity of undetected infectious agents. Molecular techniques for detecting infectious causes has been widely used and applied successfully in human medicine. Recently, PCR analysis detected *Bartonella* spp. infection from two dogs with hepatic disease, one with blatant pyogranulomatous inflammation and the other unexpectedly (Doberman pinscher with chronic hepatitis used as a disease control).⁶³ Hepatosplenic *Bartonella* infection in humans is thought to be widely under-diagnosed when it is associated with multinodular lesions involving either bacillary angiomatosis or peliosis hepatica (the latter lesion has been reported in an infected dog) or a necrotizing granulomatous reaction.^{43,93,129}

90.15.3 Feline Hepatobiliary Infections

90.15.3.1 Cholangitis-Cholangiohepatitis

The cholangitis-cholangiohepatitis syndrome (CCHS) is the most common necroinflammatory hepatobiliary disorder of the domestic cat.^{24,61,87} Inflammation involving intrahepatic bile ducts (cholangitis) is frequently associated with chronic interstitial pancreatitis possibly because of the anatomic proximity of these tissues (anatomic fusion of the common bile and pancreatic ducts), because of shared epitopes on epithelial cells of these ductular structures, or because of a common, as of yet unidentified, infectious organism. Concurrent presence of IBD and interstitial nephritis is also clinically recognized. Cholangiohepatitis as a classification exists when cholangitis extends to involve surrounding hepatic parenchyma. CCHS may be suppurative or nonsuppurative; cats with suppurative disease are more acutely and severely ill. Although some researchers have postulated that suppurative inflammation may progress to nonsuppurative disease, this has not been confirmed. CCHS has been detected in cats infected with a variety of agents, including trematodes, *Toxoplasma* (see [Chapter 80](#)), an organism resembling *Hepatozoon canis* (see [Chapter 74](#)), gram-negative intestinal bacteria, *Clostridium piliforme*, formerly *Bacillus piliformis* (see [Chapter 39](#)) ([Fig. 90-4](#)), *Bartonella* (experimentally), and recently, *Helicobacter* DNA found in archived formalin-fixed tissue from two cats.⁷¹ Given that a general unifying infectious cause of CCHS has not been discovered, most cats are classified as having idiopathic disease if infectious agents are not identified cytologically or cultured from liver and bile samplings. Although infectious agents may initiate inflammation, the process appears to

922

924

Infectious Diseases of the Dog and Cat, 3rd Edition

involve chronic and self-perpetuating immunologic and oxidative tissue injury. However, some cats with nonsuppurative CCHS have had positive bacterial cultures from liver tissue and bile.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 90-5 Dosages of Drugs for Treatment of Hepatobiliary Infections and Modifications for Hepatic Insufficiency or Jaundice

DRUG ^a	DOSE ^b		ROUTE	INTERVAL (HOURS)	TOXICITY WITH ACCUMULATION ^c
	STANDARD	LIVER-IMPAIRED			
Antimicrobials					
Penicillin G	20,000–40,000 U/kg	—	IV, IM, SC	4	Low
Amoxicillin-clavulanate	10–20 mg/kg	—	PO	12	Low
Ticarcillin	15–25 mg/kg over 15 min then CRI	—	IV, IM, SC	IV loading then CRI or discrete dosing at 6–8	Low
	7.5–15 mg/kg/hr or 40–80 mg/kg	—	IV, IM, SC	IV loading then CRI or discrete dosing at 6–8	Low
Imipenem	5–10 mg/kg	—	IV/IM	6–8	Low
Cephalosporins					
1st generation	10–30 mg/kg	—	PO, IV, IM, SC	8	Low
2nd generation	10–20 mg/kg	—	IM, IV	8	Low
Ceftazidime	30–50 mg/kg	—	IV	8–12	Low
Metronidazole	15 mg/kg	7.5 mg/kg	PO	12	Neurotoxic
Clindamycin	10–16 mg/kg	5 mg/kg	SC	24	Anorexia, vomiting, diarrhea
	5–10 mg/kg	5 mg/kg	PO	12	Anorexia, vomiting, diarrhea
Chloramphenicol (rarely indicated)	D: 25–50 mg/kg C: 16–22 mg/kg	12–25 mg/kg 8–11 mg/kg	PO, IV, IM, SC	8	Myelosuppression
			PO, IV, IM, SC	8	Myelosuppression
Tetracycline	10–20 mg/kg	—	PO	8	Potential hepatotoxic
Doxycycline	2.5–5 mg/kg	—	PO	12	Low
Enrofloxacin	D: 2.5–5 mg/kg	— ^d	PO, IM, SC	12	Drug interactions, seizures
	C: 2.5 mg/kg/day	— ^d	PO, IM, SC	24	Drug interactions, seizures
Gentamicin	6–8 mg/kg	—	IV, IM, SC	24	Nephrotoxic, ototoxic; therapeutic monitoring
Amikacin	10–15 mg/kg	—	IV, IM, SC	24	Nephrotoxic, ototoxic; therapeutic monitoring
Trimethoprim-sulfonamide	30 mg/kg	15 mg/kg	PO, SC	12–24	Cholestasis, immune complex disease
Vancomycin	15–20 mg/kg	—	IV (slowly over 30–60 min)	8–12	Nephrotoxic, painful IM; therapeutic monitoring recommended esp. cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

Supportive Therapy					
B-Vitamins	2 ml/liter fluid therapy	—	IV	Each fluid allocation	Low
Vitamin K ₁	0.5–1.5 mg/kg	—	SC	12 ^e	Anaphylaxis if IV, hemolysis if too great a dose: heinz bodies
Vitamin C (avoid if high liver tissue Cu or Fe concentrations in biopsy)	100–500 mg total	—	PO, IV	24	Low, may augment hepatic oxidative injury associated with transition metals (Cu & Fe)
Vitamin E	10–15 U/kg	—	PO	24	Low
Ursodeoxycholic acid	7.5 mg/kg	—	PO	12	Pruritus ^f
Crystalloids	66 ml/kg	—	IV, SC	24	Edema, hypertension
Hetastarch	D: 10–20 mg/kg	—	IV	24	Hypertension
	C: 10–15 mg/kg	—	IV	24	Hypertension
Desmopressin acetate DDAVP	1–5 µg/kg 20 min before effect, lasts only 2 hr	—	IV	1 time treatment	High dose may augment water retention and aggravate edema or ascites, rarely a problem
				Also use as pretreatment for blood donor to increase vWF & Factor VIII	

CRI, Constant rate infusion; *D*, dog; *C*, cat; *DDAVP*, deoxy-d-arginine vasopressin; *vWF*, vonWillebrand's factor

- a For further information on antimicrobial drugs, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c For additional information on toxicity, see Drug Formulary, [Appendix 8](#).
- d Data on dose reduction not established.
- e Use for 1–3 doses, then dose every 7–10 days. Too frequent administration or too high a dose will cause Heinz body hemolytic anemia in cats.
- f Avoid use until complete biliary obstruction is relieved.

90.15.3.2 Suppurative Cholangitis

Suppurative cholangitis occurs least commonly.* Most cats are middle aged or younger, predominantly male, and have only a short duration of clinical illness (under 5 days). Fewer than 50% of patients have hepatomegaly, and most are jaundiced, febrile, lethargic, dehydrated, and exhibit abdominal pain. Vomiting or diarrhea occurs in approximately 50% of cases.

924

Fig 90-4 Photomicrograph of hepatic tissue from a cat with suppurative cholangiohepatitis. Even though the suppurative nature of the inflammation is recognizable, infectious organisms could not be seen (H and E stain, $\times 600$). Bacterial organisms were clearly evident on an impression cytologic imprint.

Most cats with suppurative CCHS have underlying disorders of the biliary system, causing bile stasis (cholestasis), including EHBDO, cholelithiasis, cholecystitis, choledochitis, or periductal pancreatic and biliary duct fibrosis derived from ascending infection, pancreatitis, trematode infection, immune-mediated mechanisms (presumed) or congenital biliary tract malformation (polycystic liver disease). Inflammatory bowel disease is a common concurrent problem and is thought to contribute to infection. Culture of tissue, bile, and choleliths have disclosed infections with, in descending order of frequency, *Enterococcus*, *E. coli*, *Enterobacter*, *Staphylococcus* spp., α -hemolytic *Streptococcus*, *Klebsiella*, *Acinetobacter*, *Citrobacter freundii*, *Pseudomonas*, *Actinomyces*, *Clostridium perfringens*, *Clostridium* spp., and *Bacteroides*. Unfortunately, a positive result on bacterial culture does not define a causal relationship because cholestasis predisposes to infection by opportunists translocated from enteric flora, ascending the biliary tree, or hematogenously dispersed. Most cats have intermittent vomiting and diarrhea, which circumstantially may coincide with portal bacteremia or reflux of enteric flora into biliary or pancreatic ducts.

Suppurative cholangitis is characterized by a neutrophilic infiltrate around and within intrahepatic bile ducts and associated periductal edema, hepatocellular cholestasis (canalicular bile plugs), and eventually, with chronicity of greater than several weeks, a circumferential periportal fibrolamellar mantel.

* References: 22, 24, 55, 61, 79, 84.

90.15.3.3 Nonsuppurative Cholangitis

Nonsuppurative cholangitis is the most common form of CCHS, occurring in middle-aged to older cats. This form of disease is associated with variable clinical signs and slow, insidious progression. No sex or breed

Infectious Diseases of the Dog and Cat, 3rd Edition

predisposition has been found, feline leukemia or feline immunodeficiency virus infection is not a predisposing factor, most cats are ill for more than 3 weeks, and many are ill for greater than 2 months or for several years. Intermittent anorexia, vomiting and diarrhea, weight loss, cyclic fever, hepatomegaly, and jaundice occur in 70% of cats. Most cats are not consistently lethargic, and chronic disease may lead to polyphagia, apparently associated with maldigestion induced by impaired bile flow and chronic IBD. Common concurrent chronic disorders include IBD, fibrosing pancreatitis, and cholecystitis. In some cats, a history of EHBDO or prior suppurative CCHS exists, which may have initiated the disease process (presumably). However, in some cats, chronic CCHS is the only identified disorder. Importantly, some of these cats develop hepatobiliary infections possibly as a consequence of immunosuppressive therapy or overlooked primary infectious origins. Some of these cats progress to develop biliary tree neoplasia (adenocarcinoma).

Retrospective and prospective evaluation of affected cats in the author's hospital suggests several different histologic categories included in the morphologic description of nonsuppurative CCHS: (1) *lymphoplasmacytic cholangitis*, (2) *lymphocytic cholangitis*, (3) *lymphoproliferative disease* (low-grade lymphosarcoma confined to the liver), and (4) a *sclerosing cholangitis* form associated with destruction of small to medium sized bile ducts.^{22,24} Discussion of each subset is beyond the scope of this chapter. Histologically, nonsuppurative inflammation is characterized by bile duct hyperplasia, periportal and periductal fibrosis, lymphoid or lymphoplasmacytic aggregates in the portal triads, and (with chronicity) biliary cirrhosis. Duct destruction in certain cats leads to “ductopenia” or a sclerosing cholangitis category characterized by obliteration of small and medium-sized bile ducts proven by application of an epithelial specific immunocytokeratin stain. The least common type of portal inflammation in cats is characterized by portal lymphocytic or lymphoplasmacytic infiltrates lacking an apparent involvement of bile ducts; these are more appropriately described by the term *lymphocytic portal hepatitis*.⁶¹

90.15.3.4 Clinical Laboratory Findings

Suppurative cholangitis is usually associated with a moderate-to-severe neutrophilic leukocytosis, which may be accompanied by a left shift with or without toxic changes. Nonsuppurative cholangitis may be associated with a mild nonregenerative anemia, normal leukogram, neutrophilic leukocytosis, or lymphocytosis. Variable magnitudes of increased serum activities of ALT, AST, ALP, and γ -glutamyltransferase (γ -GT) develop, depending on the duration and degree of tissue inflammation and cholestasis. Hyperglobulinemia and prerenal azotemia are common on initial presentation of overtly ill animals. Hyperbilirubinemia is more consistent in cats with nonsuppurative cholangitis and has an insidious onset and cyclic nature. In the anicteric cat, detection of bilirubinuria is a sensitive measure of impending hyperbilirubinemia. Measurement of serum bile acids can also detect cholestasis before overt hyperbilirubinemia. Abnormal coagulation test results and bleeding tendencies responsive to vitamin K₁ are observed in severe CCHS accompanied by anorexia of several days' duration, EHBDO, or intrahepatic ductopenia. Radiography is fairly unrewarding, although dystrophic mineralization is sometimes observed in cats with chronic intrahepatic bile duct inflammation and infection, when radiodense choleliths exist, or when unexpected hepatomegaly is confirmed. Hepatic US may fail to disclose altered liver echogenicity, may reflect diffuse hyperechogenicity (a result either from fibrosis, inflammation, or development of hepatic lipidosis), or disclose a heterogenous multifocal pattern. Mineralization of intrahepatic bile ducts is rarely observed. Thickening of biliary structures and evidence of EHBDO may be found. Abdominal effusion is rare in cats with CCHS unless suppurative inflammation and infection exist or severe portal hypertension caused by extensive periportal fibrosis has developed.

Infectious Diseases of the Dog and Cat, 3rd Edition

90.15.3.5 Therapy

Surgical exploration is necessary for definitive diagnosis of necroinflammatory hepatobiliary disorders in the cat because it allows visual and mechanical inspection of the biliary tree, sampling of multiple tissues (biopsy of liver, gut, pancreas, and mesenteric lymph nodes), and collection of samples (tissue, bile) for aerobic and anaerobic bacterial culture. If the common bile duct is occluded, a biliary diversion can be implemented or inspissated bile removed. Hydrocholeresis can be used to improve bile flow postoperatively in these cats through administration of ursodeoxycholic acid. Surgical biopsies provide better intestinal samples as compared with endoscopically retrieved samples and have the advantage of permitting biopsy of jejunum and ileum in addition to duodenum and stomach, as well as safe pancreatic sampling, bile aspiration, and collection of liver biopsies from several different liver areas in a short period. Biopsy of several liver lobes is recommended because differential liver lobe involvement has been shown in patients with high liver enzymes (i.e., minimal involvement in one liver lobe with concurrent severe involvement in another). 925 926

A therapeutic strategy is formulated after examination of the liver and bile for sepsis. Aggressive antibiotic therapy is implemented if infection is suspected while aerobic and anaerobic bacterial culture results are pending. Hepatic tissue should be submitted for routine histologic evaluation and reviewed for infectious agents with special stains or immunohistochemistry or subjected to PCR-amplification techniques for unusual organisms. If flukes are considered a possibility, feces should be examined preoperatively and bile collected intraoperatively for trematode egg detection.

Management of CCHS requires long-term supportive care, including fluid therapy, nutritional support by feeding appliance if necessary (esophagostomy or gastrostomy is preferred in most cases) with a balanced feline ration, supplemental water-soluble vitamins (two times normal dosing), antibiotics tailored to the involved infectious organisms, ursodeoxycholic acid for its immunomodulatory-antifibrotic-choleretic and hepatoprotective effects, and, in cases of nonsuppurative CCHS in which no infectious agent has been detected, immunomodulation (antiinflammatory doses of prednisolone are customary).^{22,24} Suppurative cholangitis should be treated with antibiotics for at least 6 to 8 weeks. Periodic reevaluation (every 2 to 3 weeks) using physical assessment, hemogram, liver enzyme activities, and bilirubin concentration, is used to monitor patient response. Assessments are based on patient physical status, including body weight and condition, absence of fever, resolution of leukocytosis and jaundice, and reduced liver enzyme activities. Reevaluation of a liver biopsy is desirable but often cannot be justified. In some cases, an US-guided hepatic and bile aspiration permits reevaluation of infection (cytology and cultures). Aspiration of hepatic parenchyma may also disclose developing hepatic lipidosis and initiate further metabolic and nutritional supportive efforts and restriction of glucocorticoids. Some cats with nonsuppurative CCHS appear to be glucocorticoid intolerant, developing hepatic lipid vacuolation or becoming diabetic.

Cats with nonsuppurative cholangitis should be prophylactically treated with antibiotics for possible infectious causes until culture results, antibody titers, cytology of impression smears, and histopathology rule out an infectious cause or decrease it from consideration. If peribiliary fibrosis is observed and culture and titer results deny infectious agents, prednisolone is given initially at a dose of 2.0 to 4.0 mg/kg, orally, once per day. This dose is tapered after the first 1 to 4 weeks depending on patient drug tolerance and clinical response. Chronic administration of antiinflammatory and chemotherapeutic drugs is necessary to control severe nonsuppurative CCHS. Given that hepatic glutathione concentrations have been shown to be low in cats with CCHS, antioxidants are now routinely recommended in the form of (1) S-adenosylmethionine (Denosyl-SD4 [Nutramax Laboratories, Inc., Edgewood, Md.] 200 mg/cat per day) and (2) α -tocopherol

Infectious Diseases of the Dog and Cat, 3rd Edition

(vitamin E; 10 IU/kg/day), along with a daily source of water-soluble vitamins because deficiency of certain B vitamins can limit important metabolic pathways that may facilitate antioxidant function and development of hepatic lipidosis. The adequacy of vitamin B₁₂ is appraised in all cats with CCHS because this vitamin undergoes enterohepatic circulation and is known to be seriously compromised in cats with substantial gut disease (infiltrative disease such as lymphoma or severe IBD and enteric lamina propria fibrosis). An important subset of cats with hepatic lipidosis exhibits vitamin B₁₂ deficiency, possibly leading to both glutathione deficiency and inadequacy of l-carnitine, dependent on adequate methylation reactions (influenced by SAMe availability and vitamin B₁₂). In cats with the sclerosing CCHS form of disease, methotrexate is used by the author at a total dose of 0.4 mg, given every 8 hours per day once weekly, along with folinic acid (folate) at 0.25 mg/kg and the other medications described previously.^{22,24} Most of these cats also receive chronic low-dose metronidazole (7.5 mg/kg, orally, every 12 hours) for its immunomodulatory effect useful in managing IBD (typically a coexistent problem), as well as its excellent protection against anaerobic bacterial organisms that may opportunistically complicate the illness.

90.15.4 Cholecystitis and Extrahepatic Bile Duct Occlusion

Septic inflammation of the bile ducts and gallbladder can develop in dogs and cats as a distinct entity.⁵⁶ With chronicity, many of these patients eventually develop EHBDO or a ruptured biliary tree (bile peritonitis). Bile peritonitis is discussed in another section. Although the pathogenesis of acute cholecystitis is not clearly understood, a variety of associated causes are implicated, including any disorder causing obstruction of the biliary tree, gallbladder dysmotility, septicemia, or ascending bacterial invasion of the biliary structures.²² Acute cholecystitis can be experimentally created by introducing pepsin, activated proteolytic pancreatic enzymes, neutrophils, or bacteria into the bile duct.^{65,158} Such spontaneous reflux of initiating agents up the shared bile duct may occur in the cat, especially considering ductal pressure changes invoked by the vomiting reflex. Cholelithiasis and choledocholithiasis may each be associated with septic and nonseptic cholangitis, cholecystitis, and choledochocystitis (gallbladder and duct inflammation) in both dogs and cats.⁹² In dogs, old, small- to medium-sized breed females are more commonly afflicted with cholelithiasis, especially if an underlying disorder of lipid metabolism exists (e.g., hereditary defect of lipoprotein metabolism, hypothyroidism). Bile stasis, biliary inflammation and infection, altered bile composition (increased cholesterol or bilirubin concentrations), or biliary mucosal irregularity associated with neoplasia or cystic mucinous hyperplasia can promote biliary lithiasis or gallbladder mucocoele formation. The slow, insidious onset of duct occlusion by choleliths or slow-growing neoplasia augments development of biliary infection. *E. coli* is a common isolate from biliary tissue and bile in animals with cholecystitis. Aerobic bacterial culture results of bile from dogs with gallbladder mucocoeles have been positive¹⁰; however, microscopic abnormalities did not suggest primary biliary tract infection, and bacterial colonization may likely be secondary to biliary stasis. Chronic cholecystitis also has been associated with *Salmonella* (dogs) and *Pasteurella* (cats). Acute cholecystitis has been reported in dogs with *Campylobacter* (likely *Helicobacter*) infections (see Chapter 39). Although still controversial, the pathologic role of *Helicobacter* in certain forms of biliary tree disease in humans and animal models is expanding.¹⁰² Most diagnoses are based on PCR detection of *Helicobacter* DNA, and whether this represents enterohepatic circulation of DNA in bile, transient colonization, or colonization with pathogenicity remains arguable.¹⁰² Given that conditions such as biliary infection, cystic duct occlusion, EHBDO, and acute cholecystitis are known to decrease bile pH significantly, markedly, researchers have suggested that *Helicobacter* spp. may opportunistically appear in patients with more primary hepatobiliary disorders.

926

927

Infectious Diseases of the Dog and Cat, 3rd Edition

In human and in experimental animal models, the general belief holds that bacteria play an important role in the formation of pigment gallstones. Glucuronidases produced by certain Enterobacteriaceae can deconjugate bilirubin diglucuronide, resulting in precipitation of calcium bilirubinate, which may culminate in stone formation.¹⁷⁰ Other organisms may interact with bile through production of hydrolyzing enzymes, perpetuated inflammation (foreign body effect), and provision of nucleating proteins such as immunoglobulins or debris derived from bacteria, mucus, or cells that can act as a nucleation nidus.

90.15.4.1 Clinical Signs

Infections involving the bile ducts and gallbladder generate clinical signs of infection and EHBDO. These signs include fever, anorexia, vomiting, abdominal tenderness, hepatomegaly, jaundice, and (with EHBDO) acholic feces and bleeding tendencies. Clinical signs can be persistent, intermittent, or episodic.

90.15.4.2 Diagnosis

Cholecystitis is frequently associated with clinicopathologic abnormalities typical of EHBDO and severe CCHS in cats. A nonregenerative anemia attributable to chronic inflammation may develop. A strongly regenerative anemia may reflect substantial enteric hemorrhage derived from gastroduodenal ulcers associated with gastroduodenal vascular ectasia, portal hypertensive gastroenteropathy compromising mucosal perfusion and repair, and co-existent IBD. Portal hypertension derives from biliary cirrhosis, which is a predictable sequela to complete EHBDO after 6 weeks. A marked leukocytosis with a left shift is common. Liver enzyme activities, especially ALP and γ -GT, are markedly increased (5 to 10 times reference values). Severe cholestasis is common, with hyperbilirubinemia reaching as much as 20 times reference values. Serum concentrations of total cholesterol usually increase two to four times reference values in complete EHBDO. Prolonged coagulation times may develop as a result of vitamin K₁ depletion or DIC. Lack of an enterohepatic circulation of vitamins B₁₂ and K₁ (and possibly folate) are seemingly more problematic for cats. Septic bile peritonitis may prevail if the biliary system ruptures subsequent to necrotizing cholecystitis. Abdominocentesis yielding yellowish-orange fluid containing bile with or without bacteria indicates the need for abdominal lavage and surgical intervention. Abdominal radiographs may disclose the presence of abdominal effusion and, in exceptional cases, radiodense mineralized choleliths (Fig. 90-5). Although many choleliths are radiopaque in cats and dogs, a considerable subset of cats have radiodense choleliths identifiable on good quality survey abdominal radiographs.

Fig 90-5 Radiograph showing radiodense choledocholithiasis within the intrahepatic biliary tree in a mature cat that 2 years previously underwent cholecystotomy for cholelith removal. Chronic cholangitis, biliary infection, and sludged bile were contributing causes of cholelith development.

US images provide important diagnostic information, revealing changes consistent with EHBDO as early as 72 hours of onset. Initial changes include thickening and distention of biliary structures, obstruction-induced tortuosity of the common duct, and choleliths, reflecting acoustic shadows in the gallbladder (Fig. 90-6).^{121,176} Choleliths within the common or cystic ducts are less easily imaged because of adjacent enteric gas. Care must be taken to avoid confusion caused by commonly visualized gallbladder “bile sludge” or “sediment” observed in anorectic patients. Gravitational mobility can be used to evaluate bile fluidity. The “kiwi fruit” sign indicative of a biliary mucocele also may be disclosed (Fig. 90-7). A bi- or trilaminar appearance of the gallbladder wall associated with a heterogenous or kiwi fruit sign suggests a biliary mucocele associated with necrotizing cholecystitis and a need for emergency cholecystectomy, biliary diversion, common duct repair, or any combination of these measures (Fig. 90-8). US evaluation may also disclose pericholecystic effusion and guide accurate needle sampling for cytologic and culture analyses.

90.15.4.3 Cholecystocentesis

Diagnostic sampling of bile may be useful in certain cases in which infection of the biliary tree or cholecystitis is considered possible.^{177,147} This procedure is ill advised in the presence of suspected EHBDO

Infectious Diseases of the Dog and Cat, 3rd Edition

or US changes indicative of necrotizing cholecystitis. Sampling of bile can be safely achieved by US guidance using a transhepatic approach. The transhepatic approach provides some degree of compression on the site of gallbladder puncture limiting bile extravasation. Nevertheless, sampling should be completed with the intent of removing as much liquid bile as possible to reduce subsequent leakage. Sampling by US guidance is done using a 22-gauge spinal needle, a 3-way valve, extension tubing, syringe, and receptacle; sterile tubes for collecting culture specimens should be available. Penetration of the gallbladder is accomplished using a rapid thrusting motion rather than slow-dull pressure because the latter technique may induce a vasovagal response that can lead to pathologic bradycardia, hypotension, and asystole (see later discussion under Cholecystitis). During exploratory laparotomy or laparoscopy, direct gallbladder puncture for bile collection should also be completed with the intent of emptying the gallbladder to reduce postsampling leakage. US evaluation of the biliary tree 24 to 48 hours after nonsurgical transhepatic sampling is advised to monitor for the presence or extent of focal bile accumulation, especially if biliary sepsis is found on cytologic evaluation of the aspirated bile.

927

928

Fig 90-6 Ultrasonographic image showing a mineralized cholelith with acoustic shadowing in a cat with suppurative CCHS (GB, gallbladder; CBD, distended common bile duct; ST, stone).

Fig 90-7 Ultrasonographic image showing the “kiwi fruit” sign, consistent with the presence of a biliary mucocele. A biliary mucocele is composed of thick tenacious mucous and biliary debris entrapped in a dysfunctional gallbladder. This phenomenon can lead to necrotizing cholecystitis complicated by infection.

Fig 90-8 Ultrasonographic image of the gallbladder in a dog with necrotizing cholecystitis. Notice the laminar appearance of the gallbladder wall (arrows), consistent with edema and tissue necrosis, obvious on histologic section.

Infectious Diseases of the Dog and Cat, 3rd Edition

90.15.4.4 Therapy

Treatment of septic cholecystitis includes prolonged administration of antibiotics effective against involved aerobic and anaerobic bacteria. Selection of antibiotics that achieve good systemic concentration is important. Laparotomy is necessary to confirm the diagnosis, to identify etiologic factors, and to perform cholecystectomy or biliary diversion, or both (e.g., biliary decompression, provision of an alternate route of bile drainage, cholecystoenterostomy, choledchoenterostomy). The need for cholecystectomy is determined by the surgeon and is advised when even a small portion of the gallbladder wall appears devitalized or when neoplasia is suspected. Emergency laparotomy is essential if biliary rupture or septic bile peritonitis is detected. Management of bile peritonitis is discussed later. Hydrocholeresis in conjunction with appropriate antibiotics is used on a long-term basis to diminish bile stasis, after biliary obstruction is resolved. See General Treatment Considerations.

Fig 90-9 Radiograph demonstrating emphysematous cholecystitis observed in a dog with diabetes mellitus (*arrows denote gas in gallbladder*).

90.15.5 Emphysematous Cholecystitis

Emphysematous cholecystitis is an uncommon and life-threatening condition diagnosed in dogs with and without diabetes mellitus.^{18,73,104,105} Diagnosis in the cat is rare. The most commonly recognized precipitating factor is cystic duct obstruction. Ischemia of the gallbladder wall as a result of tense gallbladder distention potentiates an environment conducive to invasion by gas-producing anaerobes. Accessed bacteria can proliferate in the gallbladder wall and spread within adjacent tissues or shared microvasculature. Left untreated,

Infectious Diseases of the Dog and Cat, 3rd Edition

the gallbladder may rupture and organisms spill into the abdominal cavity, leading to pneumoperitoneum and septic peritonitis (Fig. 90-9).

90.15.5.1 Clinical Findings

Clinical signs associated with emphysematous cholecystitis include abdominal tenderness, fever, jaundice, anorexia, and vomiting. Neutrophilic leukocytosis with a left shift and toxic changes; hyperbilirubinemia; increased serum ALP, γ -GT, ALT, and AST activities; and prerenal azotemia are common. A tympanic abdomen may follow gallbladder rupture. Initial radiographic features may consist only of poorly defined gas infiltrates in the gallbladder wall. Over time, this activity may expand to fill the gallbladder lumen and progressively involve pericholecystic tissues. A sufficient volume of gas for radiographic detection usually accumulates within a few days of overt clinical signs; radiography, however, is insensitive for an early pivotal diagnosis. US may disclose small amounts of gas in the gallbladder wall as an echogenic line. Large amounts of gas may prevent visualization of the gallbladder wall, casting a distinct acoustic shadow. Unfortunately, US may not clearly differentiate whether gas localizes to the gallbladder wall or extends into the surrounding tissue.⁹² Rarely, small amounts of gas may be detected within intrahepatic bile ducts. Conditions other than emphysematous cholecystitis compromising US visualization of the gallbladder include the presence of a porcelain gallbladder (mineralized wall), a contracted gallbladder filled with choleliths, and duodenal ileus (gas-filled intestines that may be overcome by intercostal positioning of the probe or imaging of patient in standing posture). The most common bacteria isolated from humans and dogs with emphysematous cholecystitis are *Clostridium* spp. (Fig. 90-10).

928

929

90.15.5.2 Therapy

Management of emphysematous cholecystitis involves cholecystectomy combined with prolonged administration of antibiotics effective against anaerobes, but even then, the prognosis is poor. Only rarely have patients with emphysematous cholecystitis survived without surgical intervention. Medical and surgical treatment for septic peritonitis is usually needed.

90.15.6 Bile Peritonitis

Bile peritonitis is a serious complication of biliary tree infection, inflammation, ischemia, or trauma. The toxicity of bile on tissues and hypovolemic shock associated with the pooling of fluid in the peritoneal cavity are responsible for most clinical signs. Pleural effusion of a similar composition may also accumulate.⁸ Bacterial contamination of biliary ascites may spontaneously develop and is the usual cause of death.^{19,22,124} Bile-induced permeability changes in the intestinal wall promote passage of enteric flora into the peritoneal effusion. Anaerobic organisms (*Clostridium* spp.) have also been shown to spontaneously invade experimentally created biliary ascites in dogs.

90.15.6.1 Clinical Findings

Animals with bile peritonitis usually have histories of anorexia, vomiting, abdominal tenderness and distention, fever, and lethargy. Most patients are overtly jaundiced. However, some animals with aseptic bile peritonitis can be relatively free of clinical signs because of omental and adhesion loculation of spilled bile. Animals with septic peritonitis may develop emphysematous peritonitis subsequent to growth of gas-producing bacteria; this condition may progress, causing a tense and tympanic abdomen (see Fig. 90-3).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 90-10 **A**, Sporulating *Clostridium* spp. found in the abdominal effusion. **B**, Free spores (*arrows*) from a dog with an emphysematous hepatic abscess, pneumoperitoneum, and septic peritonitis (Wright-Giemsa, $\times 680$). Same dog as that shown in Fig. 90-3.

90.15.6.2 Diagnosis

Hematologic abnormalities typically include a left-shifted neutrophilic leukocytosis with toxic changes. Some patients have a degenerative left-shifted leukon, representing systemic sepsis and peritoneal leukocyte migration. However, some patients with walled-off abdominal infection show no hematologic features. Biochemical abnormalities typically reflect the underlying disease process involving biliary structures. Increased serum activities of liver enzymes and moderate to severe hyperbilirubinemia are typical. Hypercholesterolemia develops if EHBDO precedes biliary tree rupture. Progressive hypoalbuminemia reflects sequestration of a protein-rich abdominal effusion. Prerenal azotemia reflects systemic volume contraction and reduced renal perfusion and may indicate endotoxemia. Prolonged hypovolemia or hypotension may provoke acute renal failure.

Abdominal radiography typically discloses a diffuse loss of visceral detail. Careful evaluation for free abdominal gas or gas within the biliary structures is essential because anaerobic bacterial infection is indicated. Cholangiography or cholescintigraphic studies are rarely indicated. Cholangiography may not delineate the site of biliary rupture because of competition between iodinated imaging agents and bilirubin, as well as reduced flow within the biliary tree. Cholescintigraphy using an iminodiacetic analog can provide a noninvasive method of documenting the site of bile leakage, but this too lacks practicality, can be done only in selected centers, and does not reliably indicate the anatomic site of bile leakage.⁹⁸

Abdominocentesis reveals a yellowish-orange or golden-green effusion. Cytologic evaluation usually discloses a modified or exudative effusion with many neutrophils, macrophages, erythrocytes, and variable numbers of bilirubin crystals (Fig. 90-11). Given that yellow discoloration of effusion is expected in a jaundiced animal, effusion color alone cannot be used as definitive evidence of bile peritonitis. The presence of bile “crystals” and a very high fluid bilirubin concentration in relation to serum are useful in confirming the diagnosis. The presence of bacteria is confirmed using a Wright-Giemsa's or new methylene blue stain. Thereafter, Gram stain elucidates bacterial morphology and the presence of sporulated anaerobes, which can greatly facilitate initial antimicrobial selection. Aerobic and anaerobic cultures of abdominal effusion should

929

930

Infectious Diseases of the Dog and Cat, 3rd Edition

be collected and immediately submitted when bile peritonitis is suspected, irrespective of whether bacteria have been observed. Antimicrobial therapy is indicated when this diagnosis is considered probable.

Fig 90-11 Photomicrograph showing cytologic features of an abdominal effusion observed in a dog with septic bile peritonitis. Neutrophils, macrophages, erythrocytes, intracytoplasmic large Gram stain positive rod-form bacteria, and golden bilirubin crystals were observed (Wright-Giemsa, $\times 680$).

90.15.6.3 Therapy

Surgical intervention is indicated whenever bile peritonitis is suspected. The presence of sepsis makes the situation urgent. Before general anesthesia and laparotomy, the patient must receive aggressive supportive care, including colloid administration to reinstate deficient oncotic pressure, vitamin K₁ to ensure its repletion, blood-component therapy to correct acute symptomatic bleeding tendencies, and IV antimicrobials targeting enteric aerobes and anaerobes derived from transmural enteric translocation. Whether colonic lavage with nonabsorbable antimicrobials should be routinely enacted remains controversial. Experimental and clinical evidence in humans suggests that this procedure may reduce enteric bacterial translocation that predisposes the patient to endotoxemia and septicemia. Neomycin given at 22 mg/kg as a retention (high) enema may be used up to every 8 hours. At surgery, visual inspection of visceral structures usually reveals the site of biliary rupture and provides information essential for an appropriate operative approach. If the gallbladder appears inflamed or devitalized, a cholecystectomy is necessary. If a portion of the common bile duct is damaged, a biliary diversion such as a cholecystoduodenostomy or cholecystojejunostomy may be

Infectious Diseases of the Dog and Cat, 3rd Edition

needed. If the cystic duct is damaged, cholecystectomy is usually done; alternatively, placement of a T tube, or choledochenterostomy, may be implemented. A careful and systematic inspection of the biliary tree with appraisal of its patency and bile fluidity is essential. Choleliths or mass lesions, as well as inspissated bile or biliary mucocoeles, must be removed. Biliary mucocoeles are firm conglomerations of bile that lead to necrotizing cholecystitis (more common in hyperlipidemic dogs such as Shetland sheepdogs and Schnauzers with hereditary hyperlipidemia); these are associated with a unique kiwi fruit appearance on abdominal US; these also require cholecystectomy (see Fig. 90-7). Biopsy specimens optimally should be collected from adjacent and distant portions of the hepatic parenchyma, as well as from representative portions of the diseased biliary system. Parenchymal samples collected from tissues located distal to the biliary structures clarify the presence of diffuse and preexisting hepatobiliary disease. Samples should be evaluated for cytologic and histopathologic features and submitted for both aerobic and anaerobic bacterial culture. During surgical manipulations, remaining vigilant for an induced vasovagal crisis derived from iatrogenic pressure on main biliary structures is important. Vasovagal crisis is characterized by hypotension, bradycardia, and asystole, and correction requires elimination of vagal stimulation (relief of biliary tree pressure or manipulation) and administration of atropine. A similar response may be noted during cholecystocentesis when slow penetration of the gallbladder occurs before needle puncture.

Peritoneal sepsis may be apparent at laparotomy by discovery of a notable fetid odor when the abdomen is first opened. Before abdominal closure, peritoneal lavage with sterile saline is recommended in all cases of bile peritonitis to diminish chemical peritonitis and to remove bacterial organisms mechanically. Appropriate antibiotics should be continued for 4 to 6 weeks postoperatively. Repeated administration of blood components or synthetic colloids may be necessary to correct for bleeding tendencies and to maintain plasma oncotic pressure during surgery and during the immediate postoperative interval because of prodigious loss of plasma proteins and fluid into the abdominal cavity. In cases in which surgery is delayed, abdominal lavage should be aseptically performed to assist in eliminating bile (causing chemical peritonitis) and infectious organisms.

90.15.7 General Treatment Considerations

90.15.7.1 Supportive Care

90.15.7.1.1 Fluids, Electrolytes, Oncotic Support, and Blood Component Therapy

Initial management of the animal with hepatobiliary infection involves provision of fluid therapy and correction of electrolyte abnormalities. Polyionic crystalloid fluids are given to correct dehydration deficits, to cover contemporary losses, and to provide for maintenance needs. A commercially available colloid (hetastarch, Hespan® [Bristol Myers Squibb, New York, N.Y.], or generic) may be used to reinstate colloid oncotic pressure; however, its use may promote bleeding tendencies because of effects on platelet aggregation. The author prefers using hetastarch rather than dextran-70 in veterinary patients with liver disease (subjectively, fewer complications with bleeding tendencies). Blood-component therapy may be essential during the first several days in treating patients with chronic EHBDO or severe diffuse parenchymal cholestasis, as well as intraoperatively in patients undergoing surgical resolution of bile peritonitis and cholecystectomy. If present, hypoglycemia is ameliorated with fluids supplemented to a 2.5% or 5.0% dextrose concentration, as necessary. If hypoalbuminemia, hepatic insufficiency, ascites, or a tendency for sodium retention exists, attention must be given to avoid sodium loading (use solutions with lowest sodium content, or prepare a mixed solution combining 5.0% dextrose in water mixed 1:1 v/v with a balanced polyionic fluid). Judicious supplementation with potassium chloride (use the conventional

Infectious Diseases of the Dog and Cat, 3rd Edition

sliding scale for potassium administration) is important, as well as monitoring serum phosphate and administration of potassium phosphate if serum phosphate is less than 2.0 mg/dl (using a constant rate infusion, provide 0.02 to 0.06 mmol/kg/hr). Close monitoring to ensure repletion of potassium and phosphate is important because subnormal electrolyte concentrations can have dire metabolic and physiologic complications in the patient with liver disease. Low potassium can promote hyperammonemia, anorexia, weakness, enteric ileus, and hyposthenuria that can aggravate electrolyte wasting. Hypophosphatemia can lead to metabolic encephalopathy, anorexia, vomiting, diarrhea, weakness, ataxia, hemolysis, rhabdomyolysis, and bleeding tendencies (platelet dysfunction). Careful sequential monitoring of electrolytes is important to avoid over-supplementation with either electrolyte. Potassium should never be given IV at a rate exceeding 0.5 mEq/kg/hour.

930

931

90.15.7.1.2

Bleeding Tendencies

Vitamin K₁ should be administered by subcutaneous injection in patients with jaundice, whether caused by EHBO or chronic diffuse cholestasis and whether patients are displaying bleeding tendencies. Vitamin K supplementation has particular relevance in patients with overt bleeding or prolonged coagulation times (see Table 90-5). Coagulation assessments include a thorough physical assessment for bleeding tendencies (including careful inspection of retina, oral cavity, prepuce and penis, vulvar mucosa, as well as more easily inspected cutaneous surfaces), bench coagulation tests (prothrombin time and activated partial thromboplastin time assessments), and a buccal mucosal bleeding time (longer than 5 minutes is abnormal). Unfortunately, routinely evaluated clotting tests are relatively insensitive for detecting clinically relevant bleeding tendencies. The author prefers using the PIVKA (proteins invoked by vitamin K antagonism) clotting test to most routinely performed bench assessments because PIVKA clotting times have higher sensitivity for detecting compromised clotting.^{26,27} Increased PIVKA clotting times appear to develop rapidly in cholestatic liver disorders treated with long-term oral antimicrobials, possibly because of synergistic influences, including suppression of enteric microbial vitamin K synthesis, impaired enteric vitamin uptake (caused by lack of sufficient alimentary bile), and compromised hepatic rejuvenation of active vitamin K. Cats appear to have increased risk.²⁵

Bleeding tendencies may be recognized before or appear only during invasive procedures (surgery, tru cut needle biopsy, catheterizations). Treatment requires initiating fresh, compatible blood transfusion and may benefit from administration of synthetic vasopressin (desmopressin, DDAVP® [Aventis, Bridgewater, N.J.], or generic; 1 to 5 µg/kg, subcutaneously, 30 minutes before tissue injury, a one-time-only therapy). Fresh whole blood rather than stored frozen plasma is usually better for patients with compromised liver function because of the possibility that thrombocytopenia or acquired thrombopathia may contribute to bleeding tendencies and because ammonia may accumulate in stored blood products. Pretreatment of a blood donor with DDAVP may augment von Willebrand's factor concentration in the collected product. Although DDAVP has been observed to reduce pathologic hemorrhage in humans and companion animals with severe liver disease, the mechanism remains ill defined and is clearly more complex than simple elaboration of von Willebrand's factor from vascular endothelium and increasing factor VIII.^{91,110}

90.15.7.1.3

Nutritional Support

Nutritional support of the patient with hepatobiliary infections requires provision of a nutritionally and calorically adequate diet. These animals should not be initially placed on a protein-restricted diet unless overt signs of hepatic encephalopathy or hyperammonemia (ammonium biurate crystalluria) exist. Avoiding a negative nitrogen balance is important in the patient with hepatobiliary disease and sepsis

Infectious Diseases of the Dog and Cat, 3rd Edition

because this precaution protects tissues from catabolism, provides nitrogen for tissue regeneration and repair, and protects cats from developing hepatic lipidosis. Anorexia is managed whenever possible using enteric modes of feeding (e.g., nasogastric, esophageal, or gastric intubation). The use of appetite stimulants cannot be endorsed (e.g., benzodiazepines, cyproheptadine) because these drugs are inconsistent in effect and are generally unreliable in establishing adequate energy intake. Furthermore, in the circumstance of hepatic insufficiency, benzodiazepines are contraindicated.

Although enteral feeding was found to enhance SIBO in dogs with EHBDO, the prerequisite for correction of biliary tree occlusion in patients makes this complication less important.^{34,35} In patients with uncorrectable biliary occlusion (e.g., cats with intrahepatic ductopenia caused by chronic CCHS), chronic antimicrobial therapy may assist in protecting the patient against the complications induced by SIBO. Use of ursodeoxycholate will not solve this problem because this bile acid has limited physiologic influence on nutrient assimilation compared with the natural primary bile acids. Patients with active pancreatitis may require enteral feeding via a weighted jejunostomy tube or temporary support with total parenteral alimentation (TPN). Use of partial parenteral nutrition (PPN) or TPN may be necessary if vomiting is persistent despite administration of metoclopramide (0.2 to 0.4 mg/kg, subcutaneously or intramuscularly, every 8 hours or IV constant-infusion drip of 0.01 to 0.02 mg/kg/hr) or ondansetron (0.1 to 1.0 mg/kg every 12 to 24 hours). Although PPN can be given through a peripherally placed long-line catheter, its use is restricted to a 5- to 7-day interval. This interval may importantly limit the extent of lean body mass catabolism during the initial treatment phase. However, after the first week, transition to an enteral feeding method is recommended. TPN requires placement of a committed central catheter, is costly, requires close monitoring, increases the risk of iatrogenic hemorrhage and septicemia, and may result in enteric changes permissive to transmural microbial translocation. Therefore other modes of nutritional support are more practical, are associated with fewer iatrogenic effects, and are advised.

Caloric intake should achieve at least 70 to 90 Kcal/kg/day optimal body weight in cats and for dogs should at least meet values for resting energy requirements ($99 \times \text{body weight [kg]}$,^{0.67} $70 \times \text{body weight [kg]}^{0.75}$ or $30 + \text{weight [kg]} + 70 \times \text{body weight [kg]}$). Although adding an illness factor (a constant that estimates energy needs above resting energy requirements) is commonly recommended, these factors have been empirically devised (1.2 to 1.6 times resting energy requirements for illness).

90.15.7.1.4

Vitamins, Antioxidants, and Conditionally Essential Nutrients

Water-soluble vitamins should be provided at a doubled conventional daily dose, whether the patient is eating or not, because they are necessary for intermediary metabolism. Antioxidants in the form of vitamin E and thiol donors (N-acetylcysteine, 140 mg/kg IV; dilute 10% solution 1:1 in saline, administer through a 0.2 mm filter; subsequent dosing at 70 mg/kg IV up to every 6 hours; or S-adenosylmethionine 20 mg/kg enteric-coated tablets on an empty stomach, orally, once a day) may be advantageous. This dosage has not been proven but is supported by disease modeling. Furthermore, research shows that spontaneous necroinflammatory and cholestatic liver disease in the dog and cat are associated with a risk of low hepatic glutathione (GSH) concentrations. (GSH is the major intracellular thiol antioxidant with pivotal importance in the liver, which provides GSH precursors for use elsewhere in the body.)²⁸ Supplementation with L-carnitine has been shown to facilitate hepatocellular regenerations in the circumstance of severe hepatotoxicity; in this capacity, increased facilitation of fatty acid oxidation may assist in cell recovery and repair.²⁹ Comparable studies in the dog and cat have not been undertaken, although L-carnitine has been proven to increase the metabolic utilization of fatty acids for energy production in healthy cats.²⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

90.15.7.2 Antibiotics

Antibiotics for hepatobiliary infections should possess relevant activity against enteric organisms commonly cultured from liver tissue and bile (see [Tables 90-1 to 90-6](#)).*

931

Culture and susceptibility of involved organisms remains the best measure for correct antibiotic selection.

932

Cytologic evaluation of each sampled tissue and bile may importantly contribute to identification of infectious agents because a positive culture result may be denied by prior antibiotic therapy or mechanistic factors interfering in organism growth in vitro. Using a simple Wright-Giemsa's staining procedure, infectious organisms that are difficult to visualize on routinely prepared histologic specimens may be readily apparent. Bacterial morphology, including Gram stain characteristics, assists in selecting the initial course of antimicrobial therapy (see [Tables 90-2 to 90-4](#)).†.

Satisfactory and clinically effective biliary excretion of many antibiotics is achieved in an unobstructed biliary system.^{163,164} Although selection of an antimicrobial having good penetration into the biliary tract seems logical ([Table 90-6](#)),^{145,170} the achieved systemic activity may be most important. Preventing bacteremic dissemination from the biliary tree to the systemic circulation requires that serum antimicrobial concentrations achieve effective plasma levels against involved microorganisms, especially aerobes. Antibiotics with good serum but poor biliary concentrations have proven efficacy in this scenario, preventing both systemic dispersal and infection of surgical wounds. Use of antibiotics achieving lower relative serum and yet good biliary levels may not afford comparable protection.⁹⁰ Such drugs may not achieve effective concentrations in bile in the face of cholestasis, particularly considering that the minimum inhibitory concentration of an antibiotic for a particular microorganism may be many fold higher in bile versus serum. Although antibiotic prophylaxis cannot likely prevent bacterial invasion in the face of bile stasis, antibiotics protecting against systemic infection are essential before surgical manipulations in which bacteremia, local trauma, and infection are unavoidable.¹⁶³ Although antibiotics administered during EHBDO do not attain therapeutic concentrations in bile because of the cessation of bile flow, it has been proven in animal models and humans with EHBDO that achieving a critical therapeutic plasma concentrations of an effective antimicrobial before surgical manipulations protects against septicemia and endotoxemia. To eradicate biliary tree infection in EHBDO successfully, bile flow must be reinstated by removing the obstruction or by creating a biliary-enteric anastomosis. This augments removal of infectious organisms by the responsive cholerisis concurrent with delivery of the antimicrobial into the biliary compartment. Immunocompromised patients and those with uncorrectable diffuse disease involving the intrahepatic biliary tree (e.g., certain cats with cholangitis causing destruction of small to medium sized bile ducts) will maintain a chronic predisposition for hepatobiliary infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 90-6 Achieved Biliary Concentrations of Certain Antimicrobial Agent in the Absence of Major Bile Duct Occlusion^{a,3,107}

ANTIMICROBIAL AGENT	RATIO OF ANTIBIOTIC BILE/SERUM
Aminoglycosides

Erythromycin	8–25
Metronidazole	1
Trimethoprim/sulfonamide	1–2/0.4–0.7
Vancomycin	0.5

a Data derived from experimental literature and from work in human beings.

In the absence of culture and susceptibility, or morphologic features of involved organisms, antimicrobial treatments should cover aerobic and anaerobic enteric opportunists. A combination of drugs is required. β -lactamase-resistant penicillin, clindamycin, or metronidazole is given IV as a good first-choice antibiotic for anaerobic organisms. The dose of clindamycin and metronidazole is adjusted for cholestasis and severe hepatic dysfunction; see later discussion. One of these drugs is used in combination with either an aminoglycoside or a fluorinated quinolone (e.g., enrofloxacin, orbifloxacin) to achieve efficacy against aerobic gram-negative organisms. Aminoglycosides should not be given until the patient's hydration status and prerenal azotemia are corrected. Aminoglycoside nephrotoxicity should be monitored by examining urine sediment for granular casts on at least an alternate-day schedule.

Infectious Diseases of the Dog and Cat, 3rd Edition

Antibiotics that require extensive hepatobiliary activation, biotransformation, or excretion or those that have been associated with adverse effects on the hepatobiliary system are considered poor first-choice selections when liver function is compromised. These drugs include hetacillin, tetracycline, doxycycline, lincomycin, erythromycin, sulfonamides, trimethoprim-sulfonamide, and chloramphenicol. Severe jaundice argues against using antibiotics excreted predominantly in bile and that undergo enterohepatic circulation; examples include chloramphenicol, erythromycin, doxycycline, rifampin, clindamycin, and nafcillin. Use of such drugs in the face of reduced liver function, especially overt jaundice, necessitates reduction of conventional dosing usually by as much as 50% (Table 90-7).^{3,9} Consultation with a comprehensive pharmaceutical reference is

932

933

recommended before adjusting drug doses.^{4,146} Tetracyclines are best avoided unless specific therapy is indicated (e.g., rickettsial infections, clearing leptospirosis) because of their inhibitory influence on egress of triglycerides from the hepatocyte (promotes hepatic lipid accumulation in all species studied) and because tetracyclines have experimentally induced hepatic encephalopathy in dogs with portosystemic shunts. When circumstances warrant using *contraindicated* drugs, Table 90-6 should be consulted for cases in which recommendations have been derived from multiple references pertinent to humans, considering the lack of information for animals.

Table 90-7 Influence of Hepatic Disease on Disposition of Selected Antimicrobials in Humans with Severe Hepatic Disease, Insufficiency^{3, 9}

ANTIBACTERIALS	PLASMA CLEARANCE	VOLUME OF DISTRIBUTION	HALF-LIFE
Amikacin	—	↑ 200%	No change
Ampicillin	No change	↑ 46%–200%	↑ 30%–45%

Norfloxacin	No change	—	No change
Pefloxacin	↓ 70%	↓ 20%	↑ 255%
Vancomycin	↓ 70%	No change	↑ 130%

Prophylactic treatment with a best-guess antimicrobial combination is recommended for biliary obstruction and known or suspected bacterial infection, both before and during surgery. Given that this approach diminishes the ability to culture involved organisms from surgical specimens, presurgical hepatic-bile aspiration and preparation of bile and tissue imprints for cytologic evaluation (including Gram staining) becomes imperative. Antibiotic administration is necessary until biliary tree obstruction and cholestasis have been eliminated (e.g., when EHBDO or specific infection of the biliary tree has been resolved) or may be continued as part of chronic medical therapy.

Bacterial enteric translocation is known to be reduced by long-term administration of antibiotics suppressing aerobic intestinal flora. In humans, fluorinated quinolones are used most often for this purpose in cirrhosis. Predisposition to enteric bacterial translocation during surgery (e.g., cholestasis, chronic liver disease) is also

Infectious Diseases of the Dog and Cat, 3rd Edition

diminished in humans by orally administered neomycin, fluoroquinolones, polymyxin B, or tobramycin. This effect has not been studied in veterinary patients.

90.15.8 Probiotics And Nondigestible Carbohydrates

An alternative nonantibiotic approach, *microbial interference therapy*, is receiving greater attention in human medicine owing to the increasing appearance of antibiotic-resistant enteric microorganisms. Such therapy involves maintaining or restoring health by introducing live nonpathogenic microorganisms from a probiotic to ostensibly *stabilize* the balance of intestinal flora. This concept is based on experimental work indicating that certain probiotics can reduce intestinal bacterial overgrowth, improve local immunologic host defenses, increase enteric and splanchnic neutrophil phagocytic function, inhibit enterovirulence of natural gut microbes, and reduce enteric bacterial translocation (modeled in rodents). Consequently, probiotics are claimed to reduce the risk of spontaneous infection in patients with chronic liver disease associated with portal hypertension, ascites, and cholestasis.

Bacteria considered host beneficial include bifidobacteria, eubacteria, and lactobacilli; and when these are combined with a fermented carbohydrate, they are referred to as *liver probiotics*. Whether they provide a reliable benefit remains controversial. Lactobacilli are considered an integral part of normal enteric microecology and have received the greatest investigation. These organisms have been capitalized on for their demonstrated effects on local enteric flora, immune response, and host metabolism. Adherence of lactobacilli to enterocyte receptors can induce expression of genes coding for variants of intestinal mucins that inhibit adherence of enteropathogens (e.g., *E. coli*).¹⁰⁵ They also produce antimicrobial effects through production of bacteriocin and metabolic end products, demonstrated in animals and humans. However, an important point to recognize is that different lactic acid bacterial strains have very different probiotic effects such that results obtained with a single strain cannot be universally expected for all others. Although use of probiotics to reduce opportunistic gram-negative and anaerobic enteric microorganisms is widely proposed, benefits remain controversial, and a risk of probiotic organisms achieving opportunistic hepatic or systemic infections exists.^{136,148}

Experimental evidence and limited information in humans with liver disease suggest that certain probiotics may have a prophylactic and therapeutic effect on hepatic encephalopathy and predisposition of patients with acute hepatic failure or necrosis to endotoxemia or sepsis. They also may beneficially modulate enteric inflammation co-existent with liver disease. Nondigestible carbohydrates that serve as fermentable microbial energy substrates are commonly used to ameliorate clinical signs of hepatic encephalopathy. These substances encourage bacterial nitrogen fixation, acidify the colonic lumen, modulate mucosal and microbial protease activity, and produce a cathartic effect (from osmotic solute production) useful for controlling SIBO and eliminating enteric toxins and ammonia, contributing to hepatic encephalopathy. They may also ameliorate endotoxemia through modifying the enteric microbial ecosystem, reducing the enteric bacterial pool size, or through a direct antiendotoxic effect.^{37,103,149} In this regard, lactulose is the prototype nondigestible carbohydrate.⁴⁵ Oral or rectal administration of lactulose has been proposed as an alternative means of modulating bowel flora, which may reduce postoperative sepsis. Probiotics combining the benefit of a poorly digested carbohydrate (by the mammalian host) and a *beneficial* microbial organism also are available. Many of these probiotics *likely* provide a variety of effects, but none have proven efficacy.³⁷ Based on experimental work, combined administration of a probiotic and antioxidants may significantly alter pathologic changes,

933

934

Infectious Diseases of the Dog and Cat, 3rd Edition

encouraging enteric bacterial translocation, by altering the concentration of enterobacteria and enterococci in the lower bowel, reducing peroxidative bowel wall damage, and reducing endotoxin translocation. Increased intestinal oxidative damage and bacterial translocation are observed in rats with prehepatic portal hypertension and EHBDO. Oxidative bowel damage is associated with slow enteric transit time in several experimental models and has been implicated as a cause of SIBO in cirrhotic humans.^{30,130} Proclivity for enteric bacterial translocation (using this model) is reduced with a variety of antioxidants, including vitamin C, vitamin E, allopurinol (50 mg/kg twice weekly), and glutamine (1 gm/kg per day) as a means of promoting enterocyte metabolism and cell size.^{32,150,151}

90.15.8.1 Surgery

Laparotomy may be required to alleviate the source of hepatobiliary sepsis. Surgical intervention becomes imperative when hepatobiliary abscesses cannot be effectively managed by US-guided drainage and antimicrobial therapy and in the circumstances of septic peritonitis, bile peritonitis, or major bile duct occlusion. Hepatic or bile aspirate or biopsy is the only definitive method of confirming an infectious process. Biopsy of the liver and involved biliary structures is required for definitive diagnosis of underlying disease. At surgery, the abdominal viscera should be inspected for a primary disease process. Mesenteric and hepatic lymph nodes should be visualized and biopsy specimens taken for histologic evaluation and culture, especially if a primary diagnosis remains uncertain. Liver specimens from one or more sites should be sampled to ascertain disease local to the obvious disease process and to determine whether diffuse liver disease preceded or evolved from the current condition. If entire lobes of liver appear involved in an abscess or appear necrotic, they should be resected. Infarcted or devitalized areas should be manipulated minimally before resection. Venous outflow from such tissue should be ligated as early in resection as possible to avoid systemic dispersal of noxious substances (e.g., endotoxin, bacterial products, infectious organisms). The biliary tract should be evaluated for patency by gentle compression of the gallbladder and bile fluidity and flow determined. The gallbladder and major bile ducts should be carefully palpated for choleliths, intraluminal or mural masses, and sludged bile. If abnormalities are detected, a cholecystotomy should be done, a biopsy of the gallbladder taken, and any abnormalities inspected and removed. Biliary mucocele requires gallbladder resection and removal of tenacious bile from the cystic and major bile ducts. Extrahepatic bile ducts should be flushed with sterile saline using a soft catheter to remove choleliths and sludged bile, taking care to avoid peritoneal contamination. In some cases, sludged bile may require mechanical removal using forceps or a curette. Cholecystectomy is necessary if the gallbladder wall appears devitalized or involves a suspected neoplasm.

Samples of tissue and bile should be cultured for aerobic and anaerobic organisms. Bile for culture and cytology should be collected by fine-needle (22-gauge) aspiration into a syringe. The needle should enter the gallbladder at an oblique angle to reduce postaspiration bile leakage. Using a large syringe and aspirating the entire volume of bile minimizes postaspiration bile leakage. If cholecystitis or cholangitis is suspected, biopsy and culture of a portion of the gallbladder wall and liver increases the chance of identifying the infectious agent. Choleliths also should be submitted for culture.

Cytologic smears should be made from each tissue biopsied and from bile to permit morphologic characterization of infectious agents and to achieve early recognition of neoplasia. Strict attention must be paid to the methods of handling and transporting specimens for anaerobic bacterial cultures (see [Chapter 33](#)). Gram staining of tissue and bile imprints guides selection of initial antibacterial therapy. Cytologic evaluation serves as an important quality control indicator of transport and culture procedures. If organisms are identified on smears made at surgery and yet are not grown, transport or culture methods were probably inadequate unless antimicrobial therapy is a complicating factor. If trematode infection is possible, bile and

Infectious Diseases of the Dog and Cat, 3rd Edition

feces should be examined cytologically for trematode eggs. Hepatic tissue should always be submitted for routine histologic evaluation, and the pathologist should be prompted to examine tissues for infectious agents with special stains.

90.15.8.2 Hydrocholeresis

After establishing patency of the biliary tract, hydrocholeresis can improve bile flow in patients with resolved extrahepatic cholestasis, cholelithiasis, or inspissated bile. Hydrocholeresis also improves mechanical removal of infectious organisms involved in diffuse septic cholangitis. Resolution of bile stasis assists in clearing biliary infection and reduces the potential for further stone formation. Ursodeoxycholic acid (see [Table 90-5](#)) is used as a long-term therapeutic agent in patients with persistent cholestatic liver injury. Choleresis is provided in conjunction with maintaining adequate patient hydration, which optimizes the hydrocholeretic response. In addition to choleresis, ursodeoxycholic acid also provides a large number of advantageous effects beneficial to chronic cholestatic and necroinflammatory liver disorders (i.e., it has immunomodulatory, cytoprotective effects for the hepatocyte and biliary epithelium, a choleretic influence, antiendotoxic, antioxidant, and antifibrotic effects, and importantly, attenuates accumulation of membranocytolytic bile acids in bile, hepatic tissue, and plasma).

91 CHAPTER 91 Genitourinary Infections

Jeanne A. Barsanti

Bacterial infections of the urogenital system are among the most frequently encountered infections in small animal practice. Urinary tract and genital infections can occur separately or concomitantly. Infections range in severity from asymptomatic to life threatening. *Escherichia coli* is the most common agent associated with these infections. Infections with other types of organisms, especially fungi, are found but are much rarer than those caused by bacteria.

91.1 NORMAL FLORA

The vagina, vestibule, prepuce, and distal urethra have a normal microflora. The clinical importance of this microflora is twofold: first, it must be considered when the results of cultures of urine, semen, and preputial and vaginal discharges are interpreted; second, the normal microflora is thought to be an important factor in host defense against pathogenic organisms. The oral and anal flora of neonatal puppies correlate with the flora from the milk, vagina, and oral cavity of their dams. The flora of puppies from different dams vary with the dam.¹⁸³

Bacteria are not normally found in the upper urinary tract, bladder, proximal urethra, or prostate gland.^{16,108}

Bacteria are not normally found in the uterus, except during proestrus and estrus.^{275,46}

91.1.1 Dogs

In healthy male dogs, commensal organisms cultured from the distal urethra and prepuce include gram-positive and gram-negative organisms (Tables 91-1 and 91-2).¹⁴ Mycoplasmas are found in the distal urethra and the prepuce and have also been isolated from the canine prostate. When sampling the prepuce, usually more than one organism is recovered; however, only a single species is obtained in about 20% of preputial and semen samples.³⁷ The prostatic fraction of a cleanly collected ejaculate from healthy, fertile stud dogs is usually sterile (70% of samples).³⁷

The normal flora of the vagina includes the same types of bacteria (Table 91-3).^{183,14} Aerobic and anaerobic organisms live in the vagina normally.¹⁸³ Although the same types of organisms are found throughout the vagina, the nearer they are to the cervix, the lower the number of organisms.²⁰⁰ Two or more bacterial species are usually recovered from vaginal cultures; however, 18% of vaginal cultures from healthy bitches contain only one organism, and repeated cultures from most dogs yield a pure culture on at least one occasion.³⁶ Mycoplasmas can also be isolated from the vagina of healthy bitches.^{162,36} Changes in the microflora occur with stages of the estrous cycle, but the change is primarily in the frequency of organism isolation rather than the type of organism found.³⁶ Few changes are associated with neutering.^{200,107} *Staphylococcus* species have been isolated more frequently from prepuberal and postpartum bitches than from postestrous bitches.^{36,200} The same organisms are found in the uterus during proestrus and estrus as are found in the vagina, with the exception that mycoplasmas were not found in the uterus.²⁷⁵

Treatment with either ampicillin or trimethoprim-sulfamethoxazole altered the normal microflora of the vagina in healthy bitches.²⁵⁴ The normal microflora was suppressed in only two of five ampicillin-treated dogs. In three ampicillin-treated dogs and in all dogs treated with trimethoprim-sulfamethoxazole, bacteria sensitive to

Infectious Diseases of the Dog and Cat, 3rd Edition

the antimicrobial tended to be eradicated, whereas resistant bacteria remained or appeared. Thus the use of these antimicrobial agents to “sterilize” the vagina before mating is irrational and ineffective. Commensal bacteria are occasionally transferred between dog and bitch during mating.^{36,37} This transfer does not affect the fertility of either the male or the female.

91.1.2 Cats

Aerobic bacteria are those most commonly isolated from the vagina of healthy intact female cats (Table 91-4). *E. coli*, staphylococci, and streptococci are most common.¹¹⁰ Anaerobic bacteria are rarely isolated from the vagina.¹¹⁰ Pure growth of a single organism was common in normal cats and should not be considered indicative of disease when cytology is normal.¹¹⁰ Vaginal cultures from normal cats can be negative.¹¹⁰ The bacterial population of the vaginas of cats was not influenced by mating or administration of progestins.¹¹⁰ Relative numbers of vaginal organisms were greater in young cats (younger than 1 year) and pregnant cats.⁴⁶ Although one study showed more profuse growth from cats in estrus,¹⁶ another study showed no effect of estrus on number of bacteria, but an effect was found on type of bacteria, with estral cats having more bacteria that belonged to the family Pasteurellaceae.¹¹⁰ Although one study found bacteria in 2 of 29 uterine cultures, both from cats in estrus,⁴⁶ a more recent study found no bacteria in the uterus of 66 adult female cats, nine of which were in estrus.¹¹⁰

Aerobic bacteria are those most commonly found in the prepuce of intact male cats (Table 91-5) with Pasteurellaceae, *E. coli*, staphylococci, and streptococci being most common.¹¹⁰ In contrast to female cats, anaerobic bacteria were isolated from 41% of male cats.¹¹⁰ Anaerobic species were *Bacteroides* spp., *Fusobacterium* spp., and anaerobic streptococci. The mean number of bacterial spp. isolated from the prepuce of male cats was 1.8 per cat, compared with 1.1 per cat in vaginal samples.¹¹⁰ Pure cultures from the prepuce were uncommon, and negative culture results were not found.¹¹⁰

91.2 URINARY TRACT INFECTIONS

91.2.1 Etiology

Urinary tract infection (UTI) refers to microbial colonization of the urine or of any urinary tract organ, except the distal urethra, which has a normal bacterial flora. Infection of the urinary tract may affect more than one organ or may be localized to the upper tract (kidney and adjacent ureter; bacterial pyelonephritis) or to the lower tract (bladder and adjacent urethra; bacterial cystitis; bacterial urethrocystitis). Infections of the lower

Infectious Diseases of the Dog and Cat, 3rd Edition

urinary tract in intact male dogs are considered to concomitantly affect the prostate gland (bacterial prostatitis). Infection of one part of the urinary tract increases the likelihood that the rest of the tract will become infected.^{188,189}

Corynebacterium spp.
Haemophilus spp.

It has been estimated that 14% of all dogs develop a UTI during their lifetime.¹⁵⁶ Bacterial UTIs are most common in female spayed dogs, followed by male castrated dogs and intact female dogs.⁴⁷ In dogs, UTIs are least common in intact males.⁴⁷ In a large study over a long period, 3.9% of female dogs and 2.9% of male dogs examined in one teaching hospital had positive urine culture results, although some dogs had their urine cultured only if the urinalysis was abnormal, which would lower the infection rate because some dogs with a UTI documented by culture have normal urinalyses.¹⁶¹ Infection rate in 85 asymptomatic, adult, intact male dogs was 9%.³⁸ Half of these dogs had the same organism isolated by direct aspiration of small prostatic cysts.³⁸

More than 70% of UTIs in dogs are caused by a single bacterial species.¹⁶¹ In complicated infections secondary to anatomic or functional abnormalities of the urinary tract, infection with multiple organisms becomes more likely. The most common gram-negative organisms are *E. coli*, *Proteus*, *Klebsiella*, *Pseudomonas*, and *Enterobacter*. *E. coli* is by far the most common urinary tract pathogen, causing 37% to 45% of UTIs.^{47,161,215,243a} In fact, most *E. coli* infections in dogs involve the urinary tract.²⁰¹ Certain *E. coli* isolates from canine UTIs are indistinguishable from certain human extraintestinal *E. coli* infections, even using highly sensitive typing methods.¹²⁸ In comparison with human urinary isolates, canine *E. coli* were more likely to be antibiotic resistant and to have a higher R-plasmid transmissibility rate.¹⁹⁵ Gram-positive organisms (*Staphylococcus*, *Streptococcus*, *Enterococcus*) account for 25% to 30% of naturally occurring UTIs.^{47,161,215,285} Infection with *Staphylococcus* or *Proteus* is often associated with struvite calculi because of alkalization of the urine by the organisms' metabolism of urea. Urinary tract infections due to methicillin-resistant *Staphylococcus aureus* have been reported and are of concern to human public health.^{275a} The most common eight species just listed account for 93% of all UTIs.¹⁶¹ Although mycoplasmas have been reported as causes of UTIs in dogs, their significance remains obscure because most of the reported cases were complicated by multiple disease processes.¹¹⁸ In the largest study of UTIs in dogs, 35 bacterial genera and 4 species of fungi were identified as causing UTIs.¹⁶¹ Occasionally, cases involving more unusual bacterial organisms are reported, such as *Arcanobacterium* (*Actinomyces*) *pyogenes*,^{34,161} *Corynebacterium urealyticum*,^{161,255} and *Clostridium* species.^{87,161}

UTIs are less common in cats than in dogs. Numerous studies have shown that young adult cats having signs of lower urinary tract problems (dysuria with hematuria) rarely have bacterial UTIs.^{19,142} However, bacterial UTIs may develop secondary to urinary catheterization or urinary tract surgery, such as perineal urethrostomy, in cats with urethral obstruction.^{91,18} UTIs are more common in cats older than 10 years.²³ When bacterial infection occurs in cats, the organisms most frequently involved are the same as those in dogs, except *Pasteurella* organisms are more commonly reported in cats.²⁸⁵ Viruses and mycoplasmas have been considered as potential causes of lower urinary tract signs in cats. Investigators have been unable to find evidence of viral infections in

Infectious Diseases of the Dog and Cat, 3rd Edition

clinical cases, and experimental viral infections have not induced clinical signs in cats.¹³⁹⁻¹⁴¹ *Mycoplasma felis* and *Mycoplasma gateae* could not survive in osmotic conditions present in normal feline urine, although a *Ureaplasma* species could.⁴¹ However, ureaplasmas were not isolated from any cats with signs of lower urinary tract diseases.¹⁴²

Yeast and fungi in urine can indicate contamination of the sample. However, fungi in properly collected (cystocentesis) and promptly examined urine samples are abnormal. A positive culture of urine collected by cystocentesis is needed to confirm the diagnosis of a fungal UTI. Fungal UTIs caused by *Trichosporon domesticum*, *Candida* species, or *Aspergillus* species usually have been associated with abnormalities in host defenses, antibiotic usage, and urogenital diseases.^{233,2} Systemic mycotic agents (e.g., *Blastomyces*, *Cryptococcus*) may be found in urine in animals with systemic infections caused by these organisms and may cause UTIs.¹⁹¹

91.2.2 Pathogenesis

UTIs are usually caused by bacterial organisms that are constituents of the microflora of the intestinal or lower urogenital tracts. Dogs with a UTI associated with *E. coli* or *Proteus mirabilis* were likely to carry the same organism in their intestinal tracts and prepuce or vagina.^{166,84} The usual method of infection of the bladder involves organisms ascending the urethra.²⁴⁷ Pyelonephritis is believed to be most commonly caused by ascending infection from bladder urine. The renal cortex is much more resistant to infection than the renal medulla, decreasing the likelihood of hematogenous infection.^{174,236}

Infectious Diseases of the Dog and Cat, 3rd Edition

Development of a UTI indicates an alteration in the host and bacterial flora relationship.²⁰⁵ To accomplish infection, bacteria must attach to and colonize the mucosa of the urethral orifice and transport themselves up the urethra, adhering to the uroepithelium. Both host defense mechanisms and bacterial virulence properties are important in determining whether infection occurs, as well as which part of the urinary tract is affected ([Table 91-6](#)).

91.2.2.1

Host Factors

The inflammatory response in a UTI involves three steps: the bacteria stimulate uroepithelial cells to produce inflammatory mediators, these mediators direct inflammatory cells to the site of infection, and the local inflammatory response determines if the infection is eliminated or if tissue damage results. Thus the host

response is important in determining the degree of clinical signs and severity of tissue injury.²⁵⁷ Neutrophils that migrate from blood vessels through tissue and cross the epithelial cell layer to enter the urinary space result in pyuria. In humans, as in dogs and cats, many UTIs are asymptomatic and not accompanied by pyuria. Such occult infections are associated with diabetes mellitus and hyperadrenocorticism in dogs but occur in dogs and cats without these diseases as well. The reasons for this are not understood, but one idea in humans is that these affected individuals are genetically different from those that develop symptomatic infections in regard to their host response.²⁵⁷ The genetic characteristics of a host organism have also been investigated in relation to susceptibility to UTIs and may be important in pathogenesis in some populations.^{257,81} For example, the vaginal epithelial cells of women with recurrent UTIs demonstrate more bacterial adherence in vitro than epithelial cells from women without UTIs.²³⁶

Important host factors in resistance to infection are normal, frequent emptying of the urinary bladder, the presence of the normal flora, the age and sex of the host, characteristics of urine, and normal urinary tract anatomy, including normal urinary tract epithelium with its glycoprotein coat, and immunologic responses.^{196,236} The importance of host factors is shown by the fact that many *E. coli* isolated from canine UTI have no detectable urovirulence factors.⁶⁵

Structural, functional, or metabolic abnormalities predispose to UTIs ([Table 91-7](#)).^{193,236} Such abnormalities include obstructive lesions; metabolic diseases such as diabetes mellitus, hyperadrenocorticism, and renal failure; instrumentation or catheterization or abnormal voiding, particularly with neurologic diseases; and anatomic abnormalities. UTIs have been found in more than 40% of dogs with hyperadrenocorticism and 40% of dogs with diabetes mellitus.⁷⁴ Lower urinary tract obstruction with secondary vesicoureteral reflux of infected urine is a contributing factor to the development of pyelonephritis, as are anatomic abnormalities such as ectopic ureters.²³⁷ Approximately 17% of dogs with ectopic ureters were found to have pyelonephritis.¹¹¹ Other anatomic abnormalities associated with a chronic UTI include persistent urachus, other bladder diverticuli, perivulvar dermatitis, a recessed vulva, and vestibulovaginal stenosis.^{155,165} A study found that surgical therapy for a recessed vulva was unsuccessful in resolving a UTI if severe vestibulovaginal stenosis (defined as a ratio of less than 0.2 between the height of the vestibulovaginal junction to the maximal height of the vagina on a lateral positive-contrast cystourethrovaginographic view) was present.⁵¹

Bacteria adhere poorly to normal bladder epithelium because of the presence of a glycosaminoglycan coating.⁵¹ This coating, which can be replaced within 24 hours if injured, is extremely hydrophilic, so a layer

Infectious Diseases of the Dog and Cat, 3rd Edition

of water forms at the surface. This aqueous layer provides a barrier between the transitional epithelium and the urine, explaining in part why bladder epithelium can tolerate constant exposure to a substance as irritating as urine. Infection is more likely to occur if this surface coating is damaged as by uroliths, neoplastic transformation, or exposures to chemical irritants such as cytoxan. The kidney has no natural barrier against bacterial adherence.²³⁶

Bladder epithelial cells exfoliate in response to infection and are cleared with the flow of urine, an important defense mechanism. The bladder epithelium normally has a slow turnover rate of approximately 40 weeks in humans and mice.¹⁸¹ In humans with a UTI, large numbers of exfoliated bladder epithelial cells are often found.¹⁸¹ Although this exfoliation is considered a host defense mechanism, it is also a way for bacteria to be spread into the environment and may also expose underlying epithelial cells to infection. This might allow bacteria to enter a more sheltered environment where they could persist. It has been shown in mice that uropathogenic *E. coli* can survive in low levels in bladder tissue for weeks to months in a quiescent state, protected from antimicrobial therapy.¹⁸¹

The antibacterial effects of urine include osmolality, urea concentration, and organic acid concentration.²³⁶ Variations in pH (with urine being markedly acidic, having a pH of 5) and specific gravity (with urine being markedly concentrated) have an inhibitory effect on bacterial growth. The ability of cats to highly concentrate their urine may be one explanation for the low incidence of bacterial UTIs in young cats. Urine that is less acidic and not well concentrated supports multiplication of urinary tract pathogens almost as well as nutrient broth.¹³³

Specific serum and urine antibody responses accompany acute pyelonephritis in experimental models. These antibodies can be synthesized locally within the kidney and may enhance bacterial opsonization and ingestion by phagocytic cells; however, their importance is debated.²³⁶ The role of urinary immunoglobulins in preventing infection of the bladder is even more unclear.²³⁶ The urinary tract mucosa produces secretory IgA, which is thought to have a role against the entry of pathogens—probably by interfering with bacterial adherence, although absence of its production does not lead to increased UTI susceptibility.²⁶⁴ Evidence is lacking for a protective role for cell-mediated immunity in UTIs.²³⁶

938

939

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 91-7 Terms Used to Categorize Urinary Tract Infections

BY LOCATION

Pyelonephritis: Kidney

Cystitis: Bladder

Urethritis: Urethra

Prostatitis: Prostate

BY COMPLEXITY

Simple-uncomplicated: No underlying structural or functional abnormality is suspected or found

Complicated: Infection associated with structural or functional abnormalities within the urinary tract or with impaired immunocompetence:

Urinary obstruction

Incomplete bladder emptying

Anatomic abnormalities

Congenital (urachal diverticula, ectopic ureters, vestibulovaginal stenosis)

Acquired (excessive perivulvar skin-folds)

Surgical diversion procedures

Urolithiasis

Indwelling urinary catheters

Neoplasia, polyps

Cytotoxic drugs (cyclophosphamide)

Hyperadrenocorticism or glucocorticoid therapy

Diabetes mellitus

Infectious Diseases of the Dog and Cat, 3rd Edition

Renal failure

BY RESPONSE TO THERAPY

Persistent: Bacteriuria with the same organism that continues during therapy with appropriate antimicrobial agents

Relapsing: Infection with the same microorganism that recurs within several weeks of cessation of antimicrobial therapy

Reinfection: Infection with initial microorganism that responds to therapy but is then followed by infection by a different organism weeks to months after cessation of therapy

Superinfection: Infection with new organisms that develops during therapy for the initial infecting organism; usually associated with an indwelling catheter, severe anatomic abnormalities, or surgical diversion techniques

It is clear from UTI research that minor weaknesses in host defenses necessitate more virulent organisms to induce disease. Normal host defenses clear some infections spontaneously, and some require minimal antimicrobial therapy. The more severe the host defense abnormality, the more prone the host is to infection, even with less virulent organisms, and to severe infections that require precise and extensive therapy.²³⁶

91.2.2.2

Bacterial Virulence Factors

Uropathogenic *E. coli* are a genetically heterogeneous group of *E. coli* that differ from nonpathogenic *E. coli* by the presence of virulence genes.¹⁸¹ It has been found that uropathogenic *E. coli* typically carry large blocks of genes called pathogenicity-associated islands (PAIs), which are not found in fecal isolates.⁹⁵ PAIs code for virulence factors such as hemolysin, adhesins, iron acquisition systems, fimbriae, and toxins.⁹⁵ The presence of PAIs allows virulence genes to be easily spread among bacterial populations by horizontal gene transfer.¹⁹⁶

The type of virulence genes present in a certain strain appears to determine the site of infection (lower versus upper tract) and the severity of the infection.¹⁹⁶ One genetic type of uropathogenic *E. coli* can change virulence properties depending on host response during infection.¹⁸¹ Current studies are attempting to determine whether *E. coli* isolates that cause cystitis are distinct from those that cause pyelonephritis in genetic profiles or whether the host response determines the way the genes operate.⁹⁵ *E. coli* from UTIs in dogs have been found to have varying propensities to cause pyelonephritis and renal damage in mice based on urovirulence factors.²⁸⁹ Even though bacterial virulence factors are very important, the severity of the tissue injury also depends on the inflammatory reaction of the host.

Uropathogenic *E. coli* are usually thought of as extracellular pathogens because they are cultured from the urine. Observations have found that these organisms are not always extracellular.²³⁸ Piliated type 1 *E. coli* are able to enter bladder epithelial cells. Usually, this triggers the epithelial cell to undergo apoptosis and exfoliate. However, some *E. coli* seem to be able to persist intracellularly in some hosts by moving to other superficial cells or deeper epithelial cells.^{181,238} Thus infection can persist even though bladder urine is sterilized by antimicrobial therapy. Many recurrent infections are relapses with the same bacterial strains. The ability of *E. coli* to persist intracellularly is a possible explanation for some cases of recurring UTIs.²³⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

91.2.2.3 Catheter-Induced Urinary Tract Infections

One important iatrogenic cause for UTIs is urinary tract catheterization. Bacteria, especially *E. coli* and *Klebsiella*, establish periurethral colonization, and these bacteria are inoculated into the bladder during intermittent catheterization.²³⁹ Even a single catheterization can cause a UTI in female dogs.⁵¹ In people, the risk of a UTI with intermittent catheterization is 1% to 3% per insertion, so if a catheter must be inserted several times a day, most people become infected after a few weeks.²³² Risk of infection is greater if the catheter is left in place (indwelling).^{15,51,163,232} Bacteria can readily ascend either around or through the catheter. Closed, sterile systems can prevent bacterial access within the catheter lumen, which is the most rapid route of entry, but no method to date has effectively prevented access up the extraluminal side of the catheter.^{226,192}

Biofilm formation on the catheter is important in the development of infection when catheters are indwelling. Certain uropathogenic *E. coli* can promote biofilm formation on abiotic surfaces.¹⁹⁶ Biofilms consist of host materials including Tamm-Horsfall protein and crystals and bacterial products including bacterial polysaccharides, bacterial glycocalyxes, and living bacteria.^{58,252} A biofilm can be deposited within hours of catheter insertion.⁵⁸ Bacteria embedded in the biofilm are less susceptible to antimicrobial agents. Once infections become established on a urinary catheter, they are difficult to treat successfully, and the catheter must be removed.

Consequences of bacteriuria arising from indwelling catheterization include pyelonephritis, bacteremia, prostatitis, and epididymitis. Of people with catheter-associated UTIs, 1% to 4% developed bacteremia, and fatality rates as a result varied from 13% to 30%, depending on the study.⁵⁸ The risk factors for UTI-related bacteremia in people are unclear.²³² Many catheter-induced infections are asymptomatic. In one study in children, *E. coli* caused the majority of symptomatic infections.²³⁹ Interestingly, the same *E. coli* clones were associated with symptomatic and asymptomatic infections.²³⁹

91.2.3 Clinical Findings

91.2.3.1 Asymptomatic Bacteriuria

UTIs in dogs and cats are often asymptomatic.¹⁵⁷ For example, 95% of dogs with diabetes mellitus or hyperadrenocorticism and a UTI had no UTI symptoms.⁷⁴ Because of the lack of historical and physical signs, such infections are difficult to localize to the upper or lower urinary tract. In one study, 6 of 12 clinically nonsymptomatic female dogs with UTIs had infection localized to one or both kidneys, whereas 6 had bladder infections.¹⁶⁰ Despite the absence of clinical signs, three of the dogs with renal infection and three of the dogs with bladder infection had mild to moderate inflammation in the infected organ. Animals with few historical signs have had severe tissue injury, such as renal or prostatic abscess formation. Duration of nonsymptomatic infection or other host factors may be important in determining the degree of tissue injury. This situation emphasizes the importance of routine analysis of cystocentesis-collected urine in health screening.

Infectious Diseases of the Dog and Cat, 3rd Edition

91.2.3.2 Pyelonephritis

Pyelonephritis is rarely responsible for renal failure in the absence of other underlying kidney disease, such as urolithiasis. However, in humans, renal infection may induce inflammation that impairs renal function transiently and leads to scarring.^{24,131} In the early stage of acute renal injury caused by infection, renal tubular cells produce local inflammatory mediators such as cytokines and nitrous oxide, which recruit macrophages and neutrophils. In association with bacterial virulence properties, this leads to renal injury.¹³¹ Dogs can have pyelonephritis for years without developing progressive renal failure.²⁴⁶ Pyelonephritis has been diagnosed in association with renal dysplasia in juvenile dogs, but the cause-effect relationship is difficult to establish in spontaneous cases.¹

Dogs with acute bacterial pyelonephritis may be systemically ill with fever, depression, anorexia, renal pain, and leukocytosis. Gastrointestinal (GI) signs, particularly vomiting, may be seen. In humans, GI signs have been attributed to a secondary paralytic ileus.²⁵⁹ All signs are inconsistent and in experimentally induced disease, transient (lasting less than 5 days).¹⁶ Clinical signs in cats with pyelonephritis include fever, lethargy, anorexia, renal pain, and vomiting.²⁶¹ Chronic pyelonephritis may be asymptomatic or associated with polyuria and secondary polydipsia. Polyuria can occur before the onset of renal lesions and can resolve with eradication of infection.

939

Diseases reported to develop secondarily to pyelonephritis include septicemia,²⁴⁶ diskospondylitis,²⁷⁴ and distal renal tubular acidosis.²⁷³

940

91.2.3.3 Cystitis and Urethritis

The bladder and proximal urethra are so closely associated that inflammation in one is thought to affect the other. Infection of the distal urethra unassociated with infection in the rest of the lower urinary tract is uncommon unless an anatomic abnormality exists.

Urethrocystitis is characterized by dysuria (straining) and pollakiuria (frequent voiding of urine). The urine is often cloudy and hemorrhagic and may have a foul odor. Gross hematuria at the end of urination suggests that the blood is from the bladder. Gross hematuria at the beginning of urination or a urethral discharge may be associated with urethral or prostatic disease. Prostatic disease is a more common cause of a urethral discharge independent of urination than is urethral disease in dogs. Signs of systemic illness, such as fever and leukocytosis, are not associated with bacterial urethrocystitis. The bladder may be painful on abdominal palpation, and with chronic infection, the wall becomes thickened.

91.2.4 Diagnosis

Culture of bladder urine collected by cystocentesis is the preferred method by which UTIs are confirmed. Samples of urine for urinalysis and culture should be collected before initiation of antimicrobial therapy. If antimicrobial therapy was initiated on the basis of clinical signs and the diagnosis of a UTI is in doubt, it should be discontinued for 3 to 5 days before urine culture to minimize inhibition of bacterial growth.²⁰³ Although a urinalysis can screen for UTI, the visualization of bacteria on a urine sediment examination does not

Infectious Diseases of the Dog and Cat, 3rd Edition

consistently correlate with culture results.¹⁷³ UTIs without pyuria are common also, especially in dogs with diabetes mellitus^{74,173} and hyperadrenalcorticism.⁷⁴

The presence of bacteria in urine collected from the bladder confirms UTI but does not identify the specific area of the infection. The bacteria could be originating from the kidneys, bladder, prostate gland, or all of these. Diagnostic tests in addition to history and physical examination, which help narrow the location of the infection to an anatomic site in the urinary tract, include radiography, ultrasonography, and prostatic fluid evaluation. No convenient, reliable, noninvasive means to distinguish bladder from renal infections exists.²⁵²

Table 91-8 Guidelines for Diagnostic Tests and Therapy for Urinary Tract Infections

CLINICAL CLASSIFICATION	DIAGNOSTIC TESTS	THERAPY
Simple cystitis or nonsymptomatic, initial episode	Urinalysis, urine culture	Antimicrobial agent for 10 days in cats and female or neutered male dogs, 21 days for intact male dogs
Relapsing or persistent	Urinalysis, urine culture, radiography, ultrasonography, prostatic fluid examination in intact males	Antimicrobial agent for 6 weeks, treatment of any underlying disease process
Reinfection	Urinalysis, urine culture	Therapy as for simple cystitis, but consider prophylactic therapy if reinfections are frequent
Suspect pyelonephritis	Urinalysis, urine culture, complete blood count (CBC), blood urea nitrogen, serum creatinine, excretory urography, nephrosonography	Antimicrobial agent for 4 weeks, longer if chronic
Suspect prostatitis	Urinalysis, urine culture, CBC, prostatic ultrasonography, prostatic fluid examination	Antimicrobial agent for 4 weeks, 6 weeks if chronic

Because of the difficulty in identifying the location of a UTI in an anatomic site in the urinary tract, UTIs are also subdivided on the basis of response to antimicrobial therapy (see [Table 91-7](#)). The extensiveness of the diagnostic evaluation required on each case varies with response to initial antimicrobial therapy as well as severity of illness ([Table 91-8](#)).

91.2.4.1 Urine Collection

Because the distal urethra, vagina, and prepuce have a normal bacterial flora, the method of urine collection is important for accurate assessment of the results of urinalysis and urine culture. When a urine sample is collected, the method of collection should be recorded.

91.2.4.1.1 Cystocentesis

Cystocentesis is the preferred method of urine collection for culture because lower genitourinary tract contamination is avoided. Any bacteria present in such samples are indicative of infection unless inadvertent bowel penetration or skin contamination occurs. Because of the possibility of inadvertent contamination, diagnosis is more certain if urine is cultured quantitatively, with evaluation of the number of organisms found, as well as qualitatively, to identify the infecting species. For a laboratory to do a quantitative culture, a small volume of urine must be submitted. Sterile swabs dipped in urine are not suitable.

Infectious Diseases of the Dog and Cat, 3rd Edition

Before cystocentesis is performed, a small area of skin around the site of needle insertion should be clipped free of hair and cleansed. The bladder should be palpated and immobilized against the pelvis with one hand. In animals in which the bladder is not palpable, cystocentesis can be performed using ultrasound guidance. A 21-gauge or smaller needle is inserted into the bladder at an oblique angle, and urine is withdrawn into a syringe. The palpating hand releases pressure on the bladder, and negative pressure on the syringe is discontinued. The needle is withdrawn.

Cystocentesis is performed with the animal in the position in which it seems most comfortable (standing, lying down, or suspended by the front or rear limbs; Fig. 91-1). The only serious potential complication is leakage of urine from the puncture hole in the bladder. This is rare, unless the bladder is distended because of an inability to voluntarily void urine. Animals that are unable to urinate because of distended bladders should have their bladders emptied as soon as possible after cystocentesis. Cystocentesis can cause a mild degree of hematuria to be detected on urinalysis.

940

941

Fig 91-1 Cystocentesis with animal in dorsal recumbency. The palpating hand is positioned to hold bladder back against pelvic brim. (Courtesy University of Georgia, Athens, Ga.)

91.2.4.1.2

Catheterization

If the bladder is not palpable or cystocentesis fails, urine from male dogs should be collected for culture by catheterization. Catheterization should always be performed as aseptically and gently as possible. The

Infectious Diseases of the Dog and Cat, 3rd Edition

prepuce should be retracted and the penis cleansed and dried. A sterile, disposable catheter should be used. The catheter should be passed using only sterile instruments or gloves. This method of catheterization introduces only low numbers of bacteria (less than 10^3 per milliliter) into urine.^{32,48}

In contrast, catheterization of female dogs, even when being vigilant about using aseptic technique, introduces bacteria approximately 50% of the time; occasionally, large numbers (10^5 per milliliter) of organisms are introduced.⁴⁸ Experimentally, introduction of large numbers of bacteria into the bladders of normal female dogs by catheterization does not usually result in a persistent UTI unless a complicating factor, such as a foreign body in the bladder, is present.³² However, because of the difficulty in distinguishing infection from contamination and because of the small risk of inducing a UTI, catheterization is not an adequate substitute for cystocentesis in female dogs. Diuretics such as furosemide (1 mg/kg given subcutaneously [SC]) to distend the bladder for cystocentesis are preferable to evaluate a UTI, although the effect on specific gravity must be noted.

In normal cats, catheterized samples have fewer than 10^3 bacteria per milliliter in males and females.¹⁵³ However, unsedated cats may be difficult to catheterize without causing trauma. As in female dogs, diuretics may be needed to distend the bladder so that cystocentesis can be accomplished.

Samples may be obtained through an indwelling urinary catheter for quantitative culture. In people, low numbers of organisms in samples obtained from indwelling urinary catheters usually progress within days to high concentrations of bacteria unless the catheter is removed.²³² Culture of the tip of an indwelling urinary catheter on its removal is much less accurate in identifying infection than is urine culture.^{245a}

91.2.4.1.3

Midstream Collection

Collection during voluntary voiding in normal dogs has been found to introduce bacteria in large numbers (occasionally greater than 10^5 bacteria per milliliter).⁴⁸ Because of the chance of significant contamination during voiding, midstream collection should not be used to obtain urine for culture from dogs.

Midstream-collected urine occasionally is used for culture in severely dysuric cats in which the bladder may not fill sufficiently for successful cystocentesis, even after administration of diuretics. In these cases, urine should be expressed as cleanly as possible into a sterile container. The urine should be cultured quantitatively.

91.2.4.2

Handling of Urine Samples

Once urine is collected for culture, it must be handled properly to prevent changes in bacterial numbers. Specimens should be refrigerated and cultured within 6 hours.²⁰⁷ However, tubes with preservatives maintain types and numbers of bacteria in urine for up to 72 hours with refrigeration.⁴ Before culture, urine should not be incubated, kept at room temperature, or frozen. Storage at room temperature for 2 hours or longer causes increased bacterial numbers.¹³³

If a veterinary practice cannot deliver urine samples to a laboratory in a timely manner, it can use calibrated loops to inoculate blood agar plates.²⁰³ The plates are incubated at 37° C for 24 hours. If bacteria grow, the

Infectious Diseases of the Dog and Cat, 3rd Edition

plates or swab cultures from the plates can be sent to a commercial laboratory for species identification and antimicrobial susceptibility tests.

941

91.2.4.3

Interpretation of Urinalysis

942

To evaluate a dog or cat for infection, a complete urinalysis, *including* a sediment examination, must be performed. Findings on a urine dipstick that may indicate infection are positive occult blood and protein, but these also indicate hemorrhage, which has many causes. Infection can also occur without hemorrhage and can be associated with a normal dipstick evaluation. Dipstick leukocyte assays and dipstick assays for bacteria are inaccurate in companion animals.^{135,265}

Findings on a urine sediment examination that suggest a UTI are pyuria, hematuria, and bacteriuria. Of these, the most specific is bacteriuria. Bacteriuria on urinalysis of a cystocentesis sample with a negative urine culture result can occur as a consequence of nonviable microbes, contamination of the sample, improper handling or culture of the sample, or misinterpretation of brownian movement or amorphous debris as bacteria on the urinalysis. False-negative results are possible because large numbers of organisms must be present to be consistently visualized. In one study of dogs with hyperadrenocorticism or diabetes mellitus, 31% had no bacteria visualized on urinalysis despite positive urine cultures.⁷⁴ Correlation of Gram-stained smears of canine urine with culture results was good,¹⁹⁷ whereas that of unstained smears was poor.^{227,48} In human urine, Gram-stained smears were positive in 80% of samples with 100,000 or more bacteria per milliliter but in only 20% of the samples with fewer bacteria.¹³³

Pyuria is defined as greater than 3 white blood cells (WBCs) per high-power field (hpf; 40× objective) on cystocentesis samples and greater than 8 WBCs/hpf on catheterized or voided urine samples.²⁰³ Pyuria is not always present in association with bacteriuria, thus the absence of pyuria cannot be used as evidence of absence of bacteriuria.¹³³ Pyuria without bacteriuria indicates inflammation, and a culture of urine is indicated to determine whether infection is the cause of the inflammation. Bacteria are more difficult to detect than WBCs on urine sediment examination. Infection with minimal tissue invasion may not induce pyuria, and the magnitude of the WBC response seems to vary markedly, even in the same animal.¹⁵⁷ Pyuria was only found in 60% of dogs with UTIs and hyperadrenocorticism or diabetes mellitus.⁷⁴ A UTI without pyuria was also common in another study of diabetic dogs.¹⁷³

Nineteen percent of dogs with UTIs and either diabetes mellitus or hyperadrenocorticism had neither pyuria nor bacteriuria on urinalysis.⁷⁴ Urine cultures should be routinely performed in dogs with these diseases and in dogs treated with glucocorticoids.

91.2.4.4

Interpretation of Urine Culture Results

91.2.4.4.1

Dogs and Cats

The definitive test for UTIs in dogs and cats is isolation of bacteria from a properly collected cystocentesis sample (Table 91-9). Most UTIs involve a single bacterial species, present in high numbers (more than 100,000/ml).¹⁵⁷ Urine culture that results in isolation of multiple types of bacteria or low (fewer than 1000/ml) numbers must be assessed carefully. Artifactual contamination of urine with intestinal contents leads to the presence of multiple bacterial species. Contamination from the skin or in the laboratory leads

Infectious Diseases of the Dog and Cat, 3rd Edition

to fewer organisms. Multiple types of bacteria may be isolated in UTIs and are secondary to indwelling catheters or marked anatomic abnormalities.

91.2.4.4.2

Dogs

In male dogs, more than 10^4 bacteria per milliliter in a catheterized sample indicates infection (see [Table 91-9](#)). Fewer than 10^3 bacteria per milliliter suggests contamination. Intermediate numbers may indicate either contamination or infection. Other case information such as history, physical examination, urinalysis results, and degree of potential contamination during catheterization can help guide a decision about whether infection exists when culture results are inconclusive. Midstream or expressed urine samples and catheterization of female dogs should not be used for culture because of the likelihood of contamination.

Table 91-9 Criteria for Determining Infection in Urine Specimens Based Upon Method of Collection

CULTURE METHOD	CONTAMINATION (bacteria/ml)	INFECTION
Midstream voided	$<10^5$	Cannot distinguish in dogs $>10^5$ in cats ^a
Catheterization	$<10^3$ in male dogs, any number in female dogs $<10^3$ in cats	$>10^4$ in male dogs $>10^3$ in cats any number with indwelling catheters
Cystocentesis	$<1000^b$	$>10^3$

a Small numbers of clinically healthy cats had 10^5 bacterial/ml by this collection method.

b Any bacteria in bladder urine suggest infection, but low numbers may occur with contamination from the skin or in processing since most UTI are associated with high numbers of bacteria.

91.2.4.4.3

Cats

In samples of urine obtained by catheterization, bacterial counts greater than 10^3 per ml are considered indicative of infection in male and female cats (see [Table 91-9](#)).¹⁵³ If midstream samples must be used in a dysuric cat, greater than 10^5 bacteria per milliliter suggests infection if contamination during collection was minimal. Even counts greater than 10^5 bacteria per milliliter would not confirm infection, because counts this high were found in a small number of urine specimens from cats with negative culture results by cystocentesis.¹⁵³ Urinalysis results should be correlated with culture results when making a final determination about whether the bacteria are a result of infection or contamination.

91.2.4.5

Bacterial Pyelonephritis

Bacterial pyelonephritis may be suspected on the basis of history and physical examination as discussed previously or because the UTI is persistent or recurring (see [Table 91-7](#)). The diagnosis of bacterial pyelonephritis is supported by laboratory tests, radiography, excretory urography, and nephrosonography. The diagnosis can be confirmed only by culture of urine obtained by pyelocentesis or culture of tissue obtained by renal biopsy. Treatment is often based on a presumptive diagnosis using urinalysis, urine culture,

Infectious Diseases of the Dog and Cat, 3rd Edition

and excretory urography or ultrasonography. Definitive diagnosis is usually sought if the case is difficult or unusual, the renal pelvis is easy to image by ultrasound, or anesthesia or surgery is to be performed for another reason, such as to remove nephroliths.

91.2.4.5.1

Laboratory Findings

A complete blood count (CBC) may show a neutrophilic leukocytosis with or without a left shift in acute or complicated chronic pyelonephritis, especially with renal abscess formation or ureteral or renal pelvic obstruction. An inflammatory leukogram may also indicate bacteremia secondary to acute pyelonephritis or complicated, chronic pyelonephritis. A normal CBC result does not eliminate the possibility of pyelonephritis.

Abnormalities in renal function (abnormal creatinine clearance, inadequate urine concentrating ability in spite of demand, azotemia) in association with a UTI suggest that the UTI may be of renal origin.

942

943

However, additional tests are indicated because the UTI may be a lower tract infection if an animal has a decreased concentrating ability caused by renal disease with a noninfectious origin.

As mentioned, urinalysis may reveal hematuria, pyuria, and bacteriuria, but these are not specific for pyelonephritis. Consistently low urine specific gravity readings should increase the suspicion of pyelonephritis. Concentrated urine (with a specific gravity of greater than 1.035) does not rule out pyelonephritis because the infection may be unilateral. The degree of concentrating defect depends on how diffusely and severely the renal medulla is affected. The presence of leukocyte casts suggests renal infection; however, such casts are rarely seen.²⁰⁵ In a very small study, two dogs with pyelonephritis had much higher concentrations of urinary N-acetyl- β -D-glucosaminidase than four dogs with lower UTIs, suggesting that this test might be useful in differentiating dogs with pyelonephritis from those with a lower UTI.²³⁵

91.2.4.5.2

Survey Abdominal Radiography

An abnormality in renal size or contour may be seen with pyelonephritis. Normal renal size is determined by comparing the kidneys to the second vertebral body (L2); canine kidneys are 2.5 to 3.5 times L2, and feline kidneys are 2.4 to 3 times L2.⁷³ Most textbooks state that acute pyelonephritis is associated with renomegaly; however, this has not been reported in experimentally induced infections in dogs. Renomegaly may be noted with renal abscess formation. Unilateral renomegaly was found in a cat with pyelonephritis without abscessation.²⁶¹ With chronic pyelonephritis without abscess formation, renal size decreases and renal contour may become irregular,¹⁶ changes that are nonspecific for pyelonephritis. Survey abdominal radiographs help to detect radiopaque nephroliths. The concurrent findings of UTI and nephroliths are suggestive of pyelonephritis.

91.2.4.5.3

Excretory Urography

Signs suggestive of pyelonephritis are decreased opacity of the vascular nephrogram, decreased opacity and blunting of the pelvic recesses, and renal pelvic and ureteral dilatation (Fig. 91-2).¹² In animals with experimental infections, the size of infected kidneys progressively decreased over weeks.¹⁶ Absence of these findings does not rule out renal infections, especially in acute cases (those lasting 10 days or less).^{16,189}

Infectious Diseases of the Dog and Cat, 3rd Edition

91.2.4.5.4

Nephrosonography

The major sonographic findings in pyelonephritis are pelvic dilatation (pyelectasis) and proximal ureteral dilatation (ureterectasis) and a hyperechoic line within the renal pelvis or proximal ureter.¹⁸⁹ Other common findings are a generalized hyperechoic renal cortex, focal hyperechoic areas within the medulla, focal hyperechoic or hypoechoic areas in the renal cortex, and poor corticomedullary differentiation.¹⁸⁹ These abnormalities were found within 2 days of inducing infection.¹⁸⁹ Some of these findings, such as a hyperechoic renal cortex, are nonspecific and common with most types of renal disease, and occasionally are normal. Others such as pyelectasis can be seen with other conditions such as hydronephrosis and can occur during fluid diuresis. Fluid diuresis induced pyeloectasis in 70% of dogs, and was asymmetric in most of the animals.¹¹⁷ However, diuresis did not induce ureterectasis.¹¹⁷ The combination of suggestive ultrasonic findings in a case with UTI and appropriate clinical signs or relapsing infections are highly suggestive of pyelonephritis. As with excretory urography, a normal nephrosonogram does not rule out pyelonephritis.¹⁸⁹

Using ultrasonography to examine the kidneys has many advantages. No ionizing radiation or contrast agent is required, it is unaffected by renal dysfunction, and it is safe in animals with azotemia. However, performance and evaluation of ultrasound examination are operator dependent, and the accuracy of the outcome is directly related to the skill of the examiner. The animal's body size and lack of cooperation may also limit the value of ultrasonography.

Fig 91-2 Excretory urogram showing dilation of renal pelvis with lack of opacification (blunting) of pelvic recesses and dilation of proximal ureter. These signs are consistent with pyelonephritis.

Infectious Diseases of the Dog and Cat, 3rd Edition

91.2.4.5.5 Pyelocentesis

Percutaneous nephropyelocentesis allows collection of urine for cytology and culture directly from the renal pelvis.^{261,159} Two different methods have been described. In one, the renal pelvis is visualized by means of excretory urography and fluoroscopy and dilated by application of an abdominal compression band. A 20-gauge disposable arterial needle is then directed through the skin of the lateral flank into the dilated renal pelvis. A positive culture result confirms renal pelvic infection. In the other, ultrasound is used to guide a 21-gauge needle into the renal pelvis.²⁶¹ Pyelocentesis is not commonly used.

91.2.4.5.6 Renal Biopsy

Renal biopsy is rarely performed to confirm a diagnosis of pyelonephritis, because the lesions are often focal and medullary, thus they may be missed on renal biopsy samples, which are usually only a small, cortical sample. If surgery is performed for another purpose, such as nephrolith removal, culture of urine from the renal pelvis and culture and histologic examination of renal tissue samples should be performed to confirm a diagnosis of bacterial pyelonephritis.

91.2.4.6 Bacterial Cystitis-Urethritis

The diagnosis of acute bacterial cystitis is usually based on history and clinical signs and on confirming a UTI by urinalysis and urine culture. In cases of relapsing or persistent UTIs, a complicated infection should be suspected (see [Table 91-7](#)). In these cases, imaging of the bladder is important.

Emphysematous cystitis is characterized by gas-filled vesicles in the bladder wall and often gas bubbles in the bladder lumen. Gas formation is due to infection with gas-producing bacteria, using glucose, protein, or tissue carbohydrates as substrates. Emphysematous cystitis is usually diagnosed radiographically or ultrasonically, although it may be suspected by the sound of air being voided during urination or by the palpation of crepitus within the bladder on physical examination. Although diabetes mellitus may predispose an animal to emphysematous cystitis, this type of cystitis also occurs in animals without diabetes. Because of bacterial fermentation, the absence of glucosuria does not exclude a diagnosis of diabetes mellitus, which should be determined by measurement of blood glucose.²¹⁹ In animals without diabetes, urine proteins are suspected to be the substrate for gas formation.²¹⁹ Cases in animals without diabetes are usually complicated,⁵⁶ and the usual infecting organism is *E. coli*,^{286,56} although infections with other organisms including anaerobes have been reported.⁸⁷

Polypoid cystitis is a rare disease of the bladder, in which the bladder mucosa develops villuslike sessile projections or folds. It has been reported to be related to chronic inflammatory diseases of the bladder, including chronic UTIs and urolithiasis. Affected dogs are most commonly female and show hematuria and recurrent UTIs.¹⁷¹ Although many bacterial species have been involved, *Proteus* species are most common.¹⁷¹ It is unknown whether the polyps predispose animals to UTIs or the chronic UTI results in polyp formation.

In dogs with urolithiasis and a positive urine culture, the same organism was cultured from bladder mucosal samples and uroliths, leading to the conclusion that urine cultures were sufficient in such cases.⁹⁷ However, in dogs with urolithiasis and a negative urine culture, a bacterial organism was cultured from the bladder

Infectious Diseases of the Dog and Cat, 3rd Edition

mucosa or the urolith in 18.5% of cases.⁹⁷ Thus when a urine culture is negative in a dog with uroliths, an aerobic culture of a bladder mucosal sample and the urolith should be performed.

91.2.4.6.1

Survey Radiography

Most uroliths can be detected on good-quality survey abdominal radiographs. Urolithiasis and emphysematous cystitis are the only bladder problems that are able to be diagnosed by survey radiographs.

91.2.4.6.2

Ultrasound and Contrast Cystography

Ultrasound of the bladder is an excellent diagnostic technique because of the bladder's superficial location and the excellent acoustic properties of fluid. However, an empty bladder is difficult to assess by ultrasound, whereas bladder size can be manipulated during contrast cystography. On cystography and ultrasound, increased bladder wall thickness suggests chronic inflammation (Figs. 91-3 and 91-4). Bladder wall thickness does vary with the degree of bladder distention. Mean bladder wall thickness in dogs is 2.3 mm with minimal distention (0.5 ml/kg) and 1.4 mm with moderate distention (4 ml/kg).¹⁵⁴ Bladder wall thickness in cats is about 1.7 mm.¹⁵⁴ Polyps (polypoid cystitis) can be visualized with ultrasound or cystography. Inflammatory polyps are usually located in the cranioventral bladder wall.¹⁷¹ Although the most typical location is different than transitional cell carcinoma (bladder neck and trigone), mass lesions in the bladder require biopsy for differentiation of inflammatory conditions from neoplasia.^{179,171} This differentiation is important because polypoid cystitis can resolve with appropriate antimicrobial therapy. Polyp removal also seems beneficial.¹⁷¹ A urachal diverticulum or other diverticulum may predispose animals to developing chronic lower UTIs and is visualized with bladder ultrasound or contrast cystography.¹⁶⁵

Fig 91-3 Double-contrast cystogram showing thickened bladder wall at outer edges of air-filled bladder.

Infectious Diseases of the Dog and Cat, 3rd Edition

91.2.4.6.3 Biopsy

Biopsy of the bladder wall should be performed in difficult cases.¹¹⁵ Biopsy specimens should be cultured for bacteria as well as processed for histologic evaluation. Gram stain may be helpful in examining bladder tissue for bacteria.¹¹⁵

91.2.5 Therapy

91.2.5.1 Urine Concentration of Antimicrobial Agents

The major difference between therapy for UTIs and infections in other organ systems is that most antimicrobials are present in urine in high concentrations as a result of renal excretion (Table 91-10).^{144,249} Because most antimicrobial disks contain serum concentrations, routine antimicrobial susceptibility results should be considered only as rough guidelines for treatment of UTIs. If the infecting organism is reported to be susceptible to an antimicrobial agent, that agent is likely to be effective if it is excreted in active form by the kidney and renal function is normal. Furthermore, an antimicrobial to which the organism is reported to be resistant may also give good results in vivo because of significantly higher concentrations in urine than serum in animals that can concentrate their urine.

Another method of choosing an effective therapeutic agent for UTIs is to determine the minimum inhibitory concentration (MIC) of antimicrobials for the infective agent. The MIC is defined as the least amount of an antimicrobial agent that causes complete inhibition of growth of the infecting bacteria under standardized conditions. MIC is most accurately measured by microdilution analysis with varying antimicrobial concentrations but can be estimated from the diameter of the zone of inhibition of Kirby-Bauer plates.⁷ Rather than absolute susceptibility or resistance, the concentration of antimicrobial that inhibits the growth of the organism is reported. MIC is then compared with the concentration reached by that antimicrobial in urine. If the mean urine concentration exceeds the MIC by at least 4 times, the antimicrobial agent should be effective (see Table 91-10). In renal parenchymal and prostatic infections, special considerations apply to antimicrobial penetration, which is discussed in the Bacterial Pyelonephritis and Prostatitis sections, respectively.

Table 91-10 Mean Urine Concentrations of Antimicrobial Agents Used in Management of Canine Urinary Tract Infection^a

DRUG ^b	DOSAGE (mg/kg) ^c	ROUTE	INTERVAL (HOURS)	MEAN URINE CONCENTRATION (µg/ml)
Ampicillin	22	PO	8	309
Amoxicillin	11	PO	8	201.5
Chloramphenicol	33	PO	8	124
Nitrofurantoin	4.4	PO	8	100
Trimethoprim-sulfonamide	13	PO	12	26/79 ^d
Gentamycin	2	SC	8	107
Amikacin	5	SC	8	342
Cephalexin	8	PO	8	225
Enrofloxacin	2.5	PO	12	40
Tetracycline	18	PO	8	138

Most data determined by and supplied courtesy Gerald Ling, University of California, Davis, Calif.
PO, By mouth; SC, subcutaneous.

^a Values were determined in hydrated dogs with normal renal function. To determine the efficacy of a drug, multiply by 4 the minimum inhibitory concentration (MIC) of the bacteria isolated. If the

Infectious Diseases of the Dog and Cat, 3rd Edition

total is less than the mean urine concentration for that drug, the drug has a 90% to 95% chance of being effective.

- b See Drug Formulary, [Appendix 8](#) for additional information on each drug.
- c Dose per administration at specified interval. (For duration, see [Table 91-8](#).)
- d Mean concentration of trimethoprim in urine is 26, and mean concentration of sulfonamide is 79.

Table 91-11 Type of Organism Most Likely to Cause Initial Urinary Tract Infection and Initial Antibiotic Choice

URINE pH	BACTERIAL CHARACTERISTICS	LIKELY ORGANISM ^a	INITIAL ANTIBIOTIC CHOICE ^b
Acidic	Rods	<i>Escherichia coli</i>	Trimethoprim, enrofloxacin
	Cocci	<i>Enterococcus</i> or <i>Streptococcus</i>	Ampicillin, ^c amoxicillin
Alkaline	Rods	<i>Proteus mirabilis</i>	Ampicillin, amoxicillin
	Cocci	<i>Staphylococcus</i> spp.	Cephalexin, amoxicillin-clavulanate

a Based on urine pH and bacterial characteristics on urine sediment examination.

b May need to be modified after the causative organism and its antibiotic susceptibility are determined by urine culture.

c Enterococci may often show antibiotic resistance.

91.2.5.2 Antibiotic Choice

Determination of organism type and its in vitro antimicrobial susceptibility is the optimal way to determine therapy for a UTI. However, clinicians usually begin therapy pending culture results. By examining urine pH and whether the organisms in the urine are rods or cocci on urine sediment examination, clinicians can make an educated guess about the type of organism present and a reasonable first choice of antimicrobial agent ([Table 91-11](#)). With recurrent UTIs, clinicians should compare the findings from the current urinalysis with those from prior urinalyses and urine cultures to determine the most likely causative organism and its susceptibility, pending culture results. On the basis of MIC determinations for common urinary tract pathogens, usually effective antimicrobials have been determined ([Table 91-12](#)).

Fluoroquinolones are often used to treat UTIs because they are bactericidal with high urine concentrations and effectively treat the most common causative organisms.^{47,201} Several fluoroquinolones are available for veterinary use, including enrofloxacin, marbofloxacin, orbifloxacin, and difloxacin. Enrofloxacin is metabolized to ciprofloxacin. A small proportion of cats develop irreversible blindness after treatment with fluoroquinolones. Risk factors include older age, intravenous (IV) administration, high doses, and prolonged courses of treatment.²⁸⁰ Considering the risk of blindness, fluoroquinolone use for UTIs in cats should be limited to those cases in which urine culture indicates a need for this class of drugs. Other drugs to which *E. coli* is often sensitive include aminoglycosides and trimethoprim-sulfonamide. Aminoglycosides are rarely used to treat UTIs because of the risk of nephrotoxicity.²⁰¹ Drugs with the poorest efficacy against *E. coli* include the penicillin derivatives, tetracyclines, and first-generation cephalosporins.²⁰¹

945

946

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 91-12 Antimicrobials for Genitourinary Infections Based on Causative Bacteria^{156,229,64,202,206,243,23}

IDENTIFIED ORGANISM ^a	ANTIMICROBIALS RECOMMENDED
<i>Escherichia coli</i>	Trimethoprim-sulfonamide, amoxicillin-clavulanate, fluoroquinolone, chloramphenicol
<i>Staphylococcus</i>	Amoxicillin-clavulanate, first-generation cephalosporins
<i>Streptococcus</i> or <i>Enterococcus</i>	Ampicillin, amoxicillin
<i>Proteus</i>	Ampicillin, amoxicillin
<i>Pseudomonas</i> ^b	Tetracycline, fluoroquinolone
<i>Klebsiella</i> ^b	First-generation cephalosporins, trimethoprim-sulfonamide, amoxicillin-clavulanate, fluoroquinolone
<i>Enterobacter</i>	Trimethoprim-sulfonamide, fluoroquinolone

- a Highly antibiotic-resistant UTIs can be a problem with any of these organisms, especially in animals that have received antimicrobial therapy. For this reason, this table provides general guidelines only. Identification of the organism and its susceptibility is important in each clinical case for appropriate antimicrobial selection. In highly resistant gram-negative infections, quinolones, third-generation cephalosporins, and extended-spectrum penicillins may be needed.
- b *Pseudomonas* and *Klebsiella* infections are the most difficult for which to predict susceptibility. Although these organisms are usually susceptible to aminoglycosides, aminoglycosides are not usually used because of nephrotoxicity. Repeated urine evaluations during and after therapy are essential to determine treatment efficacy in infections with these organisms.

UTIs in humans are becoming increasingly antibiotic resistant, especially to certain drug classes.^{93,94,172,252} In uncomplicated, community-acquired UTIs in women, one in three bacterial isolates are resistant to ampicillin, and approximately 20% are resistant to trimethoprim-sulfonamide.^{93,43a} Up to 45% of *E. coli* that cause UTIs are resistant to ampicillin, and up to 31% are resistant to trimethoprim-sulfonamide.¹⁷²

An increase in fluoroquinolone resistance in bacteria, especially among *E. coli*, isolated from canine UTIs has been documented in some studies^{47,49} but not others.²⁰¹ Increased fluoroquinolone use was correlated with increased resistance.⁴⁹ Resistance to multiple other drugs commonly used to treat UTIs accompanies enrofloxacin resistance.⁴⁹ *Pseudomonas aeruginosa* and *Enterococcus* species isolated from canine otitis and UTIs became rapidly resistant to enrofloxacin in vitro.⁴⁰ *Klebsiella*, *Proteus*, *Streptococcus*, *E. coli*, and *Staphylococcus* were less likely to develop resistance in this study.⁴⁰ Canine UTIs caused by *Staphylococcus* were increasingly antibiotic resistant, especially to ampicillin and penicillin.²⁰² A study found that resistance correlated with drug usage.²¹⁵ In this study, resistance of *Staphylococcus aureus* and *Staphylococcus intermedius* infections to ampicillin decreased but markedly increased to the fluoroquinolones as usage of these drugs either declined (ampicillin) or increased (fluoroquinolones). Another study found that antibiotic resistance is common in canine UTI and develops in response to treatment, especially with trimethoprim-sulfa. Antibiotic resistance could also be lost when antibiotics are discontinued.⁶⁵ Based on all these studies, it is optimal to base UTI therapy on culture and susceptibility to improve therapy efficacy and avoid inappropriate antimicrobial use.

Infectious Diseases of the Dog and Cat, 3rd Edition

A little used drug that may efficiently treat some resistant bacteria from UTIs is nitrofurantoin. Nitrofurantoin effectively treats gram-positive and gram-negative organisms, but it does not penetrate the prostate gland. Nitrofurantoin should be given only as the macrocrystalline formulation to decrease adverse GI effects and maximize efficacy.

Although selection of an antimicrobial agent by organism identification and susceptibility testing usually correlates with success of therapy in vivo, the correlation is not 100%. Various factors such as GI absorption, location of infection, renal function, polyuric state, and urine characteristics influence antimicrobial urine concentrations. The only way to be certain that the chosen drug is effective is to reexamine the urine during and after therapy. Urine should be recultured, or the sediment should be examined cytologically after a few days of therapy. If the antibiotic eliminates bacteria within a few days, the drug's efficacy against that bacterial species is confirmed. However, a longer course of therapy is necessary to eliminate the organism from infected bladder, renal, or prostatic tissues.

Whenever any antimicrobial is dispensed, adverse reactions are possible. One client survey found the highest rate of adverse reactions in dogs to be with erythromycin (52%, with the most common reaction being vomiting) and the lowest to be with amoxicillin (7.5%).¹⁴⁵ Even though reports have been made of serious toxicity with trimethoprim-sulfadiazine, this drug had a relatively low percentage of adverse reactions (18%, with the most common reactions being anorexia, lethargy, and polyuria-polydipsia), despite being the most commonly prescribed drug in the survey.¹⁴⁵ An approximately 15% incidence of keratoconjunctivitis sicca (KCS) was found with trimethoprim-sulfadiazine; dogs weighing less than 12 kg were at greater risk.²⁵ Enrofloxacin should not be given to immature dogs, to dogs prone to seizures, or to uremic animals without dosage modification.^{242,5} As noted previously, caution should be used when giving enrofloxacin to cats.

91.2.5.3 Therapy for Different Types of Bacterial Urinary Tract Infections

Optimal duration of therapy for different types of UTIs in dogs and cats has not been determined by clinical studies. The recommended duration of therapy varies with anatomic location and severity of the infection. It also varies according to whether the infection is complicated and whether the infection is an initial infection, relapsing, or persistent (see [Tables 91-7](#) and [91-8](#)). Because of these differences, it is best to classify a UTI by as many characteristics as possible. For example, an uncomplicated initial cystitis requires much less intensive diagnostic and therapeutic efforts than a complicated, relapsing pyelonephritis. In humans, a first infection is typically caused by an organism, usually *E. coli*, that is sensitive to many different antimicrobial agents.¹⁹³ However, recurrent infections are likely to be caused by organisms with increasing levels of antimicrobial resistance. This same situation is apparent in some dogs.^{243a}

91.2.5.3.1 Asymptomatic Bacteriuria

A diagnostic effort should be made to determine whether an underlying cause of immunosuppression exists, such as glucocorticoid therapy or hyperadrenocorticism. Asymptomatic infections should be treated based on urine culture results (see [Table 91-8](#)). A urine culture should be repeated approximately 1 week after concluding therapy. If the infection remains, a diagnostic effort should be made to identify the tissue source (kidney, bladder, prostate) and any underlying disease (urolithiasis, neoplasia, congenital defect).

946

947

Infectious Diseases of the Dog and Cat, 3rd Edition

91.2.5.3.2

Acute Pyelonephritis

Antibiotic therapy should be started on the basis of urinalysis and pending culture results (see [Tables 91-8](#) and [91-11](#)). Although aminoglycosides have excellent renal tissue penetrance, nephrotoxicity makes their administration risky. Other drugs that can diffuse into renal tissue are preferred ([Table 91-13](#)).¹⁶ Nitrofurantoin should not be given in acute pyelonephritis because it is ineffective for bacteremia, which may accompany acute pyelonephritis.⁵²

If the animal is systemically ill, initial therapy should consist of parenteral antibiotics as well as IV fluid support. Parenteral therapy should be continued until response is indicated by normalization of body temperature and appetite. In children, the standard protocol is 3 days of IV antibiotics. Longer courses of parenteral antibiotics did not reduce the incidence of renal scarring or the incidence of recurrent infections.²⁴

If the organism is reported to be resistant to the initially chosen antimicrobial but the animal is better clinically, a urinalysis should be checked before changing therapy to determine whether the drug is efficacious in vivo. If the drug is not efficacious, therapy should be changed. If the drug is efficacious, initial therapy should be continued for 3 to 4 weeks, with follow-up cultures 1 to 2 weeks after the conclusion of treatment. Urine cultures should be performed monthly for several months to detect recurrence ([Table 91-14](#)).

91.2.5.3.3

Chronic Pyelonephritis

Antibiotics with the ability to penetrate renal tissue are preferred if the causative organism is susceptible to one of them (see [Table 91-13](#)). Sulfonamides do not reach effective intrarenal concentrations, so only the trimethoprim component of trimethoprim-sulfonamide is effective for treating renal infections.²⁶ Nitrofurantoin can be used for chronic renal infections but not in animals with renal dysfunction.⁵² Efficacy of the chosen antimicrobial agent should be checked by urinalysis and urine culture after the first 2 weeks of therapy. If the urine is not sterile at this point, therapy should be changed. If the urine is sterile, the antimicrobial agent should generally be continued for at least 6 weeks. Urine cultures should be repeated on a periodic basis after finishing therapy (see [Table 91-14](#)). Pyelonephritis is very difficult to cure in dogs and cats.

Table 91-13 Antimicrobials for Genitourinary Infections Based on the Site of Infection

SITE	ANTIMICROBIAL AGENT
Kidney	Trimethoprim, quinolones
Prostate	Trimethoprim, quinolones, erythromycin, clindamycin
Uterus	Quinolones, trimethoprim
Mammary gland	Ampicillin, amoxicillin-clavulanate, cephalosporin (first generation)

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 91-14 When Urine Cultures Should be Repeated to Ensure Efficacy of Urinary Tract Infection Therapy

NONCOMPLICATED	COMPLICATED
1 week after conclusion	1 week after conclusion
	Monthly for 3 months
	Then at 6 months
	At 9 months
	At 12 months
	At 18 months
	At 24 months

Nephrectomy may be necessary if renal abscess formation is present. The remaining kidney must be able to maintain renal function. Crude indicators of adequate renal function are normal serum urea nitrogen, normal serum creatinine, concentrated urine, normal radiographic and ultrasonographic appearance, normal excretion of dye on excretory urography, and normal appearance at surgery. One needs to recognize that all these tests are insensitive, and normal findings do not confirm normal function.⁸⁹ Renal scintigraphy has been recommended to more thoroughly assess individual kidney function before surgery.⁸⁹ Even with this test, 9 of 21 dogs undergoing nephrectomy became azotemic, albeit mildly so, after nephrectomy.⁸⁹ At the time of surgery, urine should be collected from the renal pelvis or ureter of the remaining kidney and cultured for bacteria to direct future therapy and provide a more accurate prognosis to the owner.

91.2.5.3.4

Initial Episode of Acute Cystitis

Acute, uncomplicated bacterial cystitis in female dogs, neutered male dogs, and cats should be treated for 7 to 14 days (see [Tables 91-8](#) and [91-11](#)). Because clinical signs often improve within 48 hours, the client must be instructed to give all medication as directed. One week after therapy is concluded, a urine sample should be collected for culture to ensure efficacy. Such a follow-up is important to prompt an early search for an underlying predisposing cause for treatment failure, such as uroliths, pyelonephritis, abnormal bladder or urethral function, renal failure, urinary tract neoplasia, or hyperadrenocorticism. Whenever one part of the urinary tract is infected, the entire tract is at risk; pyelonephritis may be present with the cystitis.

In intact male dogs, prostatitis often occurs in conjunction with cystitis, necessitating longer therapy (see [Table 91-8](#)). Reexaminations should include evaluation of prostatic fluid as well as urine. Drugs with prostatic penetrance are preferred (see [Table 91-13](#)). However, one study found no difference in clinical response to ampicillin (little prostatic penetrance) and trimethoprim-sulfonamide (good prostatic penetrance) in UTIs in intact male dogs.¹⁵⁶

91.2.5.3.5

Reinfections

In some dogs, acute cystitis recurs frequently because of different organisms. The causative organism must be determined by urine culture in each instance of infection to differentiate reinfection from relapse (see [Table 91-7](#)). Reinfection suggests a problem with host defenses (see [Table 91-6](#)). A careful history should be taken and complete physical examination performed to determine whether micturition and

Infectious Diseases of the Dog and Cat, 3rd Edition

urinary tract anatomy are normal. Hyperadrenocorticism and glucocorticoid therapy are predisposing causes of reinfections. Some bitches have recurrent cystitis with no other discernible abnormalities.

Each episode of reinfection is treated individually. If infections recur frequently (more than three to four episodes per year), low-dose, prophylactic therapy can be provided (see Prophylactic Therapy).

91.2.5.3.6

Complicated Cystitis

Cystitis is considered complicated if it is associated with an underlying risk factor such as urolithiasis or diabetes mellitus (see [Table 91-7](#)). Complicated bacterial cystitis requires resolution of underlying factors and protracted treatment. Removal of polyps may improve the chance to resolve chronic UTIs in dogs with polypoid cystitis.¹⁷¹ Episioplasty was beneficial in resolving chronic bacterial cystitis in dogs with excessive perivulvar skin folds.¹⁵⁵

947

948

Urine should be recultured or checked by sediment examination 3 to 7 days after therapy begins. If the urine is sterile, that antimicrobial agent should be continued for 3 to 6 weeks. If it is not sterile, another antimicrobial should be chosen. Culturing should be repeated after approximately 7 days of treatment until an effective agent is found. Urine should be recultured 4 to 7 days after the conclusion of therapy (see [Table 91-14](#)).

91.2.5.3.7

Relapsing or Persistent Urinary Tract Infections

Treatment is considered ineffective and a UTI persistent when bacteria can be isolated from urine during therapy, even if the bacterial count has been reduced. Repeated isolations of the same organism within several months of therapy and after a negative culture result at the conclusion of therapy indicates a relapse. When no culture has been performed during or within a week of concluding therapy, it is not possible to differentiate between a persistent infection and a relapse. Potential causes of failure of antimicrobial therapy include selection of an ineffective drug or administration of a subtherapeutic dose of a drug, poor owner compliance with administration of the drug, bacteria in tissue sites impenetrable to the antimicrobial chosen, bacteria acquiring resistance to the antimicrobial agent, host factors including failure to absorb the drug, and failure to eliminate an underlying condition. Whether a relapsing or persistent UTI, all these factors should be considered. A diagnostic investigation should be undertaken to determine the site of tissue infection and any underlying disease process that is causing the infection to be complicated (see [Tables 91-7](#) and [91-8](#)). Any underlying factors discovered should be treated.^{243a} For example, surgical correction of vestibulovaginal stenosis resulted in resolution of UTIs for at least 5 months in four dogs that had an average chronic UTI duration of almost 2 years.¹⁴⁷

Antimicrobial therapy should be continued at least 6 weeks (see [Table 91-8](#)). Urine cultures should be evaluated during and after therapy (see [Table 91-14](#)). If antimicrobial therapy eliminates bacteriuria during therapy but bacteriuria recurs with discontinuation of therapy, a longer course of therapy (4 to 6 months) should be considered. When providing antimicrobials for this duration, consideration must be given to side effects. Prolonged use of drugs with significant potential side effects should be avoided. The risk of KCS and other toxicities with trimethoprim-sulfonamide should be conveyed to the owner (see Drug Formulary, [Appendix 8](#)). Tear tests should be performed before prolonged therapy with trimethoprim-sulfonamide.

Infectious Diseases of the Dog and Cat, 3rd Edition

In a study of multidrug-resistant infections, one small study of four dogs with cystitis suggested that local administration of an EDTA-Tris solution (250 mmol/L EDTA and 50 mmol/L tromethamine at a pH of 8) once a day for 7 days in conjunction with a parenterally administered cephalosporin, fluoroquinolone, or aminoglycoside was effective.⁷¹ The infecting organisms in this small study were *P. aeruginosa*, *E. coli*, or *P. mirabilis*.

91.2.5.3.8

Suppressive Therapy

If the patient experiences relapses each time antimicrobial therapy is stopped, suppressive therapy can be tried to prevent extension of the infection and control symptoms.²³⁷ Once the urine is sterile from full-dose therapy, suppressive therapy begins. A single dose per day of an antimicrobial is administered, preferably when the animal is to be confined (usually evening) so that urination is prevented for several hours. Drugs to consider for suppressive therapy are trimethoprim, nitrofurantoin, cephalexin, and enrofloxacin. Risks include antimicrobial toxicity and induction of bacterial resistance. Urine should be cultured monthly during suppressive therapy to ensure that the drug remains effective.

91.2.5.3.9

Urinary Tract Infection Associated with Catheterization

Treatment of UTIs developing during indwelling urinary catheterization should be delayed until the catheter is removed unless systemic signs of infection develop. When the urinary catheter is removed and the animal is again urinating normally, urine should be cultured and appropriate antimicrobial therapy started if infection is found. Treatment should continue for 10 days, with reculture of urine approximately 1 week after therapy is discontinued.

Catheter-induced infections may involve more than one bacterial species with different antimicrobial susceptibility patterns. In these cases, one species is treated first. Urine is reevaluated after treatment, and if infection persists with another species, that infection is treated. Except for combinations such as trimethoprim-sulfonamide, simultaneous administration of two or more antimicrobial agents is generally avoided when treating UTIs.

91.2.5.4

Fungal Urinary Tract Infections

Fortunately, fungal UTIs are rare because they are difficult to treat. If the animal is asymptomatic, as many are, the only treatment required is to eliminate or control the underlying factors compromising host immunity.^{170,216} Such factors include indwelling urinary catheters, anatomic abnormalities, diabetes mellitus, and antibacterial therapy.

If the animal is symptomatic, antifungal therapy can be provided in conjunction with control of underlying factors, although reports of results of therapy are scarce in the veterinary literature. Treatment with itraconazole or ketoconazole is not recommended because they are not excreted in therapeutic concentrations in urine.

The most common organism for which therapy is reported is *Candida*. Susceptibility of *Candida* species was found to change on exposure to antifungal agents and be unpredictable, with some species being susceptible to several drugs and other species being highly resistant.²¹⁶ 5-Fluorocytosine was used successfully, in addition to correction of a urethral stricture, in one cat with candidal urethrocystitis.⁸³ Fluconazole (FCZ)

Infectious Diseases of the Dog and Cat, 3rd Edition

was used most often in one retrospective study and is considered to be the azole of choice due to its excretion in urine in active form.²¹⁶ However, only one case was documented to resolve with this therapy, and it failed in five cases.²¹⁶ FCZ was successful in treating aspergillus cystitis in a cat at a dose of 7.5 mg/kg every 12 hours orally for 10 weeks.² Use of intravesicular clotrimazole was used successfully in one dog⁷⁵ and on one cat^{262a} with candidiasis. These reports underline the importance of following up a treated case with repeated urinalysis and urine culture during and after therapy to document resolution of infection.

91.2.6 Prophylactic Therapy

Prophylactic therapy is defined as the administration of antimicrobial drugs to prevent establishment of infection in uninfected sites.²⁸¹ In relation to the urinary tract, such therapy is provided to prevent bacterial reinfections in animals that have a history of frequent reinfection (greater than 3 to 4 times a year), to prevent sepsis during surgery in animals with UTIs, and to prevent bacterial UTIs from urinary tract manipulation and catheterization. Prophylaxis is effective only if the antimicrobial drug is present at the time of bacterial inoculation.²⁸¹ Prophylaxis with drugs is not as important as aseptic technique in preventing infections related to medical procedures.

948

91.2.6.1 Reinfections

949

Before beginning prophylactic therapy, infections should be treated until urine is sterile. Drug choice is based on the susceptibility of the most recent isolate.¹⁵⁷ The chosen drug is given once just before a 6- to 12-hour period when urine will be retained in the bladder, such as at night in house dogs. The dose is one half to one third of the usual total daily dose. Therapy is continued for 6 months. Urine should be cultured every 4 weeks to ensure UTIs are prevented. If the urine remains sterile for 6 months, prophylactic therapy can be discontinued and the animal monitored for reinfection (see [Table 91-14](#)). If reinfections do occur, each is eliminated with full-dose therapy, and prophylactic therapy is reinstituted. Potential adverse effects of prophylactic therapy include induction of antimicrobial resistance and drug toxicity. All urine samples for culture should be collected by cystocentesis in animals receiving prophylactic therapy, because they may be more susceptible to induction of infection when catheterization is performed.¹⁵⁷

91.2.6.2 Perioperative Therapy

If surgery is to be performed on an animal with a urogenital infection, antibiotics should be administered before and during surgery to reduce the possibility of sepsis. If the animal's condition permits, determination of the causative organism and its susceptibility before surgery is recommended.

91.2.6.3 Urinary Tract Manipulation

To prevent introduction of UTIs in animals without infection, short-term administration of a broad-spectrum antimicrobial may be helpful during urinary tract procedures such as cystoscopy, urethroscopy, contrast urethrocystography, electrodiagnostic procedures, urohydropulsion, and prostatic massage.²⁹ Its use for 24 to 72 hours, beginning a few hours before the procedure, should be sufficient. Drugs to consider include amoxicillin-clavulanate, trimethoprim-sulfonamide, macrocrystalline nitrofurantoin, a first generation cephalosporin, or enrofloxacin.

Infectious Diseases of the Dog and Cat, 3rd Edition

A single administration of amoxicillin or a cephalosporin may act as a preventative if a catheter is passed only once into the urinary bladder. However, a single episode of catheterization rarely results in a UTI and usually does not warrant antimicrobial therapy. With repeated, intermittent urinary catheterization, antibiotic prophylaxis is also not indicated. In children with intermittent catheterizations, antimicrobial prophylaxis was not associated with a lower rate of bacteriuria, reduction of periurethral colonization by bacteria, or a lower rate of symptomatic UTI.²³⁹ In adults with intermittent catheterizations, the incidence of UTIs was reduced by bladder irrigation with a solution of neomycin and polymyxin (Neosporin G.U. Irrigant, Burroughs Wellcome, Research Triangle Park, N.C.) or by oral methenamine hippurate or nitrofurantoin.^{52,251}

91.2.6.4 Indwelling Urethral or Cystic (Cystostomy Tube) Catheterization

The three following factors are most important in preventing UTIs in an animal with an indwelling urinary catheter: (1) aseptic catheter placement, (2) maintenance of a closed catheter system, and (3) minimization of the duration of catheterization.^{163,272} The guiding rule should be to avoid catheterization when not required and when required, to terminate use as soon as possible. Appropriate indications for indwelling catheters are temporary relief of anatomic or functional obstruction, urinary incontinence in patients with periurethral wounds, urine output monitoring in critically ill patients, and in the preoperative and postoperative management of lower urinary tract trauma.

The most important risk factor for UTIs in closed-catheter systems is duration of catheterization.²³² In humans, lack of proper hand washing by health care personnel is largely responsible for transmission of nosocomial UTIs in catheterized patients.²³² It is recommended that individuals wear gloves when manipulating or emptying urine drainage bags and wash hands after contact with every patient. In men and women, intermittent catheterization is less conducive to infection than indwelling catheters.^{232,251} This may also be true for male dogs but is less likely to be true for female dogs because the urethral orifice is intravestibular.

Antibiotics should generally not be given to prevent UTIs during indwelling catheterization because of potential adverse effects and development of drug resistance.^{16,232} Although antibiotics may delay the onset of bacteriuria, they cannot prevent infection if the catheter remains in place, especially for 3 days or longer. Prophylactic use of an antimicrobial may reduce infection rates with short-term use (less than 3 days) of a closed, indwelling catheter system. However, even with short-term catheterization, urinalysis, urine culture, and treatment after catheter removal may be preferable to prophylactic antibiotics. Use of antiseptics such as methenamine are also not recommended.²³²

Instillation of antimicrobial agents into the bladder in people with indwelling catheters is of little benefit.²³² In general, the short contact time plus the necessity of disconnecting the closed catheter system to infuse the antimicrobial substance abrogates any beneficial effect. Constant unidirectional flow from the bladder to the drainage bag is best.²³² Placing antimicrobial agents into the drainage bag has not been found to be beneficial.²³² Placing lubricants or antibiotic creams at the urethral meatus was also of no benefit in humans.²³²

Infectious Diseases of the Dog and Cat, 3rd Edition

Glucocorticoids, even at antiinflammatory doses, should be avoided in animals with indwelling urinary catheters. In cats with indwelling urinary catheters, 5 mg/day of oral prednisolone predisposed the cats to developing bacterial pyelonephritis and did not reduce catheter-associated inflammation.²²

A newer way to prevent symptomatic UTIs in people with indwelling urinary catheters is to inoculate such individuals with an *E. coli* strain associated with asymptomatic infection.⁵⁴ In 30 colonized people, the incidence of symptomatic UTIs was markedly reduced compared with the incidence in people not inoculated with this organism.

91.3 MALE GENITAL INFECTIONS

Organisms associated with genital infections in male dogs are the same as those associated with UTIs.¹³⁸ Anaerobes are occasionally associated with abscess formation. Fungal infections, especially with disseminated infections, are reported, but rarely.^{283,116} A parainfluenza virus was isolated from the prostatic fluid of a dog; however, the dog was asymptomatic.²⁶⁸ Genital infections in male cats are uncommon, with the exceptions of those being caused by scrotal injuries during fighting and associated with feline infectious peritonitis. For example, only one case of chronic bacterial prostatitis has been reported in cats.²³¹

91.3.1 Prostatitis

91.3.1.1 Etiology and Pathogenesis

Prostatitis is an inflammatory disease of the prostate gland and is most commonly associated with bacterial infection (Fig. 91-5). *E. coli* is the most common infectious agent. Strains of *E. coli* causing prostatitis in men have been found to express urovirulence factors including cytotoxic necrotizing factor-1, hemolysin, and P fimbriation.¹⁶⁴ Although benign prostatic hyperplasia is the most common canine prostatic disease and the most common cause of clinical signs in dogs with prostatic disease, prostatitis is the second most common canine prostatic disease to cause clinical signs.²⁶⁰ Prostatitis may be acute or chronic. Chronic infections are more common.¹³⁸ Prostatic cysts develop commonly with hyperplasia, and such cysts have been found in 14% of adult, male intact dogs.³⁸ Approximately 42% of such cysts are infected, and the same organism is usually found in the urine.³⁸ Abscesses develop when the infection is severe and encapsulation of purulent material occurs. Prostatic infections are mainly a problem in intact male dogs. If an infection is present before neutering, the infection may persist.

949

950

Fig 91-5 Gross appearance of purulent prostatitis in dog (Courtesy University of Georgia, Athens, Ga.)

Of the male dog's genital organs, the prostate gland is the closest to the indigenous microflora of the distal urethra. Migration of bacteria up the urethra to the prostate is inhibited by urine flow during micturition, urethral pressure, characteristics of the urethral mucosa, normal secretion of prostatic fluid, and the antibacterial nature of normal prostatic fluid. The prostate gland can also produce IgA as a local response to bacterial infection. The higher prevalence of UTIs in castrated male dogs than in intact dogs may reflect the importance of prostatic defense mechanisms.¹¹³

The pathogenesis of prostatic infections is incompletely understood. Most infections are assumed to be secondary to migration of bacteria up the urethra, although spread via blood, urine, semen, and rectal flora (via direct extension or lymphatics) has also been postulated. The close anatomic relationship between the bladder, proximal urethra, and prostate gland is reflected in the high frequency with which all three are simultaneously infected. Prostatic fluid normally refluxes into the bladder, and urine can enter prostatic ducts during micturition. Whether prostatic infection usually precedes, follows, or develops simultaneously with bladder infection cannot usually be determined. Any condition that increases bacterial numbers in the prostatic urethra predisposes the animal to infection. Examples include urethral urolithiasis, neoplasia, trauma, stricture, or a lower UTI. Diseases that interfere with normal prostatic fluid formation and excretion also predispose the animal to infection. An example is squamous metaplasia of the prostate secondary to hyperestrogenism.^{177,210}

Acute bacterial prostatitis and abscess formation may result in septicemia, which is responsible for the severity of clinical signs in some cases. Chronic prostatitis may be a sequela to acute infection or may develop insidiously. Bacteria are not always isolated from prostate glands showing histologic evidence of inflammation (Fig. 91-6). This has been found in human medicine, and some data suggest that prostatic infections can be the result of bacteria that are not detectable by conventional microbiologic culture.⁶² Reflux of urine into the prostate gland, causing a chemical inflammatory response, may also be an

Infectious Diseases of the Dog and Cat, 3rd Edition

underlying mechanism for culture negative prostatitis.⁶² Abscess formation is thought to result from chronic infection and prostatic cyst infection. Abscesses may rupture, leading to peritonitis.

91.3.1.2

Clinical Findings

Signs associated with acute bacterial prostatitis include fever, depression, anorexia, urethral discharge, and pain on prostatic palpation. Vomiting is possible because of localized peritonitis. Less common signs are a stiff, stilted rear-limb gait and constipation from defecation avoidance because of pain. The size, symmetry, and contour of the prostate gland are normal unless it is enlarged as a result of hyperplasia.

Chronic bacterial prostatitis is usually not associated with signs of systemic illness, although some dogs may be more lethargic than normal.¹³⁸ A purulent or hemorrhagic urethral discharge may be present. In some dogs, the only indication of chronic bacterial prostatitis is recurrent UTI or mild hematuria. Chronic prostatitis should be considered in stud dogs with signs of infertility. The prostate gland is not painful on palpation, and infection alone does not affect prostatic size,⁶ although some variation in consistency is associated with increased fibrous tissue.

The most common signs of prostatic abscess formation in dogs are fever, depression, and lethargy, associated with caudal abdominal pain.^{180,279} The prostate is often enlarged and asymmetric, causing tenesmus and constipation. A constant or an intermittent urethral discharge, which is hemorrhagic, purulent, or both, may be present. Dysuria can occur as a result of interference with normal urethral function. Chronic partial urethral obstruction resulting from abscess formation can lead to a distended bladder, eventual detrusor dysfunction, and overflow urinary incontinence. About 10% of dogs have signs of septic shock (tachycardia, pale mucous membranes, delayed capillary refill, and weak pulse).¹⁸⁰ Icterus from hepatic compromise may be present. Rupture of a prostatic abscess can cause localized or diffuse peritonitis with signs of abdominal pain and vomiting. If the abscess is secondary to squamous hyperplasia from hyperestrogenism, other signs of hyperestrogenism such as pendulous prepuce, truncal alopecia, hyperpigmentation, and gynecomastia may

Infectious Diseases of the Dog and Cat, 3rd Edition

be seen. In the one reported case of chronic prostatitis with abscess formation in a cat, the presenting sign was dyschezia caused by constipation resulting from encroachment on the colon by the enlarged prostate.²³¹ No signs of systemic disease were found in this cat.

950

91.3.1.3

Diagnosis

951

The main diagnostic techniques used to determine whether bacterial prostatitis is present are history and prostatic palpation, CBC, urinalysis and urine culture, prostatic fluid evaluation, ultrasonography, and prostatic aspiration and biopsy. Associated clinical signs and physical examination findings in conjunction with CBC and urinalysis and urine culture results are often sufficient to establish a tentative diagnosis of acute prostatitis. Additional tests are necessary in cases of chronic prostatitis to localize the site of infection to the prostate gland, because clinical signs are minimal. Prostatic ultrasonography with aspiration is necessary to confirm the presence of an abscess.

91.3.1.3.1

Laboratory Findings

An inflammatory leukogram with or without a left shift is often associated with acute bacterial prostatitis and prostatic abscess formation.²⁷⁹ The CBC is usually normal in dogs with chronic prostatitis without abscess formation.²¹ Urinalysis and urine culture indicate UTIs in most but not all cases. In one study, four of five dogs with infected prostatic cysts had the same bacterial species isolated from urine cultures.³⁸

Blood chemistry is usually normal with acute and chronic prostatitis but may be abnormal with abscess formation and bacteremia secondary to acute infection. Serum bilirubin concentration and liver enzyme activities (especially alkaline phosphatase [ALP]) may be increased.²⁷⁹ Even in the absence of icterus, liver function tests such as bromsulphalein retention or bile acids may be abnormal. Hypoglycemia was found in 40% of cases with abscess formation.¹⁸⁰

91.3.1.3.2

Prostatic Fluid Evaluation

Prostatic fluid is usually not evaluated in dogs with acute prostatitis because affected dogs are often in too much pain to ejaculate and because of the difficulty in interpreting prostatic massage samples when a UTI is present. However, an ejaculate is usually essential for diagnosis of chronic prostatic infection. The prostatic fluid is the last and largest fraction of the ejaculate, after the sperm-rich fraction. When collecting the ejaculate, the dog is allowed to urinate and is then returned to a run or to a quiet environment. Any preputial discharge is removed from the sheath by gentle, minimal cleansing with moistened gauze sponges. The area is gently dried. The ejaculate is collected with a sterile funnel and tube; a large, sterile plastic syringe case; or a sterile urine cup. If a dog's semen cannot be collected after manual manipulation, the dog can be teased by an estrous bitch or an anestrous bitch to whose vulva *p*-methyl hydroxybenzoate (Eastman Kodak, Rochester, N.Y.) has been applied. Part of the ejaculate is used for cytologic study and part for quantitative culture. Quantitative culture is essential because of the normal flora of the distal urethra.

Both ejaculate cytology and culture results must be considered when determining whether an infection is present. Normal dogs occasionally have leukocytes and positive culture results. Bacteria number fewer than 10^5 per ml and are usually gram-positive. In dogs with bacterial prostatitis, the prostatic fluid is usually purulent and septic and may be hemorrhagic (Fig. 91-7). Quantitative culture of urine and

Infectious Diseases of the Dog and Cat, 3rd Edition

prostatic fluid should yield significant numbers of the same organism. Dogs with experimental chronic bacterial prostatitis had greater than 1000 organisms per milliliter, but establishing a definitive number to distinguish infection from urethral or preputial contamination is difficult. High numbers of gram-negative organisms with large numbers of leukocytes indicate infection. Large numbers of gram-positive organisms with large numbers of leukocytes also indicate infection if preputial contamination did not occur. Lower numbers of gram-negative or gram-positive organisms must be correlated with clinical signs and ejaculate cytologic findings to determine their significance. If results of culture and cytology are questionable, a second sample should be evaluated. The finding of macrophages in prostatic fluid correlated with prostatic infection in experimentally induced prostatitis in dogs.

Fig 91-7 Microscopic appearance of purulent and hemorrhagic ejaculate from dog with prostatitis showing many erythrocytes and degenerate neutrophils. (Courtesy University of Georgia, Athens, Ga.)

For detection of chronic prostatitis, evaluation of prostatic fluid collected by ejaculation is preferred to fluid collected after prostatic massage. The results of prostatic massage in dogs with UTIs are difficult to interpret because of the large number of bacteria already in the urinary tract. To effectively use prostatic massage to diagnose bacterial prostatitis, a UTI must be controlled first with prior antimicrobial therapy. Prostatic massage in normal dogs yields only a few erythrocytes and transitional epithelial cells.

With prostatic massage, the dog is allowed to empty the bladder by normal voiding. A urinary catheter is passed to the bladder with aseptic technique. Residual urine volume should be measured as the bladder is emptied. The bladder is flushed several times with sterile saline to ensure that all urine is removed. The last flush of 5 to 10 ml is saved as the premassage sample. The catheter is then retracted distal to the prostate, as determined by rectal palpation, and the prostate is massaged rectally or abdominally for 1 to 2 minutes. After massage, sterile physiologic saline is injected slowly while the urethral orifice is occluded around the catheter to prevent reflux of the fluid. The catheter is slowly advanced to the bladder, with repeated aspiration in the prostatic urethra. The bulk of the fluid is aspirated from the bladder. The premassage and postmassage samples are examined by cytology and quantitative culture. It is important to

Infectious Diseases of the Dog and Cat, 3rd Edition

compare the postmassage sample with the premassage sample to ensure that any abnormalities arose in the prostatic fluid and did not preexist in the bladder or urethra.

91.3.1.3.3

Radiography

The only radiographic sign of acute prostatitis is an indistinct cranial prostatic border. This is not noted in all cases. Contrast radiography is not often performed in acute prostatitis, because the diagnosis can usually be made without it.

A change associated with some cases of chronic prostatitis is granular, parenchymal mineralization, but the prostate is often radiographically normal with chronic infection, and prostatic mineralization occurs more commonly with prostatic neoplasia.⁷³ Infection without abscess formation does not cause marked prostatomegaly. With abscess formation, the prostate is usually enlarged and irregular,⁷³ and the caudal abdomen may have poor contrast. The iliac lymph nodes may be enlarged. Radiography revealing gas within the prostate gland indicates emphysematous prostatitis from infection with gas-forming bacteria, most commonly *E. coli*.¹²⁹ Prostatic calculi may accompany bacterial prostatitis. These calculi are composed of bacteria, debris, and minerals.²⁶²

951

952

Radiography is important for detecting bone lesions caused by metastasis from prostatic neoplasia and detecting diskospondylitis caused by bacteremia from an associated UTI.⁷³ With chronic prostatitis, greater than normal urethroprostatic reflux may be noted on retrograde urethrography, but this is not specific and accompanies most other prostatic diseases. With abscess formation, periurethral asymmetry and narrowing of the prostatic urethra may be observed in addition to urethroprostatic reflux.¹²⁹ Urethroprostatic reflux is not present in all cases. The prostatic urethral lumen may appear undulant but is not distorted or destroyed.¹⁶ A prominent colliculus seminalis is sometimes seen with squamous metaplasia of the prostate gland. The colliculus seminalis appears like a protuberance into the urethra; it is differentiated from a neoplasm by its smooth, round borders.

91.3.1.3.4

Ultrasonography

Ultrasonography provides more information about prostatic internal structure than radiography.

Ultrasonographic measurements have been shown to correlate with physical measurements.⁶

Ultrasonography of the canine prostate gland has been most often performed transabdominally. A transrectal approach allows a higher resolution transducer to be placed closer to the prostate gland, resulting in a better image.²¹⁰ Ultrasonography is less sensitive in imaging the prostatic urethra; thus in dogs that are dysuric, urethrocystography should be performed in addition to ultrasonography.⁷³

The normal prostate is uniformly hyperechoic compared with surrounding structures, with a small hypoechoic area in the center that is the prostatic urethra. Ultrasound alone should never be relied on to make a definitive diagnosis as there is considerable overlap in ultrasonographic appearance with different prostatic disease processes. In asymptomatic dogs, Doppler ultrasound could not differentiate between a normal prostate and one with inflammation.¹⁹⁰ Nevertheless, some ultrasonographic patterns are more typical of some diseases than others. Focal, multifocal, or diffuse hyperechogenicity has been associated with prostatic inflammation. Neoplasia tends to produce a complex combination of hyperechoic and hypoechoic areas with some unaffected parenchyma.⁷³ With abscess formation, the prostate gland is

Infectious Diseases of the Dog and Cat, 3rd Edition

usually hyperechoic with parenchymal hypoechoic cavities (Fig. 91-8), irregular outlines, and asymmetric shapes.¹⁶⁷ The cavitory areas exhibit distal enhancement, suggestive of being fluid filled, but these cannot be distinguished from noninfected prostatic cysts, cavitory neoplasias, or hematomas.⁷³ Ultrasonography is useful in guiding aspiration of fluid-filled areas and biopsy of solid areas (see Needle Aspiration and Biopsy). In dogs with fluid-filled areas in the prostate, aspiration using ultrasound guidance is replacing collection of ejaculates and prostatic massage samples as a method for obtaining prostatic fluid.

91.3.1.3.5 Urethroscopy

Urethroscopy of male dogs greater than 12 kg is usually possible using flexible endoscopic equipment.²⁶² The prostatic urethra can be visualized. It may be possible to verify that an exudate or a hemorrhage is entering the prostatic urethra and to exclude nonprostatic urethral lesions as a cause for a urethral discharge.

91.3.1.3.6 Needle Aspiration or Biopsy

Diagnosis of prostatic disease can also be approached by needle aspiration or biopsy by the perirectal or transabdominal route, depending on the location of the prostate. Transrectal fine-needle aspiration with a Franzen needle guide (Precision Dynamics, Burbank, Calif.) and a 22-gauge needle has also been described.²¹⁰ Ultrasonography can guide the process. If the prostate contains fluid-filled spaces, they should be aspirated before a needle biopsy. If the prostate is solid, both aspiration and biopsy can be performed. If ultrasonography is not available, fine-needle aspiration should always be performed before needle biopsy because of the possibility of an occult abscess.

Fig 91-8 Ultrasound examination showing hypoechoic areas within hyperechoic prostate gland. Aspiration of largest hypoechoic area (*asterisk*) confirmed abscess formation. (Courtesy University of Georgia, Athens, Ga.)

Before aspiration and biopsy, hair at the site should be clipped and the site prepared aseptically. If ultrasound guidance is used, the transducer should be covered with a sterile sleeve, and sterile acoustic gel should be used. Clean but not aseptic technique for prostatic aspiration resulted in conversion of a prostatic cyst to a prostatic abscess in one dog.¹³

Needle aspiration is performed with a 21-gauge, 1- to 2½-inch needle, depending on the size of the animal and prostate. The needle used in the perirectal approach should have a stylet (such as that on a spinal needle) and is guided by rectal palpation. The procedure can be performed in most dogs with mild tranquilization. Perirectal aspiration is best avoided in dogs with suspected abscesses, because bacteria may be seeded along the needle track. After aspiration of abscesses, some dogs have developed signs of

Infectious Diseases of the Dog and Cat, 3rd Edition

localized peritonitis that required parenteral antibiotic therapy to resolve. Cytology should be performed on all aspirates. If pus is aspirated, aerobic and anaerobic bacterial cultures are indicated.

Prostatic biopsy can be performed perirectally or transabdominally or via a caudal abdominal surgical exposure. Nonsurgical biopsy procedures require tranquilization and local anesthesia. An automatic, spring-loaded biopsy device (Biopty gun, Radiplast AB, Uppsala, Sweden), with a 14- to 18-gauge needle makes the procedure less difficult. Closed biopsy can be directed by palpation or by ultrasonography. The only complication reported from blind prostatic biopsy is mild hematuria, although significant hemorrhage is possible in any blind biopsy procedure. The dog should always be monitored closely for several hours after biopsy. Biopsy samples can be cultured for bacteria as well as examined histologically.

Ultrasound-guided aspiration, biopsy, or both of the prostate resulted in an accurate diagnosis in 14 of 17 cases (82%) in one survey.¹³ In the remaining cases, neoplasia was confirmed or suspected, but aspiration revealed hemorrhage or abscess formation. One difficulty with diagnosis by aspiration or biopsy is that the prostate may be affected by more than one disease process. This possibility necessitates that all the data about a clinical case be evaluated together. A diagnosis must be reconsidered if response to therapy is not as predicted. Biopsy samples should be collected if surgery is performed.

91.3.1.4 Therapy

91.3.1.4.1 Acute Bacterial Prostatitis

In acute bacterial prostatitis, an antibiotic should be administered for 28 days (see [Table 91-8](#)). The choice of antibiotic can be based on urine culture results, because the organism in the urine probably originated from the prostate. Because the blood-prostatic fluid barrier is damaged in acute inflammation, a wide choice of antibiotics similar to that for UTIs may be considered for initial treatment (see [Table 91-12](#)). If the presenting signs are severe, the antimicrobial is initially given IV. Supportive therapy should be given as necessary for systemic illness. Once the dog's condition is stable, an oral antimicrobial with prostatic penetrance is preferred for the remainder of therapy (see [Table 91-13](#)). Because acute infections may become chronic, reexamination should be performed 7 days after antibiotic therapy is finished. This examination should include physical examination, urinalysis, urine culture, and prostatic fluid cytology and culture.

91.3.1.4.2 Chronic Bacterial Prostatitis

Cases of chronic bacterial prostatitis are very difficult to treat effectively. One factor is the blood-prostatic fluid barrier. This barrier is related to the pH difference between the blood and prostatic interstitium and the prostatic fluid and the characteristics of the prostatic acinar epithelium. A drug's ability to enter prostatic fluid depends on its lipid solubility, its degree of ionization in plasma (ionization constant—pKa), its molecular size if it is water soluble, and its plasma protein-binding characteristics.¹⁶⁴

The pH of the blood and the prostatic interstitium is 7.4, whereas the pH of normal and infected prostatic fluid in dogs is less than 7.4.²¹ Most antimicrobial agents are weak acids or weak bases and ionized to varying degrees in biologic fluids. The degree of ionization is determined by the pKa of the drug and the pH of the fluid. Drugs with a pKa close to 7.4 are only slightly charged in serum, whereas those with a pKa higher or lower than 7.4 are charged in serum.⁷⁷ Because canine prostatic fluid is usually acidic, basic antibiotics (pKa greater than 7) such as erythromycin, clindamycin, and trimethoprim cross the

Infectious Diseases of the Dog and Cat, 3rd Edition

barrier more readily than other antibiotics (see Table 91-13; Fig. 91-9).¹⁷ In men, infected prostatic fluid is alkaline, thus drug efficacy in men cannot be directly extrapolated to dogs. Fluoroquinolones are more active in alkaline environments (pH greater than 7.4) for gram-negative bacteria and thus may be more effective in chronic prostatitis in men than in dogs.⁴²

Lipid solubility is also an important factor in determining drug movement across the prostatic epithelium. Chloramphenicol, macrolide antibiotics, trimethoprim, and enrofloxacin are examples of lipid-soluble drugs that can cross the barrier effectively.^{42,63} In general, diffusion of tetracyclines into canine prostatic fluid is minimal. Although clinical studies in men with prostatitis demonstrated efficacy of minocycline and doxycycline, these lipid-soluble drugs did not penetrate well into canine prostatic fluid. Drugs with low lipid solubility, such as penicillin, ampicillin, cephalosporin, and aminoglycoside, cannot cross into the prostatic acini.

Fig 91-9 Diffusion into prostate of antibiotic that is a weak base (ionization constant [pK_a] of 8.4) is shown at equilibrium. More acidic pH within prostate causes drug to become more ionized, hence it cannot leave prostatic fluid. Prostatic fluid-plasma ratio is 101:11 (B , basic drug [pK_a greater than 7]; BH , HB , ionized drug). (From Barsanti JA, Finco DR. 1979. Canine bacterial prostatitis, *Vet Clin North Am* 9:679-699.)

Protein binding in plasma also determines the amount of drug that enters prostatic fluid. The more drug bound to protein, the less drug that is available to cross the prostatic epithelium. This factor is probably less important than lipid solubility or ionization, because biologic systems rarely reach equilibrium. Examples of drugs with significant protein binding are clindamycin and chloramphenicol.

In addition to a blood-prostatic barrier, chronic bacterial infections of the prostate gland may be difficult to cure because of the local microenvironment. One study of chronic prostatitis in rats showed that

Infectious Diseases of the Dog and Cat, 3rd Edition

successful eradication of infection was not related to norfloxacin concentrations. This suggested that the bacteria were protected in microcolonies and biofilms in those rats that were not successfully treated.⁶²

Recommendations for the treatment of chronic bacterial prostatitis are based on whether a gram-positive or gram-negative organism is the infective agent. If the causative organism is gram-positive, erythromycin, clindamycin, or trimethoprim can be given, depending on the organism's susceptibility. If the causative organism is gram-negative, trimethoprim or a quinolone, such as enrofloxacin, is best. Although trimethoprim is often combined with a sulfonamide drug, sulfonamides do not diffuse into the prostate gland.⁹ Trimethoprim alone is considered as effective as the combination in men⁷⁷ and may have fewer side effects. Fluoroquinolones typically have a small molecular size, high lipid solubility, and low protein binding, which makes them useful in chronic prostatic infections. It has been suggested that the dose of enrofloxacin be determined by the degree of sensitivity of the infecting organism as determined by MIC.²⁶² If the organism has an MIC of 0.1 µg/ml, then a dose of 5 mg/kg once a day is appropriate. If the organism has an MIC of 0.1 to 0.5 µg/ml, then a dose of 10 mg/kg once a day is suggested. If the organism has an MIC of 0.5 to 1 µg/ml, then a dose of up to 20 mg/kg once a day may be needed. Because a higher maximum concentration is more important in efficacy than duration of time above the MIC, a higher

953

954

once-daily dose is considered more effective than a lower twice-daily dose. Side effects of oral enrofloxacin in mature dogs include anorexia, vomiting, and depression. Other fluoroquinolones that would be predicted to have efficacy in chronic prostatitis include marbofloxacin and ofloxacin. Ofloxacin was shown to concentrate in the prostate gland of normal dogs after oral administration.¹⁰ Ofloxacin was also administered by intraprostatic injection. The prostatic tissue concentration was similar to that of orally administered ofloxacin, even though a much lower dose was injected than that given orally.¹⁰

Antibiotic therapy should be continued for 6 weeks (see [Table 91-8](#)). If a UTI is present, urine should be reevaluated by culture during therapy to be sure that the administered drug has eliminated the UTI. After discontinuing antibiotics, urine should be recultured (see [Table 91-14](#)) to ensure that the infection has been eliminated, not merely suppressed. In men it has been noted that if chronic bacterial prostatitis is not eliminated with 6 to 12 weeks of therapy, longer courses of therapy do not increase the likelihood of cure.^{77,164} In this situation in men, suppressive therapy for UTIs is recommended. The prognosis for cure in men is approximately 70% with 6 months of follow-up,^{77,184} but success rates seem to decrease beyond 6 months because of recurrence.¹⁸⁵ Similar studies have not been performed in dogs, but the author's experience is that canine infections are similarly difficult to cure in intact dogs.

Castration is recommended as adjunctive therapy in dogs to control infection. Limited studies indicate that castration in dogs is beneficial in resolving prostatic infection.⁵⁰ Estrogens used as chemical castration are not recommended as therapy for prostatitis because estrogens can induce squamous metaplasia and thus predispose the dog to infection.¹⁶ Estrogen therapy can also be associated with the rare complication of significant bone marrow toxicity. Whether other drugs that cause prostatic involution in dogs, such as flutamide or finasteride, would be useful in resolving prostatic infections in intact dogs has not been studied.

If the animal is not cured within 6 weeks of antimicrobial therapy and castration, suppressive therapy should be considered. The goal of suppressive therapy is to eliminate the UTI. It has been found in men that this regimen often results in symptomatic relief and little progression of infection within the prostate gland. Suppressive therapy involves indefinite treatment with a once-daily dose of the antimicrobial agent. Drugs chosen must be well tolerated and must be active against the infective agent at obtainable urine

Infectious Diseases of the Dog and Cat, 3rd Edition

concentrations. In men the drugs of choice are trimethoprim, trimethoprim-sulfamethoxazole, a fluoroquinolone, or nitrofurantoin.⁷⁷ Long-term therapy with trimethoprim-sulfonamide in dogs can result in KCS, mild anemia because of folate deficiency, secondary hypothyroidism, and immune-mediated diseases.^{282,16} Folic acid can be supplemented when administering trimethoprim-sulfonamide for longer than 6 weeks.

91.3.1.4.3

Prostatic Abscesses

Prostatic abscesses require surgical drainage. Relatively small (smaller than 1.5 by 2.4 cm), infected prostatic cysts in asymptomatic dogs are often cured with ultrasound-guided drainage and antimicrobial therapy.³⁸ Some abscesses and symptomatic cysts in dogs whose owners have financial limitations have been managed with ultrasound-guided drainage and long-term antimicrobial therapy, but this therapy is unlikely to be curative.²²¹ Intracapsular prostatic omentalization is considered the surgical approach of choice.²⁷⁹ Partial prostatectomy with an ultrasonic surgical aspirator has few complications and allows an equally rapid recovery, but the equipment is expensive.²²¹

If prostatic enlargement has resulted in partial urethral obstruction, bladder and urethral function should be carefully assessed. Prolonged bladder distension may have resulted in bladder atony. An indwelling urinary catheter may be necessary to allow the detrusor muscle to recover. If the bladder wall has been chronically distended and infected, it may be irreversibly damaged.

Castration is recommended as adjunctive therapy. Castration without abscess drainage leads to reduction of prostatic tissue but continuation of the abscess pockets.

An affected dog should also be treated with antibiotics as described previously for chronic prostatitis. The antibiotic choice should be modified based on the results of culture and susceptibility and the presence or absence of bacteremia. IV antimicrobials should be provided when the dog is systemically ill and during surgery. If possible, surgery should be delayed until after culture results are obtained. The prostate gland should be reexamined by palpation and ultrasonography at monthly intervals until abscess resolution is confirmed. In one survey, 31% of dogs with a successful surgical outcome had a UTI recurrence within 1 year.²²¹ These dogs are usually asymptomatic, so detection of such recurrences requires urinalysis and urine culture, not just questioning of the owner about the presence of clinical signs.

Polyuria and polydipsia, similar to those expected with nephrogenic diabetes insipidus, have been noted in a few dogs with prostatic abscesses.⁹⁹ These problems resolved within 1 month after surgery. Evidence of hepatopathy also resolved postoperatively. It is assumed that these signs are caused by secondary septicemia or endotoxemia.

If the owners decline surgery, the dog can be managed with long-term suppressive antibiotic therapy after the UTI is controlled with at least 6 weeks of standard, full-dose therapy. The owners must realize that the abscess will persist and may result in a life-threatening infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

91.3.2 Epididymitis and Orchitis

91.3.2.1 Etiology

Bacterial infection is the most common cause of epididymo-orchitis, which is relatively uncommon, especially in cats.¹¹⁴ As in UTIs, *E. coli* is a common causative organism. *Brucella canis* infection should always be a consideration in dogs. Infection may be secondary to trauma (such as a bite wound) or may result from breeding a healthy male with an infected female, hematogenous spread of a systemic infection, or spread from a urinary tract or prostatic infection. Infection with feline infectious peritonitis virus has been reported as a rare cause of orchitis in cats.^{76,246} In both reported cases, orchitis was the initial presenting problem, and then the disease progressed to its systemic form.

91.3.2.2 Clinical Findings

Any age or breed of dog may be affected, although dogs younger than 2 years were most common in one small series of cases.²¹⁷ Both the testicle and epididymis may be involved, and the infection may be unilateral or bilateral (Fig. 91-10). Clinical signs in acute infections include pain (which may manifest as rear-limb lameness), heat, and swelling, which is doughy to firm in consistency. The dog often licks the edematous scrotum, which may cause dermatitis. Systemic signs such as fever vary. With chronic infections, fibrosis produces increased firmness and contracture. Localized areas of abscess formation may feel soft.

91.3.2.3 Diagnosis

Orchitis or epididymitis is usually strongly suspected on the basis of physical examination. Diagnostic tests should include CBC, urinalysis, urine culture, and brucellosis testing. The CBC may show leukocytosis if the inflammation is active. Urinalysis and urine culture determine whether the animal has an associated UTI. If a UTI is confirmed, the responsible organism is assumed to be the cause of the epididymitis-orchitis. In dogs with brucellosis, urine may contain the organism, although usually only in low numbers (fewer than 1000 per milliliter).⁴⁴ Although semen is a more productive *Brucella* culture sample, handling it has greater public health risk (see Chapter 40).

954

955

Fig 91-10 Dog with unilateral epididymitis-orchitis. (Courtesy University of Georgia, Athens, Ga.)

If the dog does not have a UTI and will ejaculate, cytologic examination and quantitative culture of semen should be performed. With semen, the cytologic finding of bacteria and neutrophils and the culture of more than 10^5 gram-negative organisms per milliliter suggest infection. Because of the urethral microflora, quantitative cultures are mandatory for assessment of results.

If the urine is not infected and semen cannot be collected, aspiration of the testicle or epididymis with a 21- to 23-gauge needle and a 12-ml syringe can be performed for cytology and culture. Before the aspiration, dogs are usually sedated, depending on their nature, and the scrotal skin should be cleansed. Ultrasonography can guide the aspiration to abnormal areas of the epididymis or testicle. In one study, no adverse effects from aspiration were noted.⁵³

Ultrasonography can also be used to determine whether a palpable abnormality in the scrotal contents is testicular, epididymal, or both or is outside the testicles and epididymides. A cause of swelling can be defined as being caused by fluid or a solid mass.^{68,129} It may be possible to differentiate an inflammatory disease from testicular torsion, traumatic rupture, or neoplasia.²¹⁷ Ultrasonographic findings associated with acute epididymitis-orchitis include a diffuse, patchy, hypoechoic pattern; testicular enlargement, epididymal enlargement, or both; and occasionally, extratesticular fluid.²¹⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

91.3.2.4 Therapy

Bilateral orchidectomy is the treatment of choice for orchitis and epididymitis. If the dog is a valuable sire and the condition is unilateral, the testicle and epididymis on the affected side should be removed to save the other from thermal degeneration (Fig. 91-11).^{68,136} If unilateral orchidectomy is performed, the owner should be advised that a subclinical infection of an apparently normal testicle and epididymis or a concurrent prostatic infection could cause future problems for the dog.

Fig 91-11 Unilateral *E. coli* epididymitis in a dog. Epididymis is enlarged on left, and both testicles are shrunk from atrophy caused by increased temperature in scrotal sac. (Courtesy University of Georgia, Athens, Ga.)

Antibiotics should be given regardless of whether surgery is performed. Isolation of the causative organism and antimicrobial susceptibility testing should guide therapy. Therapy should be continued for at least 2 weeks. While culture results are pending, an antibiotic such as enrofloxacin, chloramphenicol, or trimethoprim-sulfonamide should be started. Adjunctive soaks in cool water may help to reduce testicular degeneration from the hyperthermia of inflammation.

91.3.3 Balanoposthitis

Balanoposthitis is usually caused by bacteria that are normally present in the prepuce (see Table 91-2). Herpesvirus infections and blastomycosis also have caused balanoposthitis.

Mild balanoposthitis is so common that it is considered normal in male dogs. It is characterized by a purulent exudate within or dripping from the prepuce, with variable degrees of inflammation of the preputial mucosa. The animal has no signs of systemic illness. Dogs usually are asymptomatic, but some lick the prepuce.

Infectious Diseases of the Dog and Cat, 3rd Edition

No specific diagnostic test exists for balanoposthitis except cytologic examination of preputial exudate. Bacteria and large numbers of degenerate and nondegenerate neutrophils are seen. A culture of pus is difficult to interpret because of the abundant normal flora. Culture is not required for successful management of most cases.

Balanoposthitis is not a serious medical problem but may be an annoyance to the owner. Cleansing antiseptic douches or local antibacterials may be of benefit. Neutering affected animals may help reduce the amount of secretion produced.

91.4 FEMALE GENITAL INFECTIONS

Organisms associated with genital infections in female dogs are the same as those associated with UTIs.¹⁶ *E. coli* is consistently the most common organism associated with pyometra.

91.4.1 Vaginitis

91.4.1.1 Etiology

Inflammation of the vagina can be a result of bacterial or viral infections, immaturity, or irritation from urine, foreign material, neoplasia, trauma, or anatomic abnormalities such as a recessed vulva or vaginal stenosis. Bacterial infection can be a secondary result of these irritations. Vaginitis is more common in bitches than in queens and is most common in young dogs, with affected dogs being an average age of 7 months.¹⁸² Juvenile or puppy vaginitis is common in otherwise normal, healthy prepubertal bitches and resolves spontaneously with physical maturity in most. Vaginitis in the young dog (younger than 1 year) is more likely a problem related to immaturity than to a bacterial infection.¹²¹

Bacterial organisms recovered from bitches with vaginitis are the same organisms found in the normal flora, although the numbers of bacteria may be higher in mature dogs with vaginitis.^{121,267} Isolation of a single bacterial species occurs in about 25% of bitches with vaginitis; *E. coli*, *Streptococcus*, and *Staphylococcus* are the most common.³⁵ Although infection with *Coxiella burnetii* is rare in cats, the organism can cause abortion with associated vaginal discharge. Because *C. burnetii* is a significant public health hazard, care should be taken when assessing vaginal discharges in cats (see [Chapter 29](#)).²⁰⁹

Viral infections of the canine or feline vagina are uncommon. Herpesviruses (canine herpesvirus, feline rhinotracheitis virus) cause vesicular lesions and erythema when inoculated intravaginally.^{106,112} Although genital tract infection readily occurs after experimental inoculation, genital herpesvirus infection is an uncommon clinical entity.²¹⁸ Vaginal lymphoid follicular hyperplasia, which could result from any inflammatory process, may be mistaken for vesicle formation. Confirmation of genital herpesvirus infection should include viral isolation and histologic examination of the vesicular lesions (see [Chapter 5](#)).

91.4.1.2 Clinical Findings

The most common historical and physical finding associated with vaginitis is the presence of a vulvar discharge in an otherwise healthy animal. The discharge is mucus, mucopurulent, or purulent, varying in color from cloudy white to yellow to green.¹²¹ The presence of blood in the discharge is rare.¹²¹ The

Infectious Diseases of the Dog and Cat, 3rd Edition

discharge may attract male dogs and may cause the affected dog to lick the vulvar area. The perineal hair may be discolored by saliva and exudate. Pollakiuria occurs in about 10% of affected bitches.¹²¹ Signs of systemic illness are not expected. Vaginal discharge must be related to the stage of the estrous cycle as a serosanguineous discharge is normal in proestrus, a mucoid discharge is normal in diestrus, and a dark brown or green discharge is normal for up to 6 weeks postpartum. Vaginal discharges may also be caused by a uterine disease such as metritis or pyometra or may be urine in incontinent dogs. A complete physical examination including digital rectal and vaginal examinations should be performed in all animals with an abnormal vaginal discharge.

91.4.1.3

Diagnosis

The diagnosis of vaginitis is strongly suggested by the history, presence of vaginal discharge on physical examination, and vaginal cytology. This approach is sufficient for dogs younger than 1 year without UTI signs. In older dogs, especially those with chronic vaginitis, vaginoscopy, as well as urinalysis and urine culture, should be performed. A CBC and abdominal imaging (radiography or ultrasonography) may be needed to exclude the possibility of uterine disease. The most important diagnostic considerations are whether the vulvar discharge is abnormal and whether the inflammatory process is confined to the vagina.

Cytologic evidence of inflammation (neutrophils, possibly lymphocytes and macrophages in chronic cases) with or without bacteria is expected from animals with vaginitis.²¹⁸ Vaginal cytology must be interpreted with regard to the stage of the estrous cycle. WBCs are often numerous during the first few days of diestrus. This normal phenomenon can be distinguished from inflammation because the number of WBCs declines markedly in 24 to 48 hours of diestrus, whereas it persists with vaginitis. A vulvar mucoid, green to brownish discharge is normal during the early postpartum period in the bitch and queen. A hemorrhagic vulvar discharge is normal during proestrus and estrus in the bitch.

CBCs are normal in dogs with vaginitis.¹²¹ In one study, UTIs were found in approximately 20% of mature bitches with vaginitis.¹²¹ UTIs were not found in puppies with vaginitis, but urine from only a few puppies was examined.¹²¹ At least a urinalysis and optimally a urine culture are indicated in mature dogs with vaginitis and puppies with signs of pollakiuria.

The results of vaginal cultures must be interpreted cautiously, because the most common pathogens of the vagina and uterus are *E. coli*, *Streptococcus*, and *Staphylococcus*, which are also commensal organisms (see [Table 91-3](#)). To avoid contamination from the skin and the vestibule, samples for bacterial culture from the cranial vagina should be obtained with a guarded swab or through a sterile speculum. Bacterial cultures do *not* confirm the diagnosis of vaginitis, because some bacterial growth is expected. Heavy growth of a single organism is a more convincing sign that the organism could be causing the clinical signs.

Vaginoscopy helps determine the source of the discharge and the nature and extent of vaginal lesions. Sedation or general anesthesia is usually necessary for a thorough examination. With vaginitis, the vaginal mucosa is hyperemic, and exudate in the vaginal lumen is present. Ulcers or lymphoid follicles may be seen ([Fig. 91-12](#)). The inciting cause of the vaginitis may be identified ([Table 91-15](#)). Vaginal cultures are easily obtained during vaginoscopy. Vaginal biopsy samples are taken when discrete lesions are seen.

Infectious Diseases of the Dog and Cat, 3rd Edition

91.4.1.4 Therapy

Treatment of puppy vaginitis is either none or conservative (perivulvar cleaning only), because the condition subsides with or without therapy in most cases.¹²¹ Some recommend that the affected animal be allowed to experience an estrous cycle to increase the chance of spontaneous recovery²⁶⁷; however, the majority of young bitches recover before experiencing an estrous cycle.^{121,123} Estrogen in the maturing bitch induces antibacterial activity in the vaginal mucosa, which may facilitate recovery. The recommendation is that young bitches with clinically significant vaginitis not undergo ovariohysterectomy until they have experienced estrus or the vaginitis has resolved.^{123,218} Although most cases of juvenile vaginitis resolve, about 20% of puppies have a recurrence.¹⁸³

956

957

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 91-15 Underlying Causes of Vaginitis

Atresia
Strictures
Septa
Neoplasia, granuloma
Clitoral hypertrophy
Foreign objects
Urinary incontinence
Urinary tract infection

Most mature bitches with vaginitis have a predisposing abnormality (see [Table 91-15](#)).^{121,123} Recovery from vaginitis requires correction of the underlying disorder. One study found that vaginitis associated with a recessed vulva resolved with vulvoplasty.⁹⁸ Surgical correction of vestibulovaginal stenosis resulted in resolution of chronic vaginitis in two dogs.¹⁴⁷

In mature bitches with no underlying abnormality, vaginitis, even if chronic, resolves spontaneously in 75% of cases, although a full recovery may take months.¹²³ The remaining 25% of cases are frustrating for owners and veterinarians because no current therapy is consistently effective.¹²¹ In intact bitches, an ovariohysterectomy does not improve clinical signs of vaginitis.¹²¹

The relative efficacy of various treatments for vaginitis has yet to be investigated in small animals. Antiseptic douches, instillation of antibiotic suppositories, ointments, or solutions, and systemic antibiotic therapy have been tried.¹⁴ Solutions that alter pH, such as vinegar (0.25%) or most commercial douches, may discourage the overgrowth of vaginal bacteria. Douching should not be performed during proestrus or estrus.¹²³ Many owners are unable to douche their pets effectively.

Systemic antibiotics may diminish clinical signs in mature bitches with chronic vaginitis. The antimicrobial should be chosen on the basis of urine and cranial vaginal cultures. Antibiotics usually provided are ampicillin, trimethoprim-sulfonamide, amoxicillin-clavulanate, cephalosporin, and chloramphenicol.¹²³ Although in one study, ampicillin did not concentrate in the vaginal secretions of bitches, it did eradicate susceptible bacteria within 24 hours in healthy bitches.²⁵⁴ Trimethoprim, which was shown to concentrate in vaginal secretions, did not eradicate all in vitro susceptible organisms in healthy bitches.²⁵⁴ During therapy with either ampicillin or trimethoprim-sulfonamide, organisms were still present in the vaginal secretions of 8 of 10 bitches, and additional organisms emerged.²⁵⁴

If vaginitis is concurrent with pregnancy, the possible teratogenic or abortifacient effects of therapy must be considered. If vaginitis occurs in proestrus or estrus and the bitch is scheduled for breeding, the possibility of transmission of infection to the stud and the effects of therapy on sperm survival should be considered.

Infectious Diseases of the Dog and Cat, 3rd Edition

91.4.2 Metritis

91.4.2.1 Etiology and Pathogenesis

Metritis usually refers to acute ascending bacterial infection of the uterus.¹⁶⁸ Metritis may follow abortion, dystocia, obstetric manipulation, retention of fetal or placental parts, or normal parturition. Rarely, metritis may occur after natural or artificial insemination. The most common causative organism is *E. coli*. Chronic metritis occurs but is rarely described in the literature in dogs and cats.⁸⁵

Many organisms cross the canine placenta and infect fetuses but do not infect the uterus per se. However, they may be transiently recovered from uterine or vaginal cultures of parturient or periparturient bitches. These organisms include canine herpesvirus, adenovirus, distemper virus, *B. canis*, and *Toxoplasma gondii*.¹³⁷ Experimental, intrauterine inoculation of *Mycoplasma canis* can cause uterine disease in bitches,⁶¹ but the role of mycoplasmal infection in spontaneous disease is uncertain (see [Chapter 32](#)). In cats, feline leukemia virus, panleukopenia virus, and herpesviruses can be transmitted to the fetuses of viremic queens.

91.4.2.2 Clinical Findings

Animals with acute metritis are depressed, anorectic, febrile, and tachycardic and have a fetid, septic, purulent vaginal discharge. Signs usually develop within 1 week of parturition. Dehydration, sepsis, and endotoxemia can occur. Neonates of affected dams are usually neglected and crying from hunger as milk production declines.

91.4.2.3 Diagnosis

A presumptive diagnosis is based on the history and physical findings. Cytology and bacterial culture and susceptibility should be performed on the discharge. Cytology shows a hemorrhagic, septic, purulent exudate. Cytologic evidence of endometrial cells or uterovaginal discharge indicates uterine involvement, but these are not consistently present. A neutrophilic leukocytosis is often evident on a CBC.³⁰ Abdominal radiography, uterine ultrasonography, or both should be performed to locate fetal remnants and assess the integrity of the uterus. In contrast to pyometra, the uterus is normal or minimally enlarged with metritis on survey abdominal radiographs.⁸² Ultrasonographic diagnosis of metritis is not very accurate because the changes are subtle. The uterus may be slightly enlarged, and echogenicity may be abnormal.²⁸⁸

91.4.2.4 Therapy

IV fluids should be administered if needed to maintain normal hydration. A systemic, broad-spectrum antimicrobial should be given, pending the uterine culture results. An antimicrobial that is usually effective against *E. coli* should be chosen (see [Tables 91-12](#) and [91-13](#)). Antibiotic therapy is reassessed when the culture results are returned. Therapy should continue for 7 to 10 days if the uterus is removed and 2 to 4 weeks if it is not. Neonates are usually hand reared until the mother is sufficiently recovered to care for them.

A decision must be made about whether therapy of the infected uterus should be surgical or medical on the basis of the severity of the illness and the owner's desire to maintain the animal's reproductive capability. An

Infectious Diseases of the Dog and Cat, 3rd Edition

ovariohysterectomy should be performed if the uterus has ruptured. An ovariohysterectomy or a hysterotomy with lavage is necessary if placental or fetal tissues are in the uterus.

Medical management involves stimulating the evacuation of the uterine contents. If the animal is within 24 hours of parturition, oxytocin can be administered at 0.5 to 1 U/kg, with a maximum of 20 U intramuscularly once or twice.⁹² Natural prostaglandin F_{2α} (PGF_{2α} Lutalyse, Upjohn Company, Kalamazoo, Mich.) can be given any time postpartum at a dose of 0.1 mg/kg SC once a day for 2 to 3 days.¹²⁴ Adverse effects include vomiting, panting, restlessness, vocalization, and change in pupil size. Neither oxytocin nor PGF_{2α} affects lactation or neonatal health.¹²⁴ Intravaginally administered PGF_{2α} (150 µg/kg every 12 to 24 hours) was also found to be effective in conjunction with antibiotics.⁸⁵

Intrauterine infusion of antiseptic or antibiotic solutions is of questionable value. The canine cervix is difficult to cannulate, therefore most infusions via the vagina are probably intravaginal rather than intrauterine. Intrauterine infusion of nitrofurazone may actually decrease subsequent fertility in some species.¹⁶⁸ Surgical placement of drains within the uterus and subsequent flushing is usually not successful.¹⁰⁰

91.4.3 Pyometra

91.4.3.1 Etiology and Pathogenesis

Pyometra is an inflammatory disease of the uterus associated with intraluminal accumulation of pus. Pyometra involving the uterus masculinus of hermaphrodites also occurs in dog and cats.²⁴⁰ Unlike metritis, which is usually a periparturient disease associated with infection or uterine trauma, pyometra is secondary to uterine pathologic signs induced by progesterone over successive heat cycles or by exogenous therapy.¹⁰⁰ The sustained influence of progesterone causes cystic endometrial hyperplasia, fluid accumulation within the endometrial glands and uterine lumen, suppressed leukocyte activity in the uterus, and decreased myometrial activity. The uterine disease and decreased contractility favor secondary ascending bacterial infection. *E. coli* is the most common causative organism, in part because *E. coli* binds to the endometrium more effectively during the luteal phase of the estrous cycle.⁸⁰ Because progesterone initiates the sequence of events leading to pyometra, pyometra occurs during the luteal phase of the cycle in dogs (diestrus) or after the administration of progestins.²⁷⁰ The disease does not develop during pregnancy, and nulliparous bitches have a moderately higher risk than primiparous and multiparous dogs.^{82,194}

Despite the commonly accepted pathogenesis discussed, it is clear that not all bitches with cystic endometrial hyperplasia develop pyometra, thus the relationship of cystic endometrial hyperplasia to pyometra is not accepted by all.^{57,80} Some believe that pyometra is an age-related disease, and others emphasize bacterial infections, particularly with *E. coli*, as primary causes, with coincidental cystic endometrial hyperplasia.

Pyometra occurs most frequently in dogs. In one study, affected dogs tended to be middle-aged or older, with an average age of onset of 9 years, but administration of estradiol cypionate induced pyometra in young dogs.¹⁹⁴ In this study, no significant increased risk was found with a single treatment of medroxyprogesterone acetate therapy. Repeated administrations would be expected to increase risk. Potential reasons for an increased risk with estrogen therapy are that the cervix may be relaxed for a longer time, and

Infectious Diseases of the Dog and Cat, 3rd Edition

estrogen enhances the effects of progesterone on the uterus.¹⁹⁴ The risk of a female dog younger than 10 years of age developing pyometra was 2% per year. The risk increased with age, so dogs of 8 to 10 years had a risk of 6% per year.⁶⁶ By 10 years of age, 23% to 24% of bitches developed pyometra.⁶⁶ The risk also varies by breed, with collies, rottweilers, Cavalier King Charles spaniels, and golden retrievers having a higher risk.^{66,194} Breeds with lower risk include dachshunds and mongrels. Fifteen percent of beagles older than 4 years of age develop pyometra.⁸²

The lower incidence of pyometra in cats is attributed to the fact that cats are induced ovulators and thus not under the influence of progesterone for as long a period as dogs. However, a correlation between the presence of corpora lutea and pyometra has also been found in cats. Pyometra occurs after nonfertile matings, drug-induced ovulation, and treatment with progestins.^{16,290} Some cats have been found to be in the luteal phase of the ovarian cycle, even though they were isolated from male cats and received no therapy, suggesting that the luteal phase must be able to be induced by other factors as well.^{150,151} Progesterone is not the only factor involved in cats, because some affected cats are in the follicular phase of the ovarian cycle.^{151,213} The ages of affected cats in different surveys have varied from 3 to 6 years of age,^{278,55} to older than 5 years,²¹³ to an average age of 7 years.¹²⁷ In queens, no correlation was found between development of pyometra and age at first breeding, age at first queening, or number of litters produced.²¹³

E. coli is the most common organism isolated, being the single agent in most cases.^{60,79,143,152,214,222} *E. coli* infection causes the morbidity and mortality associated with pyometra. The blood concentrations of endotoxin in dogs with pyometra are higher than control animals and the level correlated with the severity of the disease.¹⁹⁸

E. coli is thought to ascend into the uterus from the vagina when the cervix is open during proestrus and estrus. *E. coli* isolates from dogs that suffer from pyometra have been biochemically compared with corresponding fecal isolates. Strains from infected uteri were biochemically similar to fecal isolates from the same dog, confirming the hypothesis of fecal contamination of the genitourinary tract.⁸⁰ *E. coli* strains isolated from bladder urine and from the uterus in the same dog have been found to be identical.⁹⁶ Even though some uterine cultures from the same dog seemed to contain multiple types of *E. coli* based on characteristics in culture, all the organisms from the same dog were identical based on pulsed-field gel electrophoresis.⁹⁶ Even though *E. coli* strains in the same dog were identical, *E. coli* strains from different dogs were different, indicating that these *E. coli* strains are not spread among animals.⁹⁶

E. coli strains that cause pyometra are less diverse than fecal *E. coli*, suggesting the clustering of virulence properties, similar to those in *E. coli* that cause UTIs. *E. coli* isolated from dogs with pyometra have virulence factors similar to uropathogenic *E. coli*, suggesting that the pathogenetic mechanisms of *E. coli* infection in pyometra and UTIs are similar.⁴⁵

Other organisms occasionally isolated from uteri with pyometra are streptococci, staphylococci, *Proteus* species, *Klebsiella* species, *Serratia marcescens*, *Salmonella* species, and *P. aeruginosa*.^{152,222} Aerobic and anerobic cultures of purulent material from bitches with pyometra may be negative,^{60,143} suggesting that some animals may not have an infection. However, antimicrobial therapy has been used before obtaining a culture in most of these cases.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dogs with pyometra have been found to have an impaired lymphocyte response to mitogens, the degree of which corresponds with severity of illness.⁶⁹ Sera from affected dogs had higher concentrations of immunoglobulins and circulating immune complexes.⁶⁹

91.4.3.2 Clinical Findings

Affected dogs and cats are usually presented 2 months after estrus or breeding or have been given estrogens or progestogens. In dogs, owners may note vulvar discharge (generally purulent), lethargy, vomiting, and polyuria-polydipsia.^{244,278} Affected dogs lose weight.⁸² In cats, vaginal discharge (mucopurulent to hemorrhagic) and abdominal distention are the most common signs.^{55,213} Nonspecific signs of illness such as anorexia, weight loss, an unkempt appearance, lethargy, and vomiting are seen in some cats.^{126,290} Polyuria and polydipsia are seen less commonly in cats than in dogs.¹²⁶ The signs in the most severely affected animals are related to a systemic inflammatory response syndrome (sepsis, septic shock).⁸⁰

Uterine enlargement is found on physical examination. Fever is not common.^{278,127} The mean body temperature in 55 affected dogs was 102.7° F (39.3° C).¹⁰⁴ Open pyometra (with the cervix open and draining) is more common than closed pyometra.^{104,175,244,278} Approximately one third of affected cats are dehydrated.¹²⁶ Septicemia or endotoxemia may develop at any time, in which case animals may have tachycardia, tachypnea, poor peripheral perfusion, and a subnormal body temperature. Animals with closed-cervix pyometra are at greater risk for developing septicemia and endotoxemia.^{120,186}

958

959

91.4.3.3 Diagnosis

The diagnosis is established by the history, stage of the estrous cycle, physical examination, and laboratory and radiologic imaging abnormalities. A CBC, biochemical profile, and urinalysis are essential for detecting the metabolic abnormalities associated with septicemia or toxemia and to evaluate renal function and the possibility of a concurrent UTI. Urine collection should be done carefully, because of the risks of perforating the enlarged uterus during cystocentesis or introducing the organisms from the reproductive tract into the bladder during catheterization.

Results of vaginal cytology show degenerate neutrophils and bacteria.^{16,55} Endometrial cells may also be found.¹⁹⁹ It is very important to obtain a sample of uterine fluid for bacteriologic culture to direct antimicrobial therapy. With open-cervix pyometra, the sample should be obtained from the cranial vagina using a guarded culture swab or at surgery. With closed-cervix pyometra, the sample is obtained at surgery.

Laboratory abnormalities are most severe in animals with closed-cervix pyometra. Leukocytosis with a left shift is often present,^{278,55} but approximately 25% of dogs with pyometra had normal WBC and differential counts in one survey.²⁴⁴ Leukopenia with a degenerative left shift and neutrophil toxicity may be found in animals with septicemia. Anemia is mild when present and is nonregenerative, associated with the systemic inflammatory response.

Hyperglobulinemia and hyperfibrinogenemia are attributed to inflammation (acute-phase reaction), as is mild hypoalbuminemia.⁸⁰ Increased serum concentrations of ALP, bilirubin, and cholesterol are attributed to

Infectious Diseases of the Dog and Cat, 3rd Edition

cholestasis associated with the systemic inflammatory response rather than with primary hepatocyte injury. Alanine aminotransferase concentrations are usually normal. Liver biopsies in affected dogs confirm lack of hepatocellular necrosis.⁸⁰ On rare occasions, the sodium-potassium ratio is between 20 and 24.²³⁰

Azotemia is detected in approximately 15% to 30% of cases.^{16,80} More precise measurement of the glomerular filtration rate has confirmed that it varies in dogs with pyometra.¹⁰³ The cause of azotemia may be prerenal, renal, or both. Inappropriately low specific gravities in animals with dehydration azotemia, or both are common in bitches with pyometra.¹⁰⁴ Reduced urine concentrating ability is thought to be a result of endotoxin-induced unresponsiveness to antidiuretic hormone and to renal tubular injury. Tubular disease is the most consistent pathologic finding.^{103,253} Proteinuria is common on urinalysis. Proteinuria may be the result of inflammation with an associated UTI or the result of tubular injury; proteinuria may also be a result of glomerular lesions characteristic of immune complex deposition, which are found in some bitches with pyometra. In one small study, the urinary NAG index on admission was above normal in two bitches that developed azotemia after ovariohysterectomy, whereas in two other dogs, it was not.²³⁵ This suggests that this test might predict which dogs are at risk of renal failure from therapy for pyometra.

Concurrent UTIs are detected in 25% to 69% of affected bitches.^{104,244} The organism in the urine is the same as that in the uterus.^{104,241}

The most important diagnostic consideration is differentiating pyometra from pregnancy with associated vaginitis. Abdominal radiography confirms the presence of uterine enlargement in most but not all dogs with pyometra (Fig. 91-13). In 10% of cats with pyometra, the uterus appeared to be normal on survey abdominal radiographs.¹⁵⁰ The cause of uterine enlargement on survey abdominal radiographs cannot be determined until pregnancy can be confirmed by the presence of calcified fetal structures at approximately 42 to 45 days of gestation.

Ultrasonography is useful in differentiating fetal structures, solid masses, and luminal fluids. A large, fluid-filled uterus with no fetuses is characteristic of pyometra (Fig. 91-14).^{55,223} The enlargement of the uterus is usually uniform, but in some cases, the area of enlargement is focal or segmental.²⁶⁶ In pregnant dogs, fetal heartbeats may be seen by ultrasonogram as early as 17 to 20 days after breeding, and fetal structures are readily identifiable by 28 days.^{175,31} Because pyometra occurs more than 28 days after estrus, ultrasonography is the most diagnostic test in differentiating pregnancy from pyometra.

91.4.3.4 Therapy

Treatment should be prompt and aggressive because rapid deterioration can occur in animals with pyometra. The sooner that definitive therapy begins, the more quickly dogs recover.⁸² Therapy consists of administration of IV fluids and an appropriate antibiotic and evacuation of uterine contents.

91.4.3.4.1 Fluid Therapy

Fluid therapy should be prompt and continued throughout surgical or medical management to ensure adequate tissue perfusion. If the dog is hypotensive or dehydrated, these conditions should be reversed with fluid therapy before inducing anesthesia and should be accomplished within 1 to 4 hours.

Infectious Diseases of the Dog and Cat, 3rd Edition

Different types of fluid therapy have been evaluated in small numbers of dogs with septic shock secondary to pyometra. In one study, hypertonic saline with dextran 70 was compared with an eightfold higher volume of isotonic saline.⁷⁰ The hypertonic saline with dextran significantly increased the mean arterial pressure (range of mean [rom] approximately 60 to 90 mm Hg) and urine output, whereas isotonic saline did not. Most other parameters measured were not significantly different between groups. Cardiac output and index increased in both groups. Oxygen consumption and extraction and degree of acidosis did not improve with either therapy. Two dogs in the isotonic saline group died of renal failure within 2 weeks after surgery. However, comparative data on renal function between the groups before therapy were not provided in the article. This study used infused lactated Ringer's solution before and after the administration of the test fluids, which were administered just before the ovariohysterectomy.

959

Fig 91-14 Ultrasound examination of fluid-filled uterus (*arrow*) confirmed at surgery to be pyometra. (Courtesy University of Georgia, Athens, Ga.)

91.4.3.4.2

Antimicrobial Therapy

Antimicrobial therapy should be chosen on the basis of culture and susceptibility testing of the uterine exudate. This is important because almost 40% of *E. coli* isolated from the uteri of dogs with pyometra were resistant to two or more drugs, and 4% were resistant to 12 or more antimicrobial drugs.²⁷⁷

Because antibiotic therapy should begin immediately, an antibiotic generally effective against *E. coli* should be administered (see [Table 91-12](#)) until culture results are available. In one survey, *E. coli* isolated from bitches with pyometra were most commonly susceptible to enrofloxacin, trimethoprim-sulfonamide, chloramphenicol, and aminoglycosides.¹⁵² In another report, *E. coli* from uteri showed susceptibility to amoxicillin-clavulanate, cephalexin, enrofloxacin, and gentamicin.²⁸⁷ Enrofloxacin and other

Infectious Diseases of the Dog and Cat, 3rd Edition

fluoroquinolones may reach higher uterine fluid concentrations than serum concentrations.⁴² Antibiotics should be continued for a total of 1 to 3 weeks, depending on disease severity, type of therapy chosen (surgical versus medical), and response to therapy.

91.4.3.4.3

Surgical Therapy

Evacuation of uterine contents is most quickly accomplished surgically (i.e., with an ovariohysterectomy). If the animal is in critical condition, the animal has evidence of uterine rupture or peritonitis, or the pyometra is closed (no vaginal discharge), an ovariohysterectomy is recommended. An ovariohysterectomy can be performed traditionally or by laparoscopy.¹⁷⁸ The large and often friable uterus must be handled carefully to avoid spillage into the abdomen (Fig. 91-15).

The prognosis for recovery from pyometra is good after surgery. Intraoperative and immediate postoperative death occurs in 5% to 8% of cases.^{126,278} If the uterus ruptures, the mortality increases to 50%. Severely azotemic dogs (with a blood urea nitrogen level of greater than 150 mg/dl) also have poor prognoses. Postoperative complications in dogs with pyometra include intracranial thromboembolism, septicemia, and osteomyelitis secondary to septicemia.²⁷⁸

Fig 91-15 Gross view of pus-filled uterus at necropsy from dog with pyometra. (Courtesy University of Georgia, Athens, Ga.)

91.4.3.4.4

Medical Therapy to Evacuate Uterine Contents

An ovariohysterectomy may be unacceptable to owners who would like to preserve their animal's reproductive ability. In animals that are not systemically ill and have open-cervix pyometra, prostaglandin therapy is a reasonable alternative for owners who would like to breed the dog again and understand the limitations and side effects of medical therapy. Prostaglandin therapy causes contraction of the myometrium and relaxation of the cervix. The beneficial effects of prostaglandins are a result of evacuation of uterine contents rather than from changes in the endometrium or ovarian function. Only

Infectious Diseases of the Dog and Cat, 3rd Edition

naturally occurring prostaglandin should be used, because synthetic prostaglandin is much more potent, and a safe dose has not been established for dogs and cats.⁵⁵

Naturally occurring PGF_{2a} is given at a dose of 0.1 to 0.25 mg/kg SC once or twice per day for 3 to 7 days until the uterine diameter decreases, vaginal discharge stops, and a normal leukogram is obtained.^{16,31} Much lower doses (0.025 to 0.03 mg/kg twice a day to effect, generally for 5 to 8 days) are also reported to be successful and have fewer side effects.^{80,248} Intravaginal administration at 0.15 mg/kg every 12 to 24 hours was also reported to be successful in 13 of 15 dogs and had no side effects.⁸⁵ Immediately after infusion, the dogs' hindquarters were raised for 3 to 5 minutes. Efficacy of these different dose regimens has not been compared prospectively.

Clinical improvement is not generally apparent for the first 48 hours after starting therapy, reinforcing the thought that medical therapy is not appropriate for dogs with sepsis or toxemia. Adverse reactions to prostaglandin therapy are dose related and include restlessness, pacing, hypersalivation, vocalization, panting, vomiting, diarrhea, abdominal discomfort, tachycardia, mydriasis, and fever. These signs usually resolve within 1 hour of therapy.⁵⁵ Because vomiting is common, dogs should not be fed for 3 hours before therapy with higher dosage regimens.⁹² With injectable drugs, starting at a lower dosage and increasing the dose each day may reduce the severity of adverse effects because adverse reactions tend to diminish in severity and duration with repeated administrations.⁵⁵ Because adverse effects are common, hospitalization during high-dose therapy is recommended.

All medically treated dogs should be rechecked 2 weeks after therapy. If uterine enlargement, which occurs in approximately 33% of treated dogs,⁹² is still evident, therapy should be repeated. A prolonged vaginal discharge should prompt reevaluation of the choice of antibiotics.

960

When prostaglandin therapy is used, the animal should be bred during the next estrus.¹⁷⁵ PGF_{2a} is usually successful in treating open-cervix pyometra in dogs and cats (with 93% to 100% resolution of clinical signs; 55% to 87% for subsequent pregnancy).^{55,127} However, recurrence of pyometra can occur.¹²⁷ PGF_{2a} is less successful in dogs with closed-cervix pyometra (with only about a 25% to 34% success rate).^{127,175} No reports have been made of successful medical management of closed-cervix pyometra in the queen.

961

The antiprogesterin RU46534 (Aglèpristone [Virbac Laboratories, Carros, France as Alizine]) has also been used for medical treatment of pyometra.¹⁰⁹ A dose of 10 mg/kg was used in 31 bitches on days 1, 2, and 7. No side effects were observed. Antimicrobial therapy was also given. Treatment was successful in 21 bitches with serum progesterone concentrations greater than 3.2 nmol/L, which was indicative of diestrus. During a mean observation period of 14 months, pyometra recurred in one successfully treated dog. Two bitches were successfully bred. The same dose and frequency of therapy was used in four cats, had no side effects, and resolved pyometra in all four animals.¹⁰²

Infectious Diseases of the Dog and Cat, 3rd Edition

91.4.4 Mastitis

91.4.4.1 Etiology

The usual cause of mastitis is bacterial infection. *Staphylococcal* species are the most common¹³⁰; *E. coli* and *Streptococcus* species are the second and third most common.¹³⁰ Damp or unsanitary conditions and possibly trauma, such as by offspring, are potential predisposing causes.

91.4.4.2 Clinical Findings

Mastitis is most common in postpartum dogs but may also occur in late pregnancy and in pseudopregnancy.^{119,130} It is uncommon in queens.¹¹⁹ Mastitis may develop any time during lactation and until approximately 1 week after weaning.¹⁴⁹ Heavily lactating bitches are more likely to develop postweaning mastitis, especially if food intake is not restricted during the early weaning period.¹⁴⁹

Mastitis may be localized, be diffuse within one gland, or involve multiple glands. The classic clinical signs of acute mastitis are mammary gland heat, pain, redness, and swelling, which may be edematous or firm.

Crepitus may also be noted.²⁶⁹ If the dog has septic mastitis, signs include fever, anorexia, weakness, dehydration, and neglect of offspring. Shock may ensue with signs of vomiting, profound depression, tachycardia, and marked fever.²⁶⁹ Mastitis is usually acute; abscesses or gangrenous changes may occur secondarily. The only sign in dogs with subclinical or chronic mastitis is failure of puppies to thrive.

91.4.4.3 Diagnosis

Diagnosis is usually based on physical findings and examination of milk. A hemogram may show a neutrophilic leukocytosis. Reactive thrombocytopenia, possibly secondary to disseminated intravascular coagulation, was found in one animal with gangrenous staphylococcal mastitis.¹⁰¹ Milk may appear normal or abnormal. Cytology of the milk confirms septic, purulent inflammation. Bacterial culture and susceptibility of milk are recommended to determine the causative organism and the most efficacious antimicrobial therapy. A reported case involved a highly antibiotic resistant organism despite no prior antibiotic therapy. In this case, obtaining a culture on the day of admission prompted early appropriate therapy and recovery.²⁶⁹

91.4.4.4 Therapy

In acute mastitis, therapy includes systemic, broad-spectrum antibiotics, warm packs, a clean environment, frequent milking of affected glands, and fluid therapy if dehydration is present. When choosing an antibiotic, the clinician must consider the susceptibility of the responsible organism, this drug's ability to reach the milk, and the effects on nursing neonates. Because of potential bacterial resistance, culture and susceptibility testing should be used to direct therapy. Initial drugs of choice pending culture results include amoxicillin-clavulanate, first-generation cephalosporins, macrolides, or trimethoprim-sulfonamide because of efficacy and low incidence of side effects in the mother and puppies.³¹ Antibiotic therapy should be continued for several days after mastitis resolves. Most animals require therapy for approximately 1 week.¹²²

Infectious Diseases of the Dog and Cat, 3rd Edition

Occasionally, a severely abscessed gland may require surgical drainage. This should be done carefully because hemorrhage is a potential complication.¹⁴⁹ Abscessed or ruptured glands should be debrided of devitalized tissue and allowed to drain, with at least twice-daily flushing of an antibacterial solution. In this situation, the puppies should be removed from the mother and hand raised.

Whether offspring need to be removed from the dam if she is ill is not known, but they are often removed because the dam is in pain. If the mother is not systemically ill, offspring do not need to be removed.¹⁴⁹ Affected animals often have decreased milk production, so supplemental feeding of offspring may be required. Transient diarrhea may occur in neonates ingesting milk that contains antibiotics.³¹

In chronic mastitis, macrolides have been recommended pending culture and susceptibility results. This choice is based on milk's acidity, which leads to ion trapping of basic antimicrobial agents, and on the lipid solubility of macrolides.

91.4.4.5 Prognosis

Mastitis usually resolves with appropriate therapy, and future mammary gland function is not affected unless abscess formation or gangrene has required surgical therapy. The condition may recur with future pregnancies.

92 CHAPTER 92 Bacterial Infections of the Central Nervous System

Marc Kent

92.1 ETIOLOGY

Central nervous system (CNS) inflammation is described as encephalitis, myelitis, and meningitis based on whether the process affects the brain, spinal cord, and meninges, respectively. Inflammation in the CNS may be the result of an infectious process, immune-mediated inflammation in the absence of infection, neoplasia, trauma, or infarction. The underlying pathogenesis of immune-mediated disease is often unknown. Granulomatous meningoencephalitis (GME) is a classic example of an immune-mediated process without a determined cause.¹⁹ Other immune-mediated diseases preferentially affect certain breeds. Breed-specific inflammatory disease has been identified in the pug dog,³⁸ Maltese terrier,¹⁶⁹ Yorkshire terrier,¹⁷⁹ Pekingese,²⁸ and greyhound.²⁵ Other immune-mediated diseases such as steroid-responsive meningitis arteritis (SRMA) typically affects young patients, usually under the age of 2 years.¹¹⁶ See [Chapter 84](#) for more information on the inflammatory diseases described previously. Alternatively, immune-mediated disease is sometimes categorized based on the principle inflammatory reaction, GME,¹⁹ or eosinophilic meningoencephalitis.¹⁶⁰ Chemical meningitis can be induced by the subarachnoid injection of contrast agents as is seen with myelography.²⁹ Finally, some neoplasms such as meningioma have been associated with an inflammatory response.^{10,30}

Infectious diseases that affect the CNS include viral, protozoal, fungal, rickettsial, and bacterial organisms. Some viruses (canine distemper virus [CDV; [Chapter 3](#)] and rabies virus [[Chapter 22](#)]) are neurotropic, as are some protozoans such as systemic amoeba infections ([Chapter 79](#)) and *Toxoplasma gondii* and *Neospora caninum* ([Chapter 80](#)). These disorders produce primarily parenchymal inflammation.¹⁷¹ Others agents that are nonneurotropic become microembolized in the meningeal vasculature as a result of their systemic spread to many tissues. In this somewhat immunoprivileged site, they cause disease as a consequence of their induction of vasculitis and meningitis with secondary parenchymal injury, for example, feline infectious peritonitis virus (FIPV; [Chapter 11](#)), *Ehrlichia* and *Anaplasma* ([Chapter 28](#)), *Rickettsia rickettsii* ([Chapter 29](#)), *Blastomyces dermatitidis* ([Chapter 59](#)), *Cryptococcus neoformans* ([Chapter 61](#)), and *Coccidioides immitis* ([Chapter 62](#)). The main focus of this chapter is on bacterial infections of the CNS. Bacteria by their nature are nonneurotropic. They cause infection by producing meningitis or abscess formation. Bacterial meningitis is an inflammatory response to bacterial invasion of meninges and cerebrospinal fluid (CSF). Such infections can rapidly disseminate and, based on the virulence of the pathogen, lead to serious illness and death.¹⁰⁹ Bacterial meningitis, which can be localized or diffuse, occurs when pathogenic organisms overcome (or elude) host defense mechanisms and reach the subarachnoid CSF. Meningitis typically causes diffuse or multifocal lesions in dogs and cats, although the clinical signs may not reflect the diffuse nature of the disease.¹⁷⁸ Brain abscesses, which result from a focal pyogenic infection, appear to result from contiguous spread of infections, such as progression of otitis interna, more than from hematogenous spread of organisms. Brain abscesses are uncommon in the dog and cat.^{23,115} This finding may be caused in part by the inability of the CNS to form scar tissue, which restricts the spread of pyogenic infections in other tissue. Because epidural abscess develops outside the parenchyma of the CNS, true abscess formation can occur.^{44,121} This condition is much less common compared with meningitis. In people, staphylococci or streptococci are the most commonly implicated agents, and skin infections are a frequent source. In the report of this condition in two dogs, both affected animals were young Irish wolfhounds, but a

Infectious Diseases of the Dog and Cat, 3rd Edition

predisposition is uncertain.⁴⁴ Spinal epidural abscesses are more common than cranial epidural abscesses because of the greater available space in the spinal canal.

The veterinary literature details numerous examples of isolated cases and a few retrospective reviews of a limited number of cases of bacterial CNS infections.^{35,130,147,178} Consequently, much of the information regarding bacterial CNS infections in veterinary patients must be gleaned from experimental studies and the literature pertaining to cases in people. In humans, bacterial meningitis is caused by several distinct microorganisms that demonstrate neurotropism. These microorganisms include *Haemophilus influenzae* type b (Hib), *Neisseria meningitidis*, and *Streptococcus pneumoniae* serotype C.⁹⁴ In the last 15 years, the epidemiology of bacterial meningitis in people has changed dramatically. Hib infection has virtually disappeared as a result of immunizations, a decrease in *N. meningitidis*, and a slight increase in *S. pneumoniae* infections.¹⁵⁵ In addition, occurrence of clusters of cases of bacterial meningitis and septicemia in adolescents has increased as a result of contact in schools and universities.⁵⁸ Several risk factors have been identified in human cases. Age, socioeconomic factors, and cigarette smoking have all been associated with bacterial meningitis.⁵⁸

In contrast to people, bacterial meningitis in veterinary patients does not seem to be caused by microorganisms with a predilection for the nervous system. Consequently, bacterial CNS infections in small animals are relatively uncommon. A wide variety of bacterial organisms have been reported in small animals. These organisms have included *Staphylococcus* spp., *Streptococcus* spp., *Pasteurella* spp., *Escherichia coli*, *Klebsiella* sp., *Proteus* spp., *Salmonella* spp., *Actinomyces* spp., and *Nocardia* spp.* Anaerobes, such as *Prevotella oralis*, *Fusobacterium* spp., *Bacteroides* spp., *Peptostreptococcus* spp., *Eubacterium* spp., *Flavobacterium breve*, and *Propionibacterium* sp., have been identified in the CNS.†

962

92.2 PATHOGENESIS

963

Infection in the CNS requires numerous interactions between the pathogen and the host immune system. Bacterial organisms can spread to the CNS in a wide variety of ways. The most common route of infection is through hematogenous spread from a distant focus. Other less common routes into the CNS include direct penetration (blunt trauma, bite wound, or penetrating objects), contiguous spread (nasal cavity, paranasal sinuses, and otitis media and interna), and invasion along nerves and nerve roots (Table 92-1). In people, the first step in the pathogenesis of hematogenously spread infections involves mucosal colonization by bacteria, then evasion of local host mucosal defenses, and eventually entrance into the intravascular space. This process has been well defined in people.⁹⁸ Bacteria such as *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* are known to secrete proteases, which degrade mucosal IgA, allowing for colonization.¹⁸⁸ Once beyond the mucosal barrier, bacteria can enter the subepithelial vasculature. Systemic infections, which may ultimately lead to CNS bacterial infections, arise from splenic abscesses, pleuritis, lung abscesses, vegetative endocarditis, bite wounds, urinary tract infections, pneumonia, infected cranial sinuses, and middle ear infections.* Intravascular survival depends on the ability of bacteria to circumvent immune system activation. The ability to evade major host defenses against bacteremia, complement activation, circulating antibodies, and neutrophil phagocytosis has been attributed to bacterial capsular polysaccharides.⁹⁸ To gain entry into the CNS from the vascular space, pathogens must traverse a final impediment.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 92-1 Source and Localization of Nonneurotrophic Infections of the Central Nervous System

POINT OF ENTRY	USUAL LOCATION OR TYPE OF INFECTION
Hematogenous	Diffuse subarachnoid infection Focal parenchymal abscess or granuloma
Spinal cord	Diffuse subarachnoid infection
Paranasal sinuses	Frontal lobes Focal epidural abscess Diffuse epidural empyema
Petrous temporal bone (otitis media)	Temporal lobe (cerebrum) Cerebellum Brain stem (cerebellopontomedullary junction)
Cranial Nerves	Basilar meninges Most frequently cranial nerves VII and VIII

Fig 92-1 Comparison of features of systemic capillaries and the capillary endothelial cells of the brain. (From Oldendorf WH. 1977. The blood-brain barrier, pp 177-190. *In* Bito LL, Dawson H, Fenstermacher JD [eds], Experimental eye research, Supplement, vol 25: the ocular and cerebrospinal fluids. Academic Press, New York, NY. Reprinted with permission).

This last obstacle is composed principally of two barriers: the blood-brain barrier (BBB) and the blood-CSF barrier.¹²⁶ The BBB is formed primarily by the brain endothelium. The brain endothelium is unique in that it lacks the fenestrae found in other capillary beds (Fig. 92-1). Brain endothelial cells are interconnected by tight junctions composed of zona occludens and zona adherens. These tight junctions form a seal at the apical region of brain endothelial cells that result in the lack of permeability of the BBB, effectively segregating the brain from the vascular space. Of note is that the development and maintenance of this aspect of the BBB depends on astrocytes,

Infectious Diseases of the Dog and Cat, 3rd Edition

perivascular microglia, and the basal laminae.¹ In addition, the endothelial cells in the brain are relatively devoid of pinocytotic vesicles, suggesting little transcellular movement of substances. An analogous barrier is constructed between adjacent epithelial cells of the choroids plexus, making up the blood-CSF barrier, which prevents entry into the CSF.¹²⁶ For pathogens to cross the BBB, they must first adhere to the brain endothelium or the epithelium of the choroids plexus. For *E. coli* K1, fimbrial components have been identified that preferentially bind brain endothelial cells.¹⁷⁰ Attached to the endothelium, pathogens can traverse the BBB through paracellular pathways, transcellular transport, or intracellularly within white blood cells as they undergo diapedesis. Bacteria traversing the BBB can lead to infection of the CNS parenchyma, resulting in encephalitis or myelitis; the leptomeninges via blood vessels of the pia mater, causing meningitis; or entering across the choroid plexuses, leading to ventriculitis.¹³⁶ Regardless of the site of penetrance, infection can disseminate through the brain parenchyma to the CSF or from the CSF to the brain parenchyma because the extracellular fluid in the brain is contiguous with the CSF.

Alternatively, the BBB can be circumvented by direct penetration. Normal anatomic structures such as the vertebral column, calvaria, and meninges help protect the nervous system. However, with blunt impact trauma or penetrating objects, this aspect of the protective barrier around the CNS tissue can be overcome. Microorganisms can also enter the CNS during infections in adjacent structures containing penetrating nerves. Nasal aspergillosis can result in significant osteolysis of the nasal turbinates and cribriform plate,¹⁵⁷ which may allow for direct invasion into the brain. Encephalopathy and suppurative meningoencephalitis have been reported secondary to topical treatment of nasal aspergillosis in the dog.¹¹⁰ Similarly, otitis interna and media can invade the adjacent brain stem, usually along cranial nerves VII and VIII, which penetrate the petrous temporal bone on their course to the brain stem, producing meningitis, with or without abscess formation of the neuroparenchyma (Fig. 92-2).¹⁶⁶ Although hematogenous spread predisposes the patient to meningitis or parenchymal infarction, or both (see Fig. 87-5,C), contiguous spread into the CNS along nerve access often causes subdural abscesses.¹⁸⁵ Despite the close proximity, diskospondylitis rarely progresses to invade the adjacent spinal cord parenchyma.⁵² Spinal empyema has been reported in the dog.⁴⁴ Microorganisms can also invade the CNS by traveling within axons from peripheral nerves. In ruminants, *Listeria monocytogenes* likely gains access to the CNS along axons of the trigeminal nerve.¹⁷¹ Concurrent CNS and sinonasal infections with *C. neoformans* has been documented.¹³ Whether CNS involvement is related to direct penetration through a damaged cribriform plate, the result of extension along the olfactory nerves, or through hematogenous spread is unclear.

963

964

Fig 92-2 Ventral surface of brain showing cerebellopontine angle abscess that began as a result of otitis interna spreading from the infected petrous temporal bone.

Once inside the BBB, the host defenses are severely limited. The CSF is largely devoid of complement, opsonizing proteins such as immunoglobulins and neutrophils, which, in part, allow for bacterial replication to occur largely unchecked.⁹⁸ With increased bacterial replication and autolysis, concentrations of the bacterial cell wall products, lipopolysaccharides, teichoic acid, and peptidoglycans are increased, which stimulate the host inflammatory response.⁹⁸ Unlike in extraneural sites, in CNS infections, the damage is largely the result of the inflammatory response rather than the pathogen itself.¹⁷⁴ The inflammatory response involves the production numerous cytokines and chemokines (tumor necrosis factor- α [TNF- α], interleukin [IL]-1, IL-6, IL-8, and IL-10), matrix metalloproteinase (MMP), reactive oxygen species (ROS), and nitric oxide synthetase (NOS).⁹⁸ Cytokines and chemokines are small proteins that are crucial in the development and modulation of inflammation. In general, cytokines are factors that bind to cell membrane receptors and modulate leukocyte function, whereas chemokines bind to transmembrane receptors and function as chemoattractants.²⁶ Many different cells possess the capability of producing these various proinflammatory molecules. Brain cells such as endothelial cells, ependymal cells, resident macrophages, astrocytes, and glial cells can express cytokines in response to stimuli in bacterial meningitis.¹⁵² Among the cytokines, IL-1 and TNF- α , play a crucial role early in the inflammatory process in the CNS.¹³³ In bacterial meningitis, IL-1 and TNF- α concentrations increase early in the disease course. Both IL-1 and TNF- α induce the generation of IL-6, IL-8, and IL-10. IL-6 induces the release of acute-phase reactants, fever, and leukocytosis. IL-8 is important in mediating neutrophil chemotaxis, adhesions, and migration into the subarachnoid space. IL-10 is largely antiinflammatory, causing a reduction in the levels of IL-1, IL-6, IL-8 and TNF- α . TNF- α also causes the production of MMPs. Metalloproteinases are a family of proteinases that help break down the extracellular matrix, thereby allowing for the migration of leukocytes. MMP-8 and MMP-9 are elevated in meningitis and contribute to the breakdown of the BBB.¹⁵² ROS and NOS also play prominent roles in the

Infectious Diseases of the Dog and Cat, 3rd Edition

inflammatory process. As a result of their free radical actions, ROS are cytotoxic. The brain is particularly sensitive to free-radical injury owing to a lack of antioxidants, relative high oxygen consumption, and high concentration of unsaturated fatty acids.⁹⁸ Nitric oxide (NO) also plays a substantial role in perpetuation of inflammation, the alterations in cerebral vascular perfusion, and the production of peroxynitrite, a potent free radical responsible for lipid peroxidation.¹⁵²

As the inflammatory process progresses, breakdown of the BBB continues. With diminished functionality of the BBB, leukocytes and other soluble mediators of inflammation can cross the damaged barrier and positively feed back on the inflammatory reaction.

Meningeal inflammation is largely responsible for the clinical signs seen in meningitis more than the direct effects of organisms. The direct toxic effects of a pathogen contribute to neuronal injury; however, the indirect effects of the inflammatory mediators are more important factors in neuronal loss. Experimental models and autopsy findings in humans reveals two distinct histologic forms of injury: extensive cortical damage and selective injury to the dentate gyrus of the hippocampus.⁸⁴ TNF- α may be responsible for apoptotic loss of neurons in the hippocampus.¹⁷³ ROS and NO likely cause the ischemic injury to the cortex through their regulation of cerebral blood flow.¹⁷³ Excitatory amino acids such as glutamate also contribute to neuronal loss.⁹⁷ In addition, the production of cytokines and other proinflammatory molecules results in endothelial damage, disrupting the BBB and allowing plasma components and leukocytes to traverse into the CNS, which plays a part in the development of vasogenic edema.¹⁷³ If the endothelial damage is severe enough, thrombosis can occur, producing ischemia and necrosis. Additionally, cerebral edema contributes to intracranial hypertension, which alters autoregulation of the cerebral vasculature and cerebral perfusion, ultimately contributing to ischemia and neuronal loss.⁷

Ependymal inflammation from bacterial meningitis may lead to obstructed CSF flow with secondary hydrocephalus,⁴³ a phenomenon also found with FIPV meningoencephalitis of cats (see [Chapter 11](#)) and parainfluenza virus meningoencephalitis of dogs (see [Chapter 7](#)).

92.3 CLINICAL SIGNS

92.3.1 Extraneural Signs

Patients with CNS infections can show a wide variety of clinical signs, ranging from those indicative of both systemic and neurologic dysfunction to those strictly referable to the CNS.¹⁷⁸ If the primary source of infection is located in another organ system, clinical signs may reflect dysfunction of that particular organ. Thorough ocular, fundoscopic, and otoscopic examinations should be performed on every patient suspected of having meningitis. The optic nerves are a direct extension of the diencephalon. Abnormalities such as papilledema, optic neuritis, chorioretinitis, retinal hemorrhages, and uveitis can be seen with inflammatory CNS disease.¹⁵⁹ Similarly, the ear canal can provide a portal of entry of organisms into the CNS. Fever may result from the inflammatory process or the consequence of components of bacterial cell walls. Alternatively, elevated body temperature (hyperthermia) may be secondary to muscular activity, seizures, or environmental factors. Severe systemically affected patients may have signs consistent with shock, hypotension, and disseminated intravascular coagulation.¹¹⁵ Abnormalities in the cardiac rate, rhythm, or a newly diagnosed murmur may be supportive of bacterial endocarditis as the primary source of sepsis. Additionally, bradycardia with concurrent systemic hypertension (Cushing's reflex) may be the consequence of intracranial hypertension.⁷ Nausea and

964

965

Infectious Diseases of the Dog and Cat, 3rd Edition

vomiting can also occur with meningitis.¹¹⁵ In advanced disease, with severe brain edema or mass effect, brain herniation with acute respiratory insufficiency may be seen.

92.3.2 Neural

As with all other aspects in neurology, the key to accurate diagnosis relies heavily on a precise neuroanatomic diagnosis. Classically, infectious diseases of the CNS have been associated with multifocal neurologic signs.¹²³ However, focal signs do not exclude the possibility of infection. Hyperesthesia is a cardinal feature of inflammatory or compressive diseases involving the meninges. In the cranial region, hyperesthesia may be demonstrated by compression of the cranial vault across the temporalis muscles or by opening the jaw. Photophobia or nuchal rigidity may also be present. Two thirds of patients with inflammatory disease processes of the CNS have focal neurologic deficits.¹⁷⁸ Focal inflammation of cranial or spinal nerves occurs in the subarachnoid space as the roots of these nerves enter and exit the CNS and are bathed by CSF. Focal signs of hyperesthesia, lower motor neuron dysfunction, or involuntary twitching of muscles may occur. Depending on the anatomic site affected, inflammation of the meninges, parenchyma of the brain, or of the spinal cord is termed meningitis, encephalitis, or myelitis, respectively. Similarly, inflammation in the CSF is referred to as meningitis. Prosencephalic (cerebrum and thalamus) lesions may alter mentation, cause seizures, and result in abnormal postural reactions with a preservation of gait. Brain stem lesions can also alter mentation. Moreover, brain stem lesions frequently result in cranial nerve deficits and gait abnormalities. Signs associated with spinal cord lesions depend largely on the level at which the spinal cord is affected. In general, proprioceptive ataxia and paresis are the hallmarks of spinal cord dysfunction. Further assessment of reflexes helps localize the affected spinal cord segments. Spinal meningeal inflammation may result in paraspinal discomfort, paraspinal muscle rigidity, and decreased vertebral.¹⁶²

92.4 DIAGNOSIS

CSF analysis and culture are the sole methods of providing a definitive diagnosis of CNS bacterial infection. Because of the BBB, the absence of fever or leukocytosis does not eliminate meningitis from consideration. However, establishing a definitive diagnosis is complicated by the difficulty in identifying an underlying etiologic agent. Ancillary laboratory tests such as a complete blood count (CBC), biochemical profile, and urinalysis provide a minimal database. When present, abnormalities in the CBC, leukocytosis (neutrophilia with or without a left shift), or leukopenia largely reflect a systemic inflammatory response rather than provide a specific diagnosis. Biochemical profile abnormalities may provide insight into a possible source of sepsis or concurrent disease process. Alternatively, results of these tests may be within reference limits.¹⁷⁸

In postoperative neurosurgical patients, distinguishing surgically induced bacterial infections of the meninges from irritant meningitis caused by contrast agents, surgical trauma, and lavage performed at the time of surgery can be difficult. In people, an overlap exists of CSF test results for patients with chemical meningitis and infectious meningitis determined by bacterial isolation or identification.²¹ Therefore administration of antibacterials may rely instead on detecting surgical wound infections, additional neurologic signs such as mental changes or seizure disorders, high rectal temperatures, or otorrhea or rhinorrhea.

92.4.1 Cerebrospinal Fluid Evaluation

Given the close physical relationship that exists between the CSF and CNS parenchyma, disease affecting the parenchyma may be reflected as changes in the CSF. Furthermore, the CNS has limited ways to respond to

Infectious Diseases of the Dog and Cat, 3rd Edition

disease. Therefore most disease processes in the CNS result in inflammation. As a consequence, even using CSF analysis, definitive diagnosis may be difficult, if not impossible, to obtain in at least one third of patients with inflammatory CNS disease.¹⁷⁸ Despite this problem, CSF analysis is necessary for determining that inflammatory CNS disease is present and obligate for the diagnosis of bacterial CNS disease.

92.4.1.1

Technique

CSF is often obtained from the cerebellomedullary cistern (CMC). Additionally, CSF can be collected from the dorsal or ventral subarachnoid space at the L5-L6 intervertebral spaces. Alternatively, CSF can also be obtained from the L6-L7 intervertebral space in some patients. In cases of hydrocephalus, CSF can also be collected from the lateral ventricles.¹²² One ml per 5 kg of body weight can safely be taken from patients.³²

Obtaining CSF for analysis does require general anesthesia, and all patients must be intubated to prevent obstruction of the airway during patient positioning. Normal endotracheal tubes are adequate; however, in certain circumstances, wire-reinforced endotracheal tubes provide added insurance that the airway will remain patent during the procedure.

Little specialized equipment is needed for collecting CSF. In general, a 22-gauge, 1.5- or 2.5-inch spinal needle is used. For small patients (cats and dogs under 5 kg), a 23-gauge, 0.5-inch scalp-infusion needle ("butterfly needle") is used, which allows for better control. Sterile surgical gloves are worn by the person performing the procedure. CSF should be collected in sterile containers without preservatives such as ethylenediaminetetraacetic acid (EDTA). EDTA can artificially lower cell counts and alter protein measurements.³¹

When obtaining CSF from the CMC, the patient is positioned in lateral recumbency on a stable, flat surface. For *right-handed individuals*, patients are placed in right lateral recumbency to allow landmarks to be palpated by the left hand and manipulation of the spinal needle with the right hand. The hair on the dorsum of the patient's neck from approximately the caudal aspect of the pinnae to the level of the second or third cervical vertebrae is shaved and surgically prepared.

With the patient in right lateral recumbency, the head is flexed to a 90-degree angle with respect to the axis of the vertebral column.⁶² The axis of the head must remain straight (parallel to the table) to ensure that the vertebral column is not rotated. Positioning is done by an assistant who is situated across the table from the person performing the procedure. Once proper positioning is attained, the assistant should be instructed not to move the patient until the spinal needle is withdrawn from the skin when the procedure is completed.

965

966

CSF from the CMC is obtained by inserting a needle between the occipital bone of the calvaria and the dorsal lamina of the first cervical vertebra. Landmarks for this site include the external occipital protuberance and the cranial aspect of the wings of the atlas.⁴² An imaginary line is drawn from the external occipital protuberance caudal along the midline. Similarly, a second imaginary line is drawn between the cranial aspects of the wings of the atlas. These lines bisect at approximately the level of needle insertion. The needle is inserted parallel to the surface of the table and directed perpendicular to the long axis of the vertebral column (Fig. 92-3).

The needle is advanced by holding it at the hub with one hand and is held steady along the shaft of the needle by the other hand. The needle is held continuously throughout the procedure. The needle is advanced slowly, approximately 1 to 2 mm at a time, after which the stylet is removed to observe for flow of CSF. If no flow is seen, the stylet is replaced and the needle is slowly advanced again. As the needle passes through tissue,

Infectious Diseases of the Dog and Cat, 3rd Edition

sudden loss of resistance results in a “pop”. After each pop, the stylet is withdrawn to observe for CSF flow. If CSF is not observed, the stylet is replaced and the needle is advanced again. If bone is struck, the needle may be withdrawn slightly, angled either cranial or caudally, and then advanced again. Although this “walking” of the needle can be successful, in many cases, the needle must be withdrawn completely and repositioned for another attempt. Alternatively, the stylet can be withdrawn from the needle once the needle has penetrated the skin. This action enables the person performing the procedure to see flow of CSF immediately on entry into the subarachnoid space. This method also provides an added measure of safety in performing the procedure; however, it can result in significant blood contamination, which may alter CSF analysis.

Fig 92-3 One landmark for cerebrospinal fluid collection is the intersection of a line drawn transversely between the wings of the atlas on the cranial aspect and along the dorsal midline drawn through the occipital protuberance (Courtesy of University of Georgia, Athens, Ga.)

The depth at which CSF is obtained at the CMC varies between individuals. In cats and small dogs, this distance can be small; therefore extreme care should be taken when collecting CSF from small patients. In overweight patients, landmarks can sometimes be difficult to palpate.

For collection of CSF from the lumbar subarachnoid space, an area of skin is clipped several inches wide along the dorsum from approximately the level of L4 through the sacrum and surgically prepared. The patient is placed in lateral recumbency, and the vertebral column is flexed by positioning the pelvic limbs cranially. As with CMC punctures, care must be taken to make sure that the vertebral column is parallel to the table. Rotation of the axis of the vertebral column will result in misdirection of the needle. The spinous processes are palpated to identify the appropriate interspace. Landmarks for lumbar puncture include the spinous process of L7 and the smaller spinous process of the sacrum, both of which are palpable between the tuber coxae of the pelvis. Once the L7 spinous process is identified, the L5-L6 intervertebral space lies between the spinous processes of L5 and L6 vertebrae. In large dogs and in overweight patients, the spinous process of L7 and the sacrum may not be palpable. In these cases, the first spinous process cranial to the

Infectious Diseases of the Dog and Cat, 3rd Edition

tuber coxae is usually L6. Generally, the L6 spinous process is larger than the L7 spinous process. Occasionally, radiographs are needed to establish landmarks.

The needle is handled as previously described. The needle is inserted through the skin at the level of the cranial aspect of the L6 spinous process (for the L5-L6 intervertebral space) on the midline and advanced perpendicularly toward the vertebral column. If bone is struck, the needle is adjusted cranially or caudally to reach the intervertebral space. Resistance is felt as the needle is advanced through the interarcuate ligament. The pelvic limbs and tail may twitch as the needle passes through the dura mater. As with CMC collection, the stylet is periodically removed to observe flow of CSF. If flow is not appreciated, the stylet is replaced and the needle advanced. Lumbar subarachnoid pressure is lower than it is at the CMC; therefore CSF flow may be slower, and the needle that is used is often longer than that used for CMC punctures. Consequently, more time should be allowed to observe for CSF flow. In both instances, once the sample is obtained, the needle is withdrawn without replacing the stylet.

966

967

92.4.1.2

Complications

Blood contamination is often encountered. If the CSF flows readily, mild blood contamination may clear with additional drops or by replacing the stylet and waiting 1 minute before collecting additional, less contaminated CSF. Correction factors have been used to predict the leukocyte count in blood-contaminated samples. These correction formulas are inaccurate.¹⁹² Moreover, mild blood contamination does not significantly alter the number of leukocytes in CSF samples.^{73,192} If substantial blood or “pure” blood is encountered, the needle is withdrawn without replacing the stylet and a new needle is used for another attempt. Many times, obtaining pure blood means that the needle was misdirected laterally.

More serious and devastating complications include penetration of the needle into the CNS parenchyma and brain herniation. With lumbar punctures, needle penetration into the nervous tissue is often unavoidable because, in many cases, CSF cannot be collected from the dorsal subarachnoid space. However, at the level of the low lumbar vertebral column, this problem rarely results in clinical deficits. In stark contrast, injury at the level of CMC can be devastating. In cases with confirmed or suspected intracranial hypertension, CSF collection can result in brain herniation.⁸² By removing CSF, a pressure gradient is created whereby intracranial contents can shift from an area of high pressure to one of lower pressure (i.e., the site of CSF collection). Brain herniation can result in alterations in mentation, pupil size and symmetry, abnormal nystagmus, tetraparesis, and abnormalities in respiration and cardiac rhythms, apnea, and death. Brain herniation can also be clinically silent. Herniation has been associated with anesthesia and CSF collection.⁹¹ Care should be exercised when considering CSF collection in patients with suspected or confirmed intracranial disease or intracranial hypertension.

92.4.1.3

Cerebrospinal Fluid Analysis

After collection of CSF, analysis should consist minimally of the following tests: gross visual inspection; total cell count, as well as leukocyte and red blood cell counts; differential white blood cell count; and total protein analysis. Further biochemical, microbiologic, and serologic testings should be performed based on the results of the aforementioned tests. Normal CSF contains a relatively low protein concentration and is therefore hypotonic. As a result, cell lysis can occur quickly. Consequently, analysis should be performed quickly after collection, ideally within 30 minutes of collection.³² If analysis cannot be performed immediately, several techniques can be used to prevent in vitro cell degeneration. Refrigeration can slow degeneration for several hours; however, several improved methods of preserving cellular morphology have

Infectious Diseases of the Dog and Cat, 3rd Edition

been developed. The addition of an equal volume of bovine albumin to the CSF sample preserves cell morphology for up to 4 hours.¹³⁴ Alternatively, an equal aliquot of serum from the patient can be mixed with its CSF, which preserves cell morphology and provides accurate cell counts for up to 48 hours.¹⁵ Precise measurements of the amount of CSF and the amount of serum mixed together are needed to calculate final cell counts. A separate aliquot of CSF, not diluted with serum or bovine albumin, is needed for measuring protein content. Mixing CSF with either 40% ethanol or 10% formalin has also been suggested to help preserve cell morphology.⁸⁸

Normal CSF is clear and colorless. In general, turbidity or cloudiness becomes grossly visible with nucleated cell counts greater than 500 cell/ μ l. Other authors have suggested that turbidity is seen with nucleated cell counts greater than 200 nucleated cells/ mm^3 and 400 erythrocytes/ mm^3 .³² Blood contamination or recent hemorrhage into the subarachnoid space will result in a pink to red discoloration of the CSF. Most often, blood contamination is iatrogenic as a consequence of the needle puncture rather than an underlying disease. Xanthochromia, a yellow-orange color in the supernatant, is usually an indication of previous hemorrhage caused by the breakdown of hemoglobin into bilirubin. In some instances, prolonged hyperbilirubinemia can cause xanthochromia. High CSF-nucleated cell counts and protein concentrations are indicative of neurologic disease, even if a moderated number of erythrocytes are present from iatrogenic blood contamination.⁷³

Normal CSF contains a leukocytes in the range of 0 to 6 cells/ μ l in dogs and 0 to 2 cells/ μ l in cats, composed primarily of mononuclear cells and little to no red blood cells.³² Further characterization of mononuclear cells is sometimes difficult because of the morphologic alteration induced in leukocytes as a result of preparation techniques.⁷⁹ An elevation in CSF nucleated cell count is called pleocytosis. Performing differential cell counts is important even in cases that have total cell counts within normal ranges.³³ One fourth of low cellularity samples were cytologically abnormal with cytocentrifuge preparations, with the most common abnormalities being increased phagocytocytic activity, neutrophils, and reactive lymphocytes.³³

In general, cell-concentration techniques are needed to improve cytologic evaluation of CSF given that most samples have low cellularity. The most accurate method is cytocentrifugation whereby CSF is spun at 1500 g for 10 minutes in a conventional centrifuge⁶⁰ or 100 g for 10 minutes in a cytocentrifuge (Cytospin, Shandon Southern Instruments, Sewickley, Penn.).³³ Sedimentation procedures can also be employed whereby CSF is mixed with serum and allowed to sediment for 1 hour. In this procedure, larger amounts of CSF are required. Various techniques can be used whereby an aliquot of CSF is allowed to sediment on a glass slide, which is then air dried and stained for interpretation.^{36,79} Another method for CSF cytologic analysis uses membrane filtration; however, this method is more technical and requires different staining techniques (trichome or hematoxylin) and results in poor morphologic preservation of cells.¹⁴¹

The hallmark of bacterial CNS infections is a neutrophilic pleocytosis. Toxic changes can be appreciated with cytologic evaluation of neutrophils in CSF. Occasionally, intracellular bacteria can be seen within neutrophils or other phagocytic cells. However, the significance of organisms observed outside of leukocytes (free, nonphagocytosed) in the CSF should be interpreted with caution. Free organisms can be the consequence of in vitro contamination. The implication of free organisms should be defined based on cytologic evidence of infection and clinical signs. Alternatively, repeat CSF analysis can be performed to validate the existence of bacterial organisms in CSF. Unfortunately, neutrophilic pleocytosis is not specific for bacterial disease. SMRA can result in a pronounced pleocytosis composed mostly of neutrophils.¹¹⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

Many of these patients will also have fever and cervical hyperesthesia, mimicking the signs of bacterial meningitis.¹¹⁶ Acute viral meningoencephalitis as a result of CDV infection can cause necrosis, resulting in an occasional marked neutrophilic pleocytosis.¹⁸⁶ Dogs with CDV infections may have systemic signs of illness, including gastrointestinal and respiratory signs. In cats, infection with FIPV usually results in a mixed pleocytosis; however, some cases have CSF inflammatory reaction composed predominantly of

967

968

neutrophils.⁸⁷ Cats infected with FIPV may also show systemic signs and clinicopathologic changes such as fever, anemia, and hyperglobulinemia. Aberrant *Cuterebra* larval migration through the CNS can also cause a neutrophilic response in the CSF.⁵⁶ Prodromal signs often include upper respiratory signs and abnormal body temperature (hyperthermia or hypothermia). Meningioma in the dog has also been associated with neutrophilic pleocytosis, although relationships between patterns of CSF changes and specific histologic tumor types cannot be made.¹⁰ Typically, dogs with intracranial neoplasia are older than 5 years and have progressive signs related to focal deficits. Myelography can also cause a change in CSF cytology consisting of primarily a neutrophilic pleocytosis (Table 92-2).^{29,191}

Mononuclear pleocytosis composed of lymphocytes and monocytes is typically seen in viral encephalitis such as that caused by CDV,^{19,92,177,186} and GME.^{9,19,147,176} The breed-specific inflammatory diseases such as those affecting the pug dog,³⁸ Maltese terrier,¹⁶⁹ and Yorkshire terrier^{179,46} have been associated with a mononuclear pleocytosis. In protracted cases of SRMA, a mononuclear pleocytosis can be observed.^{34,180} In bacterial CNS infections, the predominant inflammatory cell type in CSF may change from a neutrophilic to a mononuclear pleocytosis following treatment.⁵² CNS infections with *Ehrlichia* spp. can also cause mononuclear pleocytosis.^{70,112} *Anaplasma* is more likely to cause neutrophilic pleocytosis.¹⁰⁶

968

970

Mixed inflammatory pleocytosis is a common finding. The cell population may consist of varying numbers of lymphocytes, monocytes, neutrophils, and eosinophils. Many infectious diseases will have a mixed inflammatory reaction in the CSF. Infections with FIPV⁸⁷ and CDV have both been associated with a mixed pleocytosis.¹⁴⁷ *T. gondii* and *N. caninum* infections can result in a mixed inflammatory response.^{40,66,76,143} Degenerative CNS disease can provoke a mixed inflammatory response.¹⁸⁶ Intervertebral disk disease may have mixed pleocytosis.¹⁸⁶ Mixed inflammation has also been seen with neoplastic disease of the CNS.^{10,30}

Eosinophilic pleocytosis is a rare finding. Occasionally, CNS cryptococcosis has been associated with eosinophilic pleocytosis.¹⁴ *T. gondii* infections may invoke an inflammatory reaction in which eosinophils predominate.¹⁶⁰ Eosinophilic meningoencephalitis can also be idiopathic.^{12,160} Eosinophils can be part of the mixed inflammatory response seen in aberrant *Cuterebra* larval migration through the CNS.^{56,69}

CSF protein analysis should also be performed. Several methods can be used to quantitate CSF protein.⁷⁹ Normal CSF protein concentration varies depending on the site of collection.⁸ CSF from the CMC normally has a protein content of less than 30 mg/dl, and CSF obtained from lumbar puncture can have protein content up to 45 mg/dl.³² The Pandy reaction and Nonne-Apelt test are semiquantitative methods of assessing CSF immunoglobulin concentrations.⁷⁹

Elevations in CSF protein concentrations may be the result of disruption of the BBB and secondary transudation of serum proteins, intrathecal immunoglobulin production, necrosis of the CNS parenchyma, or alteration in the flow of CSF through the ventricular system and subarachnoid space.³² Severe blood

Infectious Diseases of the Dog and Cat, 3rd Edition

contamination can also increase CSF protein concentration. An increased CSF protein measurement with a normal cell count is referred to as albuminocytologic dissociation. This pattern has been associated with primary brain tumors in dogs.¹⁰ In addition to CSF total protein content, the specific components of CSF, albumin, and globulin fractions can be evaluated. The constituents of canine CSF have been reported from normal dogs^{93,165} and from dogs with CNS disorders.^{181,163}

Numerous other elements of the CSF have been evaluated. CSF glucose concentrations are normally 60% to 80% of the serum glucose concentrations. In humans, CSF glucose concentrations are generally less than 40 mg/dl.¹⁹³ The exact relationship between serum and CSF glucose concentrations has not been established in veterinary medicine. In the limited number of cases in which CSF glucose has been evaluated, CSF concentrations have been lower than serum, ranging from 10 to 100 mg/dl.^{75,24} CSF lactate values have been increased in the CSF of people with bacterial meningitis because of a metabolic shift toward anaerobic metabolism.⁹⁸ Enzymes such as creatine kinase, lactate dehydrogenase, alanine aminotransferase, and aspartate aminotransferase activities have been documented with various CNS disorders in veterinary medicine; however, correlation with specific diseases can not be made.³²

92.4.2 Microbial Culture and Susceptibility Testing

Microbial culture and susceptibility testing are of great importance in defining specific antimicrobial therapy. Samples should be collected in sterile containers that lack preservatives. Both aerobic and anaerobic cultures of CSF should be performed in cases of suspected bacterial CNS infections. Bacteria are often in low concentrations in CSF; therefore enrichment media may be helpful in supporting bacterial growth. However, in humans, broth cultures are more likely to result in false positive growth from bacterial skin contaminants.¹⁹³ In veterinary medicine, cultures are often negative in cases of bacterial CNS disease, which may be the consequence of a low concentration of bacteria in CSF, improper sample preparation, or improper culture technique.⁵² CSF may also suppress bacterial growth, either as a result of specific inhibitors or from a lack of nutrients to support growth.² Care must also be exercised when interpreting drug sensitivities using qualitative methods (disk diffusion) because breakpoints are derived from drug concentrations obtainable in serum and not CSF.¹²⁰

Gram staining may help identify organisms. Gram staining has a sensitivity of 60% to 90% and a specificity approaching 100% in people with bacterial CNS infections.¹⁹³ Similarly, blood cultures identify the causative organism in 80%, 90%, and 94% of humans with *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*, respectively.¹⁹³ Blood cultures were positive in one of three dogs evaluated.¹³⁰

92.4.3 Immunologic Testing

The identification of specific antibodies or antigens within the CNS is helpful in establishing the diagnosis of some viral, fungal, protozoal, and rickettsial infections. Unfortunately, such tests are not available to establish the presence of bacterial disease in veterinary patients. The finding of antibodies in the CSF that are directed against specific pathogens does suggest intrathecal production of IgG molecules. However, serum immunoglobulins can enter the CSF in the presence of meningeal inflammation unrelated to an infection. Therefore, though provocative, the finding of antibodies in the CSF does not definitively establish an etiologic diagnosis. With meningeal inflammation, both albumin and IgG contents are increased in CSF from a loss of integrity of the blood-CSF barrier or BBB, which allows for secondary transudation. Increased albumin content

Infectious Diseases of the Dog and Cat, 3rd Edition

in the CSF lends support to leakage of serum proteins across a disrupted barrier. Mathematical formulas relating serum albumin and globulin with that in the CSF can also assist in identifying local production of immunoglobulin. Unfortunately, such formulas as albumin quotient and CSF IgG index do not provide specific information regarding the cause. The concurrent measurement of serum and CSF antibody titers paired with those directed against another pathogen not known to infect the CSF and for which the patient has already developed measurable antibodies (e.g., canine parvovirus) can support a causality.⁶¹ This procedure is often used in the diagnosis of CDV and other infections. See Diagnosis in [Chapters 3, 45, 80, and 84](#). In the case of CNS *Cryptococcus*, a specific latex-agglutination test identifying intrathecal antigen has been developed that can provide a specific and accurate diagnosis (see [Chapter 61](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 92-2 Representative CSF Changes Seen in Various CNS Inflammatory Diseases of Dogs and Cats^{32,51,135,178}

DISEASE (CHAPTER)	WBC ^{a,b} COUNT	WBC TYPE	TOTAL PROTEIN CONCENTRATION (mg/dl) ^c	ALBUMIN PROPORTION	GLOBULIN PROPORTION	CSF ANTIBODIES DETECTED	ORGANISMS SEEN

CSF, Cerebrospinal fluid; WBC, white blood cell; PMN, polymorphonuclear neutrophils; *mono*, monocytes (lymphocytes, plasma cells, monocytes, and macrophages); *mixed*, mononuclear cells, neutrophils, and eosinophils; *eos*, eosinophils; *neutro*, neutrophils; *lymph*, lymphocytes; WNL, within normal limits; +, mild elevations; ++, moderate elevation; +++, marked elevation; ?, uncertain

a Symbols in parentheses indicate less frequent variations; for example + (++) indicates that typically the test results are mildly elevated but in some patients are moderately elevated.

b WNL for WBC count, <4/μl; +, 5–80/μl; ++, 81–500/μl; +++, > 500/μl.

c WNL for Total Protein Concentration, < 25 mg/dl; +, 25–100 mg/dl; ++, 100–300 mg/dl; +++, > 300 mg/dl.

Infectious Diseases of the Dog and Cat, 3rd Edition

- d For neoplasia, typically protein increase is greater than that of leukocytes (albuminocytologic dissociation); for lymphoma in subarachnoid space, greater number of cells are present of mononuclear variety.

92.4.4 Polymerase Chain Reaction

This method, which is in the early stage of evaluation of CNS pathogens, has been used to detect various infectious agents in inflammatory disorders in humans and has included primers directed at specific bacterial pathogens expected in meningitis.¹⁰¹ Given that cultivation of CSF has been frequently unrewarding, this method might be considered as a way to detect bacterial or other pathogens in the CSF from animals having inflammatory CSF analysis results. In human meningitis, bacterial pathogens such as *Neisseria* or *Haemophilus* are so specific having a predilection for the CNS that latex-agglutination and polymerase chain reaction tests that allow for the detection of specific bacterial antigens and nucleotides, respectively.¹³¹

92.4.5 Radiologic Imaging

Given that most cases of bacterial meningitis in veterinary patients are the result of hematogenous or contiguous spread of organisms, thorough screening of suspected cases is warranted. In addition to the minimal database, chest radiographs, and abdominal imaging, abdominal radiography or ultrasonography should be performed. Cultures of other bodily fluids, blood, and urine may be helpful in identifying bacteria. In patients with newly diagnosed heart murmur, echocardiography should be performed to investigate the possibility of bacterial valvular endocarditis.

The most sensitive methods of imaging the CNS are magnetic resonance imaging (MRI) and computed tomography. All patients with clinical indications of parenchymal disease, encephalitis, or myelitis, or those with focal neurologic deficits, should undergo advanced imaging procedures. Patterns of meningeal enhancement with MRI have been reported.^{99,113} Inflammatory lesions generally appear less intense with T1-weighted imaging and more intense with T2-weighted imaging. Although advanced imaging procedures provide a sensitive method for detecting disease, findings are often not specific enough to allow for definitive diagnosis. Despite this disadvantage, imaging may provide information regarding the possibility of surgical intervention for drainage of infective material in focal disease.

C_{CSF}/C_{Serum} : Concentration cerebrospinal fluid over concentration serum, expressed as a percentage.

92.5 THERAPY

Treating bacterial CNS infections presents unique challenges. The mainstay of treatment revolves around the administration of appropriate antimicrobials based ideally on antibiotic susceptibility testing. In many cases, this information is unavailable, and treatment needs to be instituted empirically based on clinical suspicion. For successful treatment, an understanding of both the pharmacokinetic and the pharmacodynamic properties of the various antibiotics is essential. Pharmacokinetics is the study of the drug concentration in serum and the site of action of the drug, and pharmacodynamics refers to the relationship between drug activity and concentration. Drug kinetics in the nervous system is very different than it is elsewhere in the body, largely because of the BBB.

970

Numerous factors influence drug penetration in the CNS. The major factor limiting penetration into the CNS is

971

lipid solubility.¹⁰³ Lipophilic drugs reach higher concentrations in the brain because they are able to penetrate by diffusion into the BBB (Table 92-3).¹⁴⁶ Hydrophilic drugs such as β -lactams are weak acids that, at physiologic pH values, are ionized and therefore hydrophilic, which limits their penetration into the CNS.⁵³ Quinolones, rifampin, and metronidazole are lipid soluble and more easily enter the CNS.⁴ Molecular size also influences drug penetration, with large macromolecules being more effectively excluded from entering the CNS. In a similar fashion, the degree of protein binding also inhibits penetration into the CNS. Because most antibiotics are, in part, bound to albumin, only the unbound portion is available to cross the BBB. Highly protein-bound antibiotics are hydrophobic and are very large molecules, both of which hinder entry into the CNS. Lastly, the choroid plexus contains an energy-dependent pump that moves agents out of the CNS. This efflux system is responsible for

Infectious Diseases of the Dog and Cat, 3rd Edition

approximately 70% of the elimination of penicillin, and other drugs such as the quinolones are eliminated to a lesser degree.⁴

Table 92-4 Recommended Antimicrobials for Specific Agents or Settings^{2,63}

ORGANISM	FIRST CHOICES	SECOND CHOICE
Gram-positive bacteria		
<i>Staphylococcus</i>	Nafcillin	Vancomycin, vancomycin + rifampin, ampicillin, trimethoprim-sulfonamide
<i>Streptococcus</i>	Penicillin, ampicillin	Ceftriaxone, vancomycin
<i>Actinomyces</i>	Ampicillin	Minocycline
Gram-negative bacteria	Cefotaxime + ampicillin	Gentamicin + ampicillin, gentamicin + ceftriaxone
<i>Pseudomonas</i>	Ceftazidime + aminoglycoside ^a	Piperacillin + aminoglycoside, ^a carbenicillin + gentamicin ^a
<i>Pasteurella</i>	Ampicillin	Trimethoprim
<i>Brucella</i>	Minocycline	Gentamicin ^a
<i>Salmonella</i>	Ceftriaxone	Ampicillin, chloramphenicol
<i>Enterococcus</i>	Ampicillin	Minocycline
<i>Bacteroides</i>	Metronidazole	Chloramphenicol, piperacillin

^a Fluoroquinolone can be substituted.

Although these factors influence the ability of a drug to penetrate the BBB, in many disease states, the functionality of the BBB is altered. With inflammation, a disruption of the BBB tight junctions occurs, which effectively allows entry of the drug and which, under normal states, would be excluded.¹²⁸ Many antibiotics will reach concentrations 5 to 10 times higher when the BBB is disrupted.¹⁵⁴ Of importance is that, as inflammation subsides, the BBB also returns to normal function, limiting again antibiotic penetration.¹⁰³ Similarly, other factors may influence drug activity in meningitis. These factors include changes in pH, which may reduce or inactivate the antimicrobial effects of antibiotics such as aminoglycoside; increased protein content in CSF with inflammation, resulting in binding of free (active) drug; and slower growth rates of bacteria.¹⁵⁴

92.5.1 Antimicrobial Therapy

Because the CSF is devoid of complement and opsonizing proteins, essentially an ineffective immune system, it is imperative that antibiotic reach the CNS in bacteriocidal concentrations to eradicate an infection.¹⁵⁴ Unlike extraneural infections in which the host can rely, in part, on the immune system to participate in removing microorganisms, the CNS cannot. Antibiotics can be divided based on their patterns of bactericidal activity in body fluids. Some antibiotics demonstrate increased bactericidal activity with increasing concentrations and are referred to as concentration-dependent drugs. Aminoglycosides and quinolone antibiotics fall into this category. Other antibiotics show no increases in bactericidal activity with increasing concentrations. Instead, these drugs demonstrate increases in bactericidal activity with increasing time over which the concentration remains above the minimum inhibitory concentration (MIC) of the organism ($T > MIC$). Antibiotics such as the β -lactams fall into this group. Knowledge of an antibiotic's bactericidal activity, concentration dependent versus concentration independent, influences dosing intervals. Additionally, bacteriostatic and bacteriocidal antibiotics should not be used together because the combination may be antagonistic.¹⁵⁴ Refer to [Chapter 34](#) for a more complete discussion of the drugs covered in this chapter.

Infectious Diseases of the Dog and Cat, 3rd Edition

Information in the veterinary literature describing the treatment of bacterial meningitis is limited. Compounding this lack of data is the fact that most of the experimental animal models are designed to evaluate pathophysiologic sequelae and therapeutic regimens related to specific patho-gens encountered in human medicine. Despite this lack of information, some generalizations regarding specific antibiotics can be made. Recommended antimicrobial agents used to treat specific infectious agents are presented in [Table 92-4](#). Dosing regimens for specific antimicrobials are presented in [Table 92-5](#).

92.5.1.1

Drug Administration

Of critical importance in the successful treatment of bacterial meningitis is obtaining CSF antimicrobial concentrations above the minimum bacteriocidal concentration (MBC) for the infecting organism. Dosing regimens should be chosen that maintain CSF concentrations well above MBC for the greatest time period.

To ensure success, concentration of 10 to 30 times the MBC should be achieved.¹⁷² Given that CSF concentrations are a reflection of serum concentrations, intravenous (IV) administration is advocated for at least 3 to 5 days, and then oral administration can be used. If possible, repeat CSF analysis, as well as culture and susceptibilities, should be performed before discontinuing antibiotic therapy to ensure eradication.

Increased BBB permeability that occurs in inflammatory CNS diseases also increases the permeability to antibacterial drugs. Antibacterials are not metabolized in the CSF and therefore their concentrations are based on the balance between drug penetration and elimination. Drugs enter the CSF predominantly via passive diffusion down a concentration gradient; the main determinant is high lipid solubility. Lipoidal drugs such as quinolones or rifampin cross intracellularly and reach peak concentrations rapidly, and water-soluble β -lactams must cross intercellularly, and transport is delayed or reduced unless tight junctions between cells are compromised. Concentrations in CSF lag behind those in serum and therefore can be predicted only by repeated CSF concentration measurements for which data is largely unavailable. Meningeal inflammation not only increases permeability, but also inhibits the elimination pump so that concentrations can be unpredictable over time. With successful antibacterial treatment, inflammation is reduced and the BBB integrity improves. Further penetration of ionic drugs becomes more difficult, which is important in considering followup or long-term therapy in which the initial response to treatment is beneficial. Fortunately, many antibacterials, with the exception of some tested quinolones, have prolonged antibacterial effects and longer half-life in the CSF as compared with serum.¹⁰³

971

972

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 92-5 Antimicrobial Drug Dosages for CNS Bacterial and Fungal Infections of Dogs and Cats^a

DRUG ^b	DOSE ^c	ROUTE	INTERVAL (HOURS)
Penicillin (aqueous)	10–22 × 10 ³ U/kg	IV	4–6
Ampicillin	5–22 mg/kg	IV	6
Carbenicillin	10–30 mg/kg	IV, IM	4–6
Oxacillin (or cloxacillin)	8.8–20 mg/kg	IV, PO	4–8
Trimethoprim-sulfonamide ^d	15–20 mg/kg	IV, PO	8–12
Gentamicin ^c	2 mg/kg	IV, IM	8
Chloramphenicol	10–15 mg/kg	PO	4–6
Cephalexin	20 (10–30)mg/kg	PO	8
Cephapirin	20–30 mg/kg	IV, IM	8
Amphotericin B ^d	0.15–0.50 mg/kg	IV	48
Flucytosine	50 mg/kg	PO	8
Rifampin	10–20 mg/kg	PO	8–12
Metronidazole	10–15 mg/kg	PO	8
Cefotaxime	6–40 mg/kg	IM, IV	4–6
Enrofloxacin ^e	5–10 mg/kg	PO	12

IV, Intravenous; IM, intramuscular; PO, by mouth.

- a See discussion of drug administration for recommended duration of therapy and precautions. See respective chapters for dosages in treating viral, protozoal, and some fungal infections.
- b For further information on those drugs, see Drug Formulary, [Appendix 8](#).
- c Dose per administration at specified interval.
- d Potential for renal toxicity is greatest in cats and young or dehydrated dogs. Closely monitor renal functions and use lowest dosage under these circumstances.
- e Other fluoroquinolones such as orbifloxacin or marbofloxacin can be substituted.

92.5.1.2 Aminoglycosides

Aminoglycoside antibiotics demonstrate concentration-dependent bactericidal activity. In addition, they display a prolonged postantibiotic effect, a period during which continued inhibition of microbial growth despite concentrations below MIC occurs. Both of these properties form the rationale for once-daily dosing. However, the penetration of aminoglycosides remains poor even in the presence of significant meningeal inflammation.⁴

92.5.1.3 Cephalosporins

Largely because of their low lipophilicity, cephalosporins poorly penetrate through the BBB, achieving relatively low CSF concentrations.¹⁰² However, third-generation cephalosporins (moxalactam, ceftriaxone, cefotaxime) can cross inflamed meninges.⁹⁴ The concentration achieved by most agents varies inversely with the protein binding of the drug. In addition to the high penetration of cephalosporins, the MBC of cephalosporins for many pathogens can be low so that CSF concentrations can be achieved at levels several times higher than MBC. To achieve greater CSF concentrations, higher doses can be administered safely for longer periods given the low toxicity. Cephalosporins demonstrate time-dependent bactericidal activity.

Infectious Diseases of the Dog and Cat, 3rd Edition

Consequently, dosing regimes that result in CSF concentrations above MIC for the longest time period should be used. For these reasons, third-generation cephalosporins are currently recommended as the drug of choice for empirical therapy of bacterial meningitis in people with common meningeal microbial pathogens.¹²⁹

92.5.1.4 Chloramphenicol

Chloramphenicol has been generally classified as a bacteriostatic antibiotic; however, in concentrations achievable in tissues and body fluids, it has been shown to be bactericidal.¹³² Chloramphenicol reaches high CSF concentration (45% to 90% of serum) regardless of meningeal inflammation.⁵⁴ This drug also appears to concentrate in the CNS, reaching levels that exceed those in serum; however, large doses are required for bactericidal effects in the CNS.¹²⁵ Despite these pharmacodynamic properties, a high relapse rate occurs with this drug, suggesting it is not bactericidal at doses used in dogs and cats.¹²⁵ Consequently, this drug should not be used as a first choice.

92.5.1.5 Clindamycin

Clindamycin does not readily cross the BBB.^{11,109} Although this drug achieves clinically useful concentrations in most tissues, a notable exception is the CSF, even with inflamed meninges.⁵⁰ Brain tissue concentrations may be higher than CSF concentrations because of the lipid solubility of clindamycin.¹⁶⁸ Usage of clindamycin is limited to specific protozoal infections in the nervous system.

92.5.1.6 Fluoroquinolones

As a whole, quinolones are moderately lipophilic, exhibit low to moderate binding to serum proteins, and have a relatively low molecular weight and therefore achieve good penetration into the CNS.⁴ The pharmacodynamic effects of quinolones in CSF are different with respect to other sites in the body because they have a short postantimicrobial effect and need to continue to exceed the bactericidal concentration to achieve maximal effect.¹⁰³ Quinolones are used primarily for gram-negative aerobic infections. They can also be considered a safe alternative to aminoglycosides.

972

973

92.5.1.7 Penicillins

Generally, penicillins tend to have low penetration into the CNS, but with meningeal inflammation, concentrations are greater. CSF concentrations are approximately 1% to 2% of serum concentrations without meningeal inflammation; however, concentrations increase to 18% to 21% with meningeal inflammation.^{71,142} As stated earlier, an efflux pump can be used to eliminate penicillins from the CSF, which limits achievable concentrations.⁴ Ampicillin is the exception to these properties in that significant CSF concentrations can be obtained regardless of the state of the meninges.

92.5.1.8 Metronidazole

Metronidazole exhibits good penetration into the CSF and brain abscesses⁵⁰ and demonstrates bactericidal activity against anaerobes. Metronidazole penetrates the CSF more completely than does any other single

Infectious Diseases of the Dog and Cat, 3rd Edition

agent, with reports of CSF levels approaching 90% of those in serum.⁴ Metronidazole is used primarily to treat anaerobic infections.

92.5.1.9 Trimethoprim-sulfonamides

Trimethoprim-sulfonamides penetrate both the normal and the inflamed meninges at therapeutic levels. Recommendations are that animals that respond to ampicillin be switched to this drug for extended therapy. This drug has not been used as a first-line medication likely as a result of a lack of availability of a parenteral formulation.

92.5.1.10 Glucocorticoid therapy

Increasingly clear is that the majority of injury to the CNS in bacterial meningitis is related to the host immune system rather than the infectious organisms. In fact, the host response is accentuated at the time bactericidal antibiotics treatment is initiated, organisms are lysed, and an abrupt release occurs of inflammatory cell wall components, lipopolysaccharides, and outer membrane vesicles from the organisms.³⁹ Studies in animals have shown that bacterial lysis, induced by treatment with antibiotics, leads to greater inflammation in the subarachnoid space, which may contribute to an unfavorable outcome.⁴¹ Steroids have antiinflammatory effects. They inhibit the transcription of mRNA for TNF- α and IL-1 and the production of prostaglandins and platelet activating factor, reduce vasogenic cerebral edema, and reduce the production of inducible NOS.⁴⁸ Consequently, the use of adjunctive glucocorticoids have been advocated in the treatment of bacterial meningitis. Current recommendations for dexamethasone therapy include 0.15 mg/kg administered 15 to 20 minutes before starting antibacterial therapy and thereafter every 6 hours for 4 days or at 0.4 mg/kg every 12 hours for 2 days.¹⁴⁵ The beneficial effects of glucocorticoids were not seen if steroid use was delayed for 12 to 24 hours after the first antimicrobial dose.⁷⁸ In addition to the side effects of glucocorticoids, some concern has surfaced that steroids may reduce the penetration of antibiotics into the CSF by restoring the BBB.

Importantly, glucocorticoid use has been studied in the setting of important pathogens for humans, particularly Hib. Therefore extrapolation to veterinary medicine must be done with caution given that bacterial meningitis in veterinary patients can involve alternate primary sources, a different time course often with relapses.¹¹⁴ Empiric glucocorticoid therapy before diagnostics remains contraindicated. Glucocorticoids can alter diagnostic test results such as CSF interpretation. In addition, although many patients may benefit from their use, patients with viral, fungal, protozoal, and rickettsial meningoencephalitis may be adversely affected. Glucocorticoids may reduce the permeability of the BBB in meningitis and therefore decrease the penetration of hydrophobic antibiotics into CSF.¹⁵³

92.5.2 Supportive Therapy

Supportive care can be divided into systemic- and brain-specific therapy. Systemic therapy is aimed at correcting metabolic abnormalities. Hydration is an important aspect of treatment. In hydrated patients that are able to drink, access to water may be all that is needed. However, in dehydrated patient or those unable to drink, fluid therapy should be aimed at the restoration and maintenance of normal hydration and intravascular fluid volume. Overhydration should be avoided because it can potentiate cerebral edema. Experimentally, fluid therapy did not worsen brain edema.¹⁷⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

Hyperthermia can be treated in a wide variety of ways, ranging from adjusting the environmental temperature with air conditioning or fans, to administering IV fluids at room temperature, to more active processes such as applying alcohol to the foot pads or placing ice packs on the patient. Unless body temperature becomes dangerously high, pharmacologic treatment of fever should be avoided because the resolution of a fever may be used as an indicator of successful antimicrobial therapy. Patients with clinical and biochemical findings indicative of a systemic inflammatory response should be treated for sepsis (see [Chapter 38](#)).

Analgesia should be provided to patients with cervical hyperesthesia. The clinician must balance patient discomfort with the ability to critically judge therapeutic success and patient assessment. Care should be exercised when administering analgesics to patients with altered mentation given that some opioid analgesics can cause sedation.

Brain-specific therapy is aimed at ameliorating intracranial hypertension and seizures. Some indications of intracranial hypertension include altered mentation (obtundation, somnolence, stupor, and coma), bradycardia with systemic hypertension, papilledema, and head pressing. Mannitol is an osmotic diuretic that can be used to reduce intracranial pressure. Mannitol can be administered at a dosage of 1 to 2 g/kg of body weight IV for 5 to 10 minutes.⁷ The effect is potentiated by the co-administration of furosemide at 0.7 mg/kg of body weight IV, 15 minutes after administering mannitol.¹³⁷

In patients with seizures, anticonvulsants should be given. Phenobarbital is a safe and effective anticonvulsant medication. In general, phenobarbital is initiated at 2 to 4 mg/kg of body weight, but it can be given to a total dose of up to 16 mg/kg in circumstances such as status epilepticus.

General nursing care should be dictated by patient needs. Recumbent patients should be placed on soft-padded bedding and frequently turned to alternate recumbent positions. Assistance with bladder and bowel evacuation should be done with patients that are unable to perform these functions. Physical therapy has been described elsewhere.¹⁰⁵

92.5.3 Prognosis

Ultimately, the prognosis depends on a timely, accurate diagnosis and implementation of appropriate therapy. Despite advances in human medicine, the mortality rate in people with bacterial meningitis ranges from 5% to 40% of patients, with 30% of survivors having permanent neurologic deficits.^{86,189} These lasting consequences are divided into three categories: loss of hearing, obstructive hydrocephalus, and brain parenchymal damage as evidenced by sensory motor deficits, cerebral palsy, learning deficits, cortical blindness, and seizure disorders.¹⁷³ Several factors have been identified in people with bacterial meningitis. The degree of impairment of consciousness⁹⁷³ was correlated with prognosis, and seizures were not.⁹⁴ The age of the patient plays a role in prognosis, with children under 1 year and adults over 40 years having a worse prognosis.⁹⁴ Biochemical parameters such as CSF leukocyte count, CSF glucose concentration, and the time required to sterilize the CSF have all been evaluated in humans with bacterial meningitis.⁸¹ Additionally, CSF concentrations of IL-1 and TNF- α correlate with prognosis.^{118,187} Although prognosis has not been well established in veterinary patients, similar aspects are likely to play a role in the prognosis.⁹⁷⁴

93 CHAPTER 93 Ocular Infections

Jean Stiles

93.1 EXTRAOCULAR INFECTIONS

93.1.1 Normal Flora

Despite the fact that all dogs probably have indigenous bacteria in their conjunctival cul-de-sac, positive isolation rates of between 46% and 91% in clinically healthy dogs have been reported ([Table 93-1](#)). Variables in the type of and frequency of isolate may be a result of geography, culturing technique, breed, and season. Fungi are isolated from 10% to 22% of dogs.^{42,100}

In contrast to dogs, cats have a relatively lower rate of cultivable bacteria in their conjunctival sac.³³ Bacteria or mycoplasmas have been isolated from 34% of the conjunctival samples and from 25% of the samples from the lid margins. In one study of 50 cats, no organisms were isolated from 42% of the cats, bacteria were isolated from the conjunctiva of 34% of the cats or 47% of the eyes, and 26% of the cats or 14% of the eyes had fungal isolates from the conjunctiva ([Table 93-2](#)). No anaerobes were isolated.⁴⁰

93.1.2 Ocular Surface and Adnexa

Most surface bacterial infections are not strictly primary; other debilitating conditions often potentiate the pathogenicity of organisms that are indigenous to the ocular surface. Other local nidi of infection, such as in the lacrimal sac and meibomian glands or structures adjacent to the eye (ears, lip-folds), should be sought and corrected to overcome persistent or recurring infection. Control of the normal ocular flora is maintained by rinsing of the ocular surface with tears and blinking, which pushes the tears into the nasolacrimal (NL) system. Tears also contain IgA and other antibacterial substances such as lactoferrin. Competitive interactions among the indigenous flora keeps the numbers of organisms lower, whereas disrupting this balance may cause an overgrowth of one species. Conditions debilitating to the ocular surface, such as reduced tear secretions, ultraviolet (UV) radiation, immune suppression (e.g., with diabetes mellitus or Cushing's disease), and trauma creating breaks in the epithelial barrier, may allow indigenous bacteria to adhere and possibly overgrow to produce disease. To become established, bacteria must adhere, replicate, and then invade the tissue. Invasion subsequently incites inflammation. Tissue damage with infection produces a combination of toxins from the organism and enzymes such as collagenase, elastase, and cathepsins liberated by the neutrophilic response.¹⁰² Bacteria, such as *Pseudomonas aeruginosa*, that have various proteolytic enzymes typically produce rapidly progressive corneal ulcers.

93.1.2.1 Blepharitis in Dogs

Blepharitis, or inflammation of the eyelids, may develop secondary to bacterial, fungal, or parasitic agents. Blepharitis can develop with other dermatologic diseases, with other ocular diseases such as conjunctivitis, or as a sole clinical presentation. Clinical features of blepharitis include eyelid swelling, erythema, skin ulceration, chalazia (granulomatous foci of inflammation along meibomian glands), and pruritis.

Infectious Diseases of the Dog and Cat, 3rd Edition

Staphylococcus species can cause a primary blepharitis and may also generate a hypersensitivity reaction. Pruritis may lead to self-trauma, exacerbating the blepharitis. Bacterial infection of the eyelids may also occur with keratoconjunctivitis sicca (KCS) or atopy.

Treatment of bacterial blepharitis should include cleansing the skin with dilute povidone iodine solution and rubbing a broad-spectrum ophthalmic antibiotic into ulcerated skin as well as placing it in the eye 3 to 4 times daily. If skin is very inflamed, an antibiotic with dexamethasone is indicated. Severe cases may require systemic antibiotic therapy such as cephalosporins and possibly antiinflammatory doses of oral glucocorticoids. Any underlying condition that can be identified should also be addressed.

Canine juvenile pyoderma develops occasionally in puppies ages 3 to 16 weeks. Early reports suggested a hypersensitivity reaction to *Staphylococcus* species, although the cause is considered unknown. Pustules and granulomatous inflammation are present in the eyelids and face. In some cases the pinna and regional lymph nodes are also affected. Rarely, joints may also be involved.

The condition responds quickly to administration of systemic glucocorticoids, suggesting an autoimmune disease. Diagnosis is based on age, history, and clinical presentation. Prednisolone (2 mg/kg/day) should be administered for 2 to 3 weeks. Lesions typically improve within a few days of beginning therapy. A systemic antibiotic such as a cephalosporin is indicated if skin has become secondarily infected with bacteria.

	<i>Bacillus</i> spp.	2–5
	<i>Corynebacterium</i> spp.	1.6

a Percentages are based on the numbers of animals from which organisms were isolated.

93.1.2.2 Blepharitis in Cats

Blepharitis in the cat is less common than in the dog. Cats appear relatively resistant to bacterial blepharitis, except when they have a traumatic injury and resulting bacterial invasion. This type of injury most commonly occurs in cat fights and may involve the head and eyelids. Abscesses near the eyelids should be opened as they would be elsewhere and appropriate systemic antibiotics administered.

93.1.2.3 Conjunctivitis in Dogs

Bacterial conjunctivitis may be a primary condition or secondary to another ocular condition such as KCS, distemper virus, a parasitic invasion, or the presence of a foreign body. Primary bacterial conjunctivitis typically occurs for unknown reasons and in some cases is secondary to an insult that is no longer apparent or is merely an overgrowth of normal conjunctival flora. The symptoms are purulent discharge with mild to moderate discomfort. Diagnosis should be based on cytologic examination of the exudate and identification of bacteria and neutrophilic inflammation. KCS should be ruled out based on a normal Schirmer tear test. Bacterial overgrowth is common when tear production is low, and the underlying problem of KCS must be addressed. Culture is typically not warranted for bacterial conjunctivitis unless response to therapy is poor. A complete ocular exam, including a Schirmer tear test, fluorescein staining of the cornea, fluorescein evaluation of NL duct patency, and a search for a foreign body in the conjunctival sac and behind the third eyelid, should be performed. Therapy should include a broad-spectrum topical antibiotic such as bacitracin-neomycin-polymixin B every 6 hours until resolution.

Viral conjunctivitis in dogs has been associated most often with distemper virus. The first signs of distemper are bilateral conjunctivitis with a discharge that progresses from serous to mucopurulent. The virus may also invade lacrimal tissue, causing an adenitis that results in KCS. In this situation the cornea may become ulcerated and possibly even become perforated. KCS typically resolves over several weeks in dogs that recover from distemper. Early diagnosis of dogs with distemper may be possible by fluorescent antibody stains of conjunctival epithelial cells obtained from a scraping.

Therapy should include cleansing of eyes, application of a broad-spectrum topical antibiotic to help prevent secondary bacterial infection, and if KCS is present, topical cyclosporine and artificial tears.

Infectious Diseases of the Dog and Cat, 3rd Edition

93.1.2.4 Conjunctivitis in Cats

Bacterial conjunctivitis in cats is unusual, with the exception of infection with *Chlamydomphila felis*, which is a common cause of conjunctivitis in cats (see [Chapter 31](#)). The typical clinical picture is unilateral conjunctivitis with involvement of the second eye a few days later. The clinical presentation is indistinguishable from conjunctivitis caused by feline herpesvirus-1 (FHV-1), and the two organisms may be present simultaneously. Diagnosis is based on seeing the typical elementary body in the cytoplasm of conjunctival epithelial cells ([Fig. 93-1](#)) or obtaining a positive fluorescent antibody (FA) test result on a conjunctival scraping. *C. felis* can also be cultured but requires special transport media. Elementary bodies are often few in number and the numbers diminish with chronicity, making them easy to miss. In an experimental study of chlamydial conjunctivitis, infection with feline immunodeficiency virus (FIV) prolonged the duration of clinical signs and led to chronic conjunctivitis.⁸⁶ Conjunctivitis caused by *Chlamydomphila* should be treated with topical tetracycline applied to both eyes 4 times daily until resolution and then an additional 1 week. Oral doxycycline at 10 mg/kg/day was found to be superior to twice-daily topical fusidic acid or chlortetracycline in one experimental study.¹⁰³ Treatment with oral doxycycline may also be advisable to clear the GI tract of infection.⁸⁶ The potential of this organism to infect people is uncertain; however, washing hands after treating an affected cat is advised.

Mycoplasma felis has been variably implicated as a cause of conjunctivitis in cats ([Fig. 93-2](#)). Some studies have recovered *Mycoplasma* species as normal flora from feline conjunctiva, whereas others have not.

975

Similarly, experimental infections of healthy, young cats have produced conjunctivitis in some studies⁵⁰ and not in others. *Mycoplasma* organisms may require a stressor such as FHV to cause disease. *Mycoplasma* species are sensitive to many topical antibiotics, including tetracycline.

976

Fig 93-1 Intracytoplasmic *C. felis* inclusions in conjunctival epithelial cells of a cat with conjunctivitis (Giemsa stain, ×330).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 93-2 *Mycoplasma* organisms within conjunctival epithelial cells in a cat with conjunctivitis (Wright stain, ×330).

FHV-1 is a frequent cause of ocular disease in cats.^{2,106,107,120} Young cats with respiratory tract disease generally have conjunctivitis with marked conjunctival hyperemia, chemosis, and serous to purulent ocular discharge (Fig. 93-3). The condition is usually self-limiting and resolves in 1 to 2 weeks. In severe cases of herpesvirus conjunctivitis, the risk of symblepharon is high. Symblepharon, or adhesions of the conjunctiva to itself or the cornea, may lead to permanent visual impairment, and an attempt to break these adhesions early should be made. After application of topical anesthesia, a cotton-tip swab can be used to break adhesions and strip off cellular debris and fibrin. This process may need to be repeated frequently until the conjunctivitis has resolved. In severe conjunctivitis a topical antiviral such as trifluridine should also be used at least 4 times daily. In addition to general supportive care, the eyes should be cleansed frequently and a broad-spectrum topical antibiotic applied to minimize secondary bacterial infection as the conjunctival surface sloughs. Once infected, cats become latent carriers of FHV-1 and may have recurrences of ocular disease, including conjunctivitis and corneal ulcers. Many cats have transient episodes of conjunctivitis, with conjunctival hyperemia, serous or purulent ocular discharge, and blepharospasm. Most cases are self-limiting and do not require treatment. If a topical antibiotic is used, tetracycline is the most appropriate choice because of its efficacy in treating *C. felis* and *M. felis*, which are common feline conjunctival pathogens that may contribute to conjunctivitis in addition to FHV-1. *Hartmannella vermiformis*, an amebic endosymbiont that contains the *Chlamydia*-like agent *Neorickettsia hartmannellae*, has been isolated in greater prevalence from cats with keratitis or conjunctivitis than from clinically healthy cats.¹²¹

Fig 93-3 Acute conjunctivitis secondary to feline herpesvirus. Note severe chemosis and conjunctival hyperemia.

Cats may develop chronic conjunctivitis or proliferative keratitis associated with FHV-1.^{17,104} Laboratory diagnostic tests, such as virus isolation from the conjunctiva and conjunctival scrapings for fluorescent antibody testing, to prove FHV-1 as a cause of conjunctivitis in cats are frequently negative, making the diagnosis uncertain.⁸⁵ Identification of FHV-1 DNA in conjunctiva or the cornea by the polymerase chain reaction (PCR) is a more sensitive test than virus isolation or FA testing, although a high percentage of clinically normal cats have positive tests for viral DNA by PCR.^{108,116} Treatment with an ophthalmic antiviral medication such as trifluridine can be used in cats with chronic conjunctivitis, although results vary. Treatment for KCS in cats with FHV-1 conjunctivitis can include topical 0.2% cyclosporine ointment in addition to antiviral therapy. Recombinant interferon (IFN) has also been administered to cats with chronic FHV-1-related ocular disease, although no studies have documented its effectiveness. Oral (see [Chapter 2](#)) and topical administration of IFN have been used.^{76,111,112} Topical administration is discussed in the later Keratitis in Cats section.

Treatment with oral lysine has been shown to be efficacious in reducing the severity of FHV-1-induced conjunctivitis in an experimental setting.^{47,110} Cats receiving 500 mg of oral L-lysine twice daily had less severe conjunctivitis than cats receiving placebo, although the length of disease and isolation of virus did not differ between the groups. Kittens with FHV-1-related disease may benefit from administration of 250 mg oral lysine twice daily. Adult cats with frequent recurrences of FHV-1-related disease can be treated long term with 500 mg of oral lysine twice daily. Lysine should be given with food to avoid gastric upset.

Infectious Diseases of the Dog and Cat, 3rd Edition

93.1.2.5 Keratitis in Dogs

Infectious keratitis in dogs develops after a corneal ulceration or traumatic wounding. Bacterial flora inhabiting the ocular surface are those most likely to invade a corneal wound. Ulcerative keratitis and corneal abscesses are the two bacterial corneal diseases of concern. *Staphylococcus* and *Streptococcus* species are especially common, although infections with gram-negative bacteria may also develop.

Bacterial keratitis usually incites a visible neutrophilic response, characterized by a yellow to white cellular infiltrate within the cornea. Vascular growth into the cornea also occurs but usually does not begin for several days after injury and infection. Vessels originate from the limbus and grow at a rate of approximately 1 mm/day toward the site of infection. Rapid corneal destruction may occur with infectious keratitis. Invading bacteria and neutrophils may release proteases and collagenases, which contribute to corneal melting. Increased cyclooxygenase-2 expression has been documented in all corneal layers of dogs with keratitis, indicating that antiprostaglandin therapy may be a potential treatment for inflammatory keratitis.¹⁰¹ Fungal keratitis, which can be indistinguishable from bacterial keratitis, is less common but can be caused by penetrating injuries with plant material or prolonged topical treatment with antibacterial or glucocorticoid therapy. White or brown infiltrates in the cornea are more likely to be caused by fungal growth. Fungal keratitis manifests as ulcerative keratitis, interstitial inflammation, or eventually iris prolapse because of damage to Descemet's membrane and corneal perforation.

Diagnosis of infectious keratitis is based on clinical findings, cytology, and culture. Fluorescein staining is used to detect epithelial ulceration. All corneal ulcers that are progressive or involve the stroma should be cultured. A mini-tip culturette with a moistened tip should be gently swabbed over the ulcer bed. After application of topical proparacaine, a flattened spatula or the blunt end of a scalpel blade should be used to gently scrape the ulcer edge for a cytology sample. Healthy corneas have noncornified epithelial cells. Keratin debris, an occasional bacterium, and mucus may also be observed. With bacterial keratitis, neutrophils are the predominant cell type, and bacteria may be either numerous or few or not visualized on cytology. Antibacterial treatment should be instituted to prevent the colonizing bacteria from causing more damage to the cornea. The initial decision about therapy should be based on whether cocci or rods have been identified. Culture is more sensitive than cytology for detecting bacteria and is the only way to confirm the species type and its antibacterial susceptibility. Until culture results are known, the broadest spectrum of antibacterial drugs possible should be used. Often, this means combination therapy, such as a topical fluoroquinolone and cefazolin. To achieve broad-spectrum bactericidal activity, commercial antibiotics can be fortified, and injectable antibiotics can be used with artificial tears or saline to create topical formulations (Tables 93-3 and 93-4). Frequency of application is critical. In a rapidly progressive corneal ulcer, topical antibiotics should be applied every 1 to 2 hours.

Systemic antibiotics are usually not indicated unless the cornea has a penetrating wound. Fungal keratitis is also treated with topical medication because systemic drug penetration of ocular tissues is poor (Table 93-5). Topical atropine can be used 2 to 4 times daily if miosis is present, although it should not be used in dogs with KCS or glaucoma. The use of topical agents to halt the proteolytic destruction of the cornea may be beneficial. Autogenous serum, acetylcysteine, or sodium ethylenediaminetetraacetic acid applied topically several times daily have all been advocated. The author favors autogenous serum because it is readily available and not irritating, although it must be handled and maintained using a sterile technique. Serum should be refrigerated and replenished every 48 hours.

Infectious Diseases of the Dog and Cat, 3rd Edition

If fungal keratitis is documented or suspected, it should be treated with a topical antifungal agent every 2 to 3 hours (see [Table 93-5](#)). Although natamycin is the only approved ophthalmic antifungal agent, other agents such as silver sulfadiazine have proven effective and safe for topical ocular use.⁸¹

Deep corneal ulcers in danger of perforating respond best to surgical therapy, such as placement of a conjunctival flap.

Ocular discharge should be cleansed frequently to remove neutrophils and their proteolytic enzymes. If tear production is inadequate, topical cyclosporine every 12 hours and artificial tears several times daily should be administered to supplement and stimulate lacrimation. Closing the lids or placing a third eyelid flap should be avoided. These procedures limit drug contact with the cornea, impair discharge drainage, increase the temperature of the environment—thus promoting bacterial growth, fungal growth, or both—and prevent visualization of the ulcer's progress.

Systemic antiinflammatory agents can be beneficial as analgesics and to aid in the treatment of uveitis associated with deep corneal ulcers. Oral carprofen at 2 mg/kg every 12 hours is well tolerated by most dogs but is not recommended for cats.

93.1.2.6

Keratitis in Cats

Bacterial keratitis in cats may occur secondary to corneal ulcers (including those initiated by FHV-1) or traumatic wounding. Appearance, diagnosis, and treatment are the same as for the dog.

Corneal ulceration and keratitis from FHV is very common and begins with invasion of the corneal epithelium by the virus.¹⁰⁶ The most common corneal abnormality is punctate or linear epithelial erosions ([Fig. 93-4](#)), which may enlarge to form geographic ulcers. Conjunctivitis usually accompanies corneal ulcers.¹⁰⁴ Mechanical debridement of loose epithelium to remove virus and treatment with a topical antiviral agent have been the most successful therapies, although many of the ulcers heal without antiviral agents. Grid keratotomies should not be performed in cats because this treatment modality appears to increase the risk of corneal sequestration.⁶⁰ Antiviral agents such as trifluridine are virostatic and should be given at least 4 times daily until the ulcer heals and for approximately 1 week afterward.

Stromal keratitis is one of the most serious manifestations of FHV-1 corneal infection and is thought to primarily be a result of an immune reaction to the virus. Clinically healthy cats without apparent infection may harbor the virus in a latent or an active form in their corneas or trigeminal ganglia.¹¹⁶ Experimentally, subconjunctival dexamethasone caused cats infected with FHV-1 to develop stromal keratitis.⁸² Stromal keratitis may develop with or without a corneal ulcer. Vascularization and cellular infiltrate of the deeper layers of the cornea, often accompanied by chronic discomfort, are typical symptoms ([Fig. 93-5](#)). Antiviral agents alone usually do not improve the keratitis. Topical antiinflammatory agents, such as glucocorticoids, nonsteroidal topical agents, or cyclosporine, may help the inflammatory response but could exacerbate the viral infection. Antiinflammatory agents should be used only in conjunction with an antiviral agent. Topical glucocorticoids may predispose cats to the development of corneal sequestration. Topical IFN has been used in humans with herpetic keratitis and may be beneficial in cats,^{76,111,112} although controlled studies are lacking. Lyophilized recombinant α -IFN can be reconstituted in saline and used as a topical drop. The dosage for cats is typically one drop every 6 hours of a solution ranging from 100 to 2500 U/ml, whereas in humans

977

980

Infectious Diseases of the Dog and Cat, 3rd Edition

up to 10^6 U/ml have been used. Oral IFN can also be used and is discussed in [Chapter 2](#). Lysine for ocular herpetic disease is discussed under feline conjunctivitis.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 93-4 Fortified and Noncommercial Topical Antibiotic Solution Preparation

Gentamicin (fortified)

Gentamicin injectable (50 mg/ml)	6 ml
Artificial tears	24 ml
TOTAL	30 ml

Final concentration = 10 mg/ml (1% solution)

or

Add 2 ml of injectable gentamicin (50 mg/ml) to the 5-ml bottle of commercial ophthalmic gentamicin solution (0.3%)

Final concentration: 14 mg/ml (1.4% solution). Shelf-life: 30 days

Amikacin

Amikacin injectable (250 mg/ml)	4 ml
Artificial tears	26 ml
TOTAL	30 ml

Final concentration = 33 mg/ml (3.3% solution)

or

Remove 2 ml from a 15-ml squeeze bottle of artificial tears and discard

Add 2 ml of injectable amikacin (50 mg/ml)

Final concentration: 6.7 mg/ml (0.67% solution). Shelf-life: 30 days

Ampicillin

Mix 125-mg vial ampicillin with sterile saline or artificial tears to a concentration of 20 mg/ml

Cefazolin

Remove 2 ml from a 15-ml squeeze bottle of artificial tears and discard

Reconstitute a 500 or 1000 mg vial of cefazolin with sterile saline to a concentration of 250 mg/ml

Add 500 mg of the reconstituted cefazolin (2 ml) to the bottle of artificial tears

Final concentration: 33 mg/ml (3.3% solution). Shelf-life: 14 days. Keep refrigerated

Cephalothin

Remove 6 ml from a 15-ml squeeze bottle of artificial tears and save

Add the 6 ml of tear solution to a 1000 mg vial of cephalothin

Add the entire 1000 mg of the reconstituted cephalothin (6 ml) to the bottle of artificial tears.

Final concentration: 67 mg/ml (6.7% solution). Keep refrigerated

Ticarcillin

Reconstitute a 1-g vial of ticarcillin with 10 ml of sterile saline

Add 1.0 ml (100 mg) of this solution to a 15-ml squeeze bottle of artificial tears.

Final concentration: 6.7 mg/ml (0.67% solution). Shelf-life: 4 days. Keep refrigerated

Tobramycin (fortified)

Add 1.0 ml of injectable tobramycin (40 mg/ml) to a 5-ml bottle of commercial ophthalmic tobramycin solution (0.3%)

Final concentration: 9.2 mg/ml (0.92% solution). Shelf-life: 30 days.

Vancomycin

Remove 9 ml from a 15-ml squeeze bottle of artificial tears and discard

Reconstitute a 500-mg vial of vancomycin with 10 ml of sterile saline

Add the entire 500 mg of reconstituted vancomycin (10 ml) to the bottle of artificial tears

Final concentration: 31 mg/ml (3.1% solution). Shelf-life: 4 days. Keep refrigerated

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 93-5 Corneal stromal keratitis in cat. Note corneal vascularization, edema, and conjunctivitis.

Corneal sequestration is a common disorder in cats, particularly Persians and Himalayans, and may follow chronic corneal ulcers or keratitis caused by FHV-1 (Fig. 93-6). It has been noted to occur after topical glucocorticoid treatment in FHV-1 experimentally infected cats, and in cats receiving grid keratotomy.^{60,83} The condition is characterized by an area of corneal degeneration with a brown to black discoloration. The lesions vary from pinpoint sequestra to those that occupy more than half the cornea; vascularization may be intense or absent; and ocular pain ranges from none to marked. Like stromal keratitis, sequestra can be one of the most serious and potentially blinding sequela of FHV-1. Most ophthalmologists recommend keratectomy followed by a graft (corneal or conjunctival) as the therapy for sequestra.

Infectious Diseases of the Dog and Cat, 3rd Edition

93.1.2.7 Dacryocystitis in Dogs and Cats

Dacryocystitis, or inflammation of the NL system, is usually associated with a bacterial infection. NL foreign bodies such as plant material are frequently the inciting cause. Dacryocystitis is more uncommon in cats than dogs. Clinical manifestations of dacryocystitis include conjunctival hyperemia, especially of the ventral conjunctival sac, purulent ocular discharge, and epiphora. Blepharospasm may or may not be present. Pain, purulent exudate, or both from the lacrimal puncta occasionally can be elicited by pressing on the skin near the medial canthus. Swelling or draining tracks in the skin near the medial canthus may also occur.

The diagnosis is confirmed by NL flushing with culture of any purulent debris recovered. Dacryocystorhinography may be necessary to identify foreign bodies or cystic structures within the NL system. If foreign bodies cannot be flushed from the system, surgical removal via a dacryocystotomy may be required.

After NL flushing, a broad-spectrum antibiotic solution such as polymixin-B-neomycin-gramicidin should be used 4 to 6 times daily. Systemic antibiotics are not indicated if the infection is confined to the NL system. Repeated flushings may be needed to maintain patency. The NL duct can also be cannulated with Silastic tubing to establish and maintain patency. Stricture of the NL duct may occur with dacryocystitis leading to chronic epiphora.

93.1.2.8 Orbital Infections in Dogs and Cats

Orbital disease caused by bacterial infection generally has a fairly rapid onset compared with the slow progression of clinical signs seen with orbital neoplasia. Typical clinical signs of orbital abscess and cellulitis include periorbital swelling, exophthalmos, elevation of the nictitating membrane, conjunctival hyperemia, and pain on palpation of periorbital area or when opening the mouth (Fig. 93-7). Swelling of the oral mucosa behind the last molar is evident in some animals.

Bacterial infection of the orbit is common, especially in dogs, although fungal infections have also been reported in both dogs and cats.^{52,126} Infectious agents may gain access to the orbit by several routes, including through the oral mucosa behind the last molar, from the frontal sinus through breakdown of medial orbital bone, from tooth root abscesses in which bacteria dissect through soft tissue planes, from penetrating wounds or foreign bodies of the skin or oral cavity, and through hematogenous spread from distant sites of infection.

Fig 93-7 Orbital abscess in dog. Note severe periorbital swelling. (Courtesy Kirk Gelatt, Gainesville, Fla.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Orbital bacterial abscesses are best diagnosed with ultrasonography, in which the abscess appears as a hypoechoic area posterior to the globe (Fig. 93-8). A fungal granuloma would appear hyperechoic and could not be readily differentiated from neoplasia. Computed tomography or magnetic resonance imaging are more helpful for delineating infections that involve the respiratory system and orbit simultaneously, which is more likely in fungal infections.

Drainage of orbital abscesses should be established when possible. Because only soft tissue separates the oral cavity from the ventral orbit in the dog and cat, an incision through the tissue behind the last molar can be used to access the orbit. A small mosquito forceps should be advanced into the orbit, using blunt probing—not grasping—to attempt to hit the abscess. Any purulent material should be cultured for aerobic and anaerobic bacteria and submitted for cytologic evaluation. Pending culture results, broad-spectrum systemic antibiotic therapy such as clindamycin and a penicillin or cephalosporin should be instituted.

The prognosis for bacterial orbital abscesses is generally good, whereas the prognosis for orbital fungal infections is more guarded.

93.1.3 Diagnosis

The decision to perform cultures from the ocular surface should be made early in the examination before various eye drops have been administered and manipulations performed. The use of a moist or calcium alginate swab improves the recovery rate.^{51,118} Because the volume of material collected is usually small and subject to drying, swabs should be inoculated quickly onto appropriate media or placed in transport media.

Cytologic examination of conjunctival and corneal scrapings is an important and rapid diagnostic aid. Topical proparacaine should be applied and the appropriate surface scraped with a small, flat spatula or the blunt end of a scalpel blade. Excessive ocular discharges should be removed before scraping. Collected material should be gently spread onto glass slides and air dried. Multiple slides should be prepared, because some slides may not have adequate numbers of cells. The slides can be stained with a modified Giemsa or Wright's stain for cytologic evaluation and a Gram stain to evaluate the type of bacteria that might be present. Slides can also be made for examination by indirect FA for distemper virus, FHV, and *C. felis*.

981

Fig 93-8 Ultrasound image of retrobulbar abscess in a cat. Markers delineate a hypoechoic structure posterior to globe.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 93-9 Nylon bristle brush used to obtain conjunctival cytology specimen.

An alternate technique is to roll a small, nylon bristle-brush applicator (Microbrush, Grafton, Wisc.) over the appropriate surface and then roll it onto a slide (Fig. 93-9). Preparations made with this method have fewer cells that are dispersed better on the slide and have less crushing artifact.^{117,127} This method is less traumatic and easier to perform on cats and small dogs with tight lid-globe conformations.

Small snip biopsy specimens of the conjunctiva can be readily obtained using topical anesthesia for the animal. These small pieces of tissue should be spread out on a piece of paper before they are placed in fixative.

93.2 INTRAOCULAR INFECTIONS

Intraocular bacterial infections may be exogenous or endogenous in origin. The source of an exogenous infection from a penetrating ocular injury may be obvious from the history and appearance of the eye, but it may be an inapparent injury, such as a self-sealing cat claw injury through the conjunctiva and sclera. Exogenously induced infections are usually unilateral, whereas endogenous infections are often bilateral.

93.2.1 Local Injury

All recent perforating ocular injuries should be considered septic and treated intensively with bactericidal broad-spectrum antibiotics, topically and systemically, until susceptibility data are obtained. Topical fluoroquinolones, especially ofloxacin, have excellent corneal penetration and achieve therapeutic levels in the anterior segment against a wide variety of bacteria.¹²⁸ In suspected or confirmed bacterial endophthalmitis, a topical fluoroquinolone should be used every 1 to 2 hours. Topical antiinflammatory therapy is also indicated and may include frequent prednisolone acetate or a nonsteroidal agent such as flurbiprofen. Systemic broad-spectrum antibiotic therapy as well as systemic antiinflammatory therapy should also be administered.

Most active intraocular inflammations associated with perforating injuries should have centesis performed. Anterior chamber centesis for cultures and cytology is safe and may yield specific information to guide future

Infectious Diseases of the Dog and Cat, 3rd Edition

therapy. Aqueous centesis is not as reliable as vitreous centesis in demonstrating bacterial growth in endophthalmitis; consequently, negative culture results from an aqueous sample are not definitive evidence of sterile inflammation.³⁷ Sepsis is indicated on oculocentesis by degenerate neutrophils and bacteria. Nondegenerate neutrophils may indicate a sterile purulent inflammation such as phacoclastic uveitis (phacoanaphylaxis, lens-induced inflammation) caused by lens capsule rupture.

93.2.2 Systemic Disease

The eye is often a target organ for systemic infectious agents. The ocular disease may be the primary complaint, with the systemic disease being unidentified or overlooked. It is important to recognize the systemic involvement to give an accurate prognosis and provide adequate therapy. Conversely, animals with systemic disease should have ocular examinations, which may provide rapid diagnostic clues and prognostic information. Most infectious agents access the eye via the uveal or vascular tunic. Typically, infectious agents or immune complexes become established in the uvea, producing a posterior uveitis or chorioretinitis, an anterior uveitis, or if overwhelming, endophthalmitis or panophthalmitis.

93.2.2.1 Canine Distemper

Ocular signs of distemper (see [Chapter 3](#)) usually include bilateral conjunctivitis with a discharge that progresses from serous to mucopurulent. The palpebral conjunctiva is primarily involved. Lacrimal adenitis may result in reduced tear production, which in turn results in more profound signs of conjunctivitis, corneal ulceration, and pain. The dry eye usually resolves if the animal recovers from systemic infection. Occasionally, conjunctival or lacrimal involvement has such mild systemic signs that distemper is not suspected.

Distemper virus often produces a multifocal, nongranulomatous chorioretinitis that does not usually cause blindness. The prevalence of chorioretinitis is unknown but probably varies, as do the neurologic signs, with strain of virus and immune competency of the host. Dogs with neurologic forms of distemper had an overall prevalence of chorioretinal lesions of 41%, but 83% of the dogs with chronic leukoencephalopathy syndromes had chorioretinal lesions.¹¹⁵ Occasionally, chorioretinitis is diffuse and blinding and may mimic the genetic syndrome of progressive retinal atrophy. Acute focal lesions in the tapetum or nontapetum have gray to white, hazy or ill-defined borders ([Fig. 93-10](#)).³⁶ Chorioretinal scars resulting from distemper virus have sharply demarcated borders, are hyperreflective in the tapetum, and are depigmented in the nontapetum. Histologically, retinal changes are characterized by degeneration of the retina with perivascular cuffing in some instances. Lesions may be focal or diffuse degeneration of ganglion cells, proliferation of retinal pigment epithelium, atrophy of photoreceptors, disorganization of retinal layers, focal gliosis, and distemper inclusion bodies in glial cells.

982

983

Fig 93-10 Multifocal acute distemper lesions in nontapetum of dog. Active lesions are recognized by their white cellular infiltrates with hazy borders.

The most serious clinical ocular problem associated with distemper is optic neuritis.³⁵ Optic neuritis is characterized by an acute onset of bilateral blindness and mydriasis. If inflammation extends rostrally to the optic papilla, ophthalmoscopic signs of peripapillary hemorrhages and edema, retinal vascular congestion, and elevation of the papilla are observed (Fig. 93-11).³⁵ If the neuritis remains retrobulbar, the diagnosis is made by exclusion (e.g., blind eyes with mydriasis and normal retinal function as tested by electroretinography). The optic neuritis may be isolated, prodromal, or concurrent with other neurologic distemper signs. Distemper-associated blindness also may occur with inflammation of the occipital cortex or optic radiations, but pupillary reflexes are usually normal under such circumstances. Optic neuritis may occur with other central nervous system (CNS) inflammatory conditions such as granulomatous meningoencephalitis (see Chapter 84).

Ocular signs are suggestive but not definitive for distemper. Acute lesions of chorioretinitis usually correlate well with concurrent systemic disease, but chorioretinal scars do not. Finding distemper inclusions or positive immunofluorescence on a conjunctival scraping may be of diagnostic help early in the course of systemic disease (5 to 21 days after inoculation), but a negative finding is inconclusive. Distemper should be considered in any animal with acute optic neuropathy or an acute onset of KCS.

Fig 93-11 Acute optic neuritis characterized by elevated disc, peripapillary hemorrhages, and loss of vision. Distemper is one cause for this syndrome.

Because no specific antiviral therapy is available, treatment is primarily symptomatic. Acute optic neuritis or severe chorioretinitis should be treated with systemic antiinflammatory dosages of glucocorticoids. Dry eye should be treated with topical cyclosporine twice daily and artificial tears. Corneal ulcers should also be treated with a topical broad-spectrum antibiotic several times daily.

93.2.2.2

Infectious Canine Hepatitis

Canine adenovirus-1 (CAV-1) infection has been estimated to produce ocular lesions in approximately 20% of dogs recovering from natural infections, whereas a 0.4% or less prevalence has been noted in CAV-1-vaccinated dogs (see [Chapter 4](#)). The universal use of CAV-2 for immunization has made the postvaccinal reaction of corneal edema and uveitis much less common. The lesion, considered to be an immune complex Arthus reaction, occurs 10 to 21 days after vaccination and requires about an equal time to resolve. The condition is bilateral in 12% to 28% of the cases. The Afghan hound has been reported to have an increased prevalence,¹⁹ and other sight hounds and Siberian huskies may have similarly high frequencies of ocular reactions to CAV-1.

The most visible ocular lesion is stromal corneal edema resulting from inflammatory damage to the corneal endothelium ([Fig. 93-12](#)). Occasionally, a dog has signs of uveitis (blepharospasm, miosis, hypotony, and

Infectious Diseases of the Dog and Cat, 3rd Edition

aqueous flare) 1 to 2 days before the corneal edema is evident. Corneal edema may be focal or generalized and is usually transient. In some instances, the edema is permanent or may require several months to clear. A marked hypotony combined with altered corneal rigidity may result in a keratoconus. Glaucoma, the most significant sequela of uveitis, may be missed in the early stages because of the preexisting corneal edema and conjunctival hyperemia. Uveitis associated with vaccination is usually diagnosed by the typical ocular lesions combined with the history of recent vaccination in a puppy or young (younger than 2 years of age) dog. Other causes of corneal edema, such as congenital pupillary membranes, glaucoma, or corneal ulceration, should be ruled out. Therapy is similar to that for other forms of nonseptic anterior uveitis—specifically, topical prednisolone acetate 4 to 6 times daily and atropine to achieve mydriasis. Oral carprofen may also be helpful.

983

984

Fig 93-12 Diffuse corneal edema induced by vaccination with canine adenovirus-1 live vaccine.

93.2.2.3 Canine Herpesvirus Infection

Canine herpesvirus (CHV) infection (see [Chapter 5](#)) in the adult dog has produced only a transient conjunctivitis and vaginitis of 4 to 5 days duration. Occasional dendritic corneal ulceration patterns are seen in the dog, but their cause has not been determined. Neonatal CHV infection produces a bilateral panuveitis with keratitis, synechiae, cataracts, retinal necrosis and disorganization, retinal atrophy and dysplasia, and optic neuritis and atrophy.¹

Infectious Diseases of the Dog and Cat, 3rd Edition

93.2.2.4 Rickettsial Agents of Dogs

93.2.2.4.1 Ehrlichiosis

Ocular lesions occur frequently in dogs with ehrlichiosis caused by *Ehrlichia canis*, although the ocular abnormalities may vary in severity and do not develop in every patient (see [Chapter 28](#)). The most typical lesions include unilateral or bilateral anterior uveitis characterized by one or more of the following: conjunctival and episcleral hyperemia, miosis, aqueous flare, hypopyon, keratic precipitates, hyphema, synechiae, and hypotony. Glaucoma may occur secondary to chronic anterior uveitis ([Fig. 93-13](#)). Signs of posterior segment inflammation may include chorioretinitis as evidenced by inflammatory cell infiltrate under and within the retina, serous retinal detachment, retinal hemorrhage, and optic neuritis. Optic neuritis may be evidenced by a swollen optic disk and peripapillary hemorrhages. Anterior uveitis has also been seen in dogs naturally infected by *Ehrlichia chaffeensis*.⁸ In an experimental study of dogs infected with *E. canis*, *E. chaffeensis*, or *Ehrlichia ewingii*, histologic examination of eyes showed uveitis only in dogs infected with *E. canis*.⁹¹ The lymphocytic inflammatory infiltrate was most intense in the ciliary body, becoming less intense in the choroid, iris, and retina, respectively.

The granulocytic ehrlichial agents *E. ewingii* and *Anaplasma phagocytophilum* have not been as extensively studied as *E. canis*. However, it appears that they may also be capable of inciting ocular inflammatory disease in dogs.¹⁰⁵ They cause polyarthritis and meningitis in dogs and would be expected to cause uveitis. Inflammation at these sites is characteristic of depositing immune complexes or bloodborne agents such as rickettsiae (see [Chapter 28](#)). More information is needed to define the pathogenesis of these agents, but serum antibody titers that include these agents should be measured in dogs being evaluated for tickborne disease.

Fig 93-13 *E. canis*–induced anterior uveitis with hyphema. Iris bombe is present.

Infectious Diseases of the Dog and Cat, 3rd Edition

93.2.2.4.2 Thrombocytic Ehrlichiosis

Anaplasma platys (*Ehrlichia platys*), the agent of canine infectious cyclic thrombocytopenia, is common, particularly in the southern states. Based on serologic evidence, dogs in Florida and Louisiana have a high rate of infection.

Uveitis with *A. platys* infection has been only infrequently reported.^{8,44} It is possible that uveitis occurs more commonly than the literature suggests and is missed. If the organism is not detected within platelets on a blood smear, an antibody test for *A. platys* may not be requested for a dog with uveitis. Likewise, if platelet numbers are not dramatically low, infection with *A. platys* may not be suspected.

93.2.2.4.3 Rocky Mountain Spotted Fever

Ocular lesions are frequently associated with Rocky Mountain spotted fever (RMSF) caused by *Rickettsia rickettsii* and primarily arise as a consequence of vasculitis (see [Chapter 29](#)). Lesions include conjunctival hyperemia, subconjunctival hemorrhage, hyphema, anterior uveitis, iris hemorrhage, retinal hemorrhage, retinal edema, and retinal perivascular inflammatory cell infiltrate ([Fig. 93-14](#)). Fluorescein angiography in experimentally infected dogs demonstrated increased retinal vascular permeability beginning on day 6 after infection and 2 days after the onset of pyrexia.²² Venules were found to be affected twice as frequently as arterioles, and smaller vessels were affected more frequently than larger primary vessels. Retinal vascular lesions in this study paralleled the progression of fever, leukopenia, thrombocytopenia, and prolongation of activated partial thromboplastin time during the second week after infection.

It is critical to examine the fundus of dogs confirmed or suspected to have RMSF, because the anterior segment may be normal, although iris hemorrhage and hyphema develop as well. Lesions tend to be bilateral in affected dogs but may not be symmetrical. Nystagmus may occur in dogs that have vestibular disease associated with RMSF.

984

985

Fig 93-14 Multifocal retinal hemorrhages in a dog with Rocky Mountain spotted fever.

Infectious Diseases of the Dog and Cat, 3rd Edition

The ocular signs of RMSF may overlap with those of canine ehrlichiosis. Although ocular hemorrhages are the most common ophthalmic sign of RMSF, hemorrhage may also occur with ehrlichiosis. Although exceptions occur, intraocular hemorrhages and inflammatory cell infiltrates tend to be less dramatic in RMSF than ehrlichiosis.⁴⁵

93.2.2.4.4

Therapy for Rickettsial Disease

Treatment of ocular signs of canine ehrlichiosis must include antiinflammatory therapy in addition to appropriate systemic antimicrobial therapy (see [Chapter 28](#)). Appropriate topical glucocorticoid preparations for treating anterior uveitis include 1% prednisolone acetate and 0.1% dexamethasone. Frequency is dictated by the severity of the uveitis, but administration every 6 hours is typically the minimum desirable frequency. Choroiditis or other posterior segment disease must be treated by the systemic route and should include an antiinflammatory dose of oral prednisolone. In addition to treating posterior segment ocular disease, oral glucocorticoids are helpful in reducing other immune-mediated consequences of ehrlichiosis, such as vasculitis and the production of antiplatelet antibodies that result in worsening thrombocytopenia.

Ocular lesions in dogs infected with RMSF may resolve quickly with appropriate systemic antibiotic therapy if they include only small retinal hemorrhages. If more severe uveitis occurs, systemic and topical glucocorticoid therapy as described for ehrlichiosis should be instituted.

93.2.2.5

Canine Brucellosis

Brucella canis has been documented as a cause of unilateral or bilateral anterior uveitis and endophthalmitis and is often accompanied by intraocular hemorrhage. Ocular involvement is often severe and blinding (see [Chapter 40](#)).⁴⁸ A retrospective study of the prevalence of ocular lesions among dogs examined for brucellosis at veterinary schools in the United States and Canada found that 38 of 313 (14.2%) dogs had ocular involvement.¹¹⁹ Testing for *B. canis* should be performed in dogs with unexplained uveitis or ocular hemorrhage. Therapy consists of systemic antibiotics as well as topical prednisolone acetate for anterior uveitis. The prognosis for uveitis associated with brucellosis is guarded.

93.2.2.6

Lyme Borreliosis in Dogs

Lyme disease, or borreliosis, produced by the spirochete *Borrelia burgdorferi* may cause ocular lesions in humans, horses, and dogs (see [Chapter 45](#)). An increasing number of humans is being diagnosed with ocular Lyme disease.^{79,95} The most common ocular manifestation appears to be uveitis, but neuroophthalmic disorders and surface inflammations such as episcleritis and keratitis have also been reported. Ocular manifestations are more likely to be seen in late-stage disease.

A single case report describes isolation of *B. burgdorferi*, which was isolated from the eye of a pony with uveitis.¹⁰ However, such documentation is lacking in dogs. In a retrospective review of 132 dogs seropositive by indirect FA, five had the primary symptom of ocular lesions. Ocular lesions reported were conjunctivitis, anterior uveitis, corneal edema, retinal petechia, chorioretinitis, and retinal detachment.¹⁶ Follow-up with Western blot was not performed. In this study 24 dogs, were also seropositive for *E. canis*, although information was not provided as to whether dogs with ocular disease were positive for ehrlichiosis, thus it is impossible to ascribe the ocular lesions to borreliosis. Although it is highly likely that Lyme disease

Infectious Diseases of the Dog and Cat, 3rd Edition

can cause ocular disease in infected dogs, more definitive information is needed to document the condition. Diagnosis and treatment of systemic borreliosis are discussed in [Chapter 45](#). Ocular disease should also be treated with topical prednisolone acetate 4 to 6 times daily for anterior segment inflammation and oral prednisolone at a dose of 1 to 2 mg/kg/day for posterior segment inflammation.

93.2.2.7

Leptospirosis in Dogs

Leptospirosis, a spirochete bacterial infection, can affect any organ but has been primarily associated with renal disease in the dog (see [Chapter 44](#)). Leptospire incite vasculitis and endophthalmitis, making the eyes a potential target organ. Although leptospire have been found in the eyes of infected dogs, the paucity of reports of uveitis associated with canine leptospirosis in the literature probably does not reflect the true incidence of disease.³⁰ Leptospirosis is considered a major cause of uveitis in horses and has also been reported in humans. In these species the development of uveitis often occurs months after acute infection. This likely represents a delayed hypersensitivity reaction between cell-bound antibodies and persistent leptospiral antigens in the eye. This delayed response has not been reported in the dog. The author has seen dogs with anterior uveitis, as well as chorioretinitis with retinal detachment, and high serum titers against serovars canicola, grippityphosa, pomona, and bratislava.

Treatment should consist of appropriate systemic antibiotic therapy. Anterior uveitis should be treated with frequent topical prednisolone acetate, whereas chorioretinitis with or without retinal detachment should be treated with oral prednisolone at a dose of 1 to 2 mg/kg/day.

93.2.2.8

Neosporosis in Dogs

Neospora caninum is a protozoal parasite that is morphologically similar to *Toxoplasma gondii* (see [Chapter 80](#)). Transplacental transmission has been documented, and reports in the dog have primarily involved infections in neonates and puppies younger than 6 months of age. Although puppies die or are euthanized because of neuromuscular signs, ocular lesions are present in many cases. The ocular lesions are primarily a retinitis with extension into the choroid (retinochoroiditis). A mild anterior uveitis was also reported.²⁸

985

93.2.2.9

Leishmaniasis in Dogs

The dog is a reservoir host for the protozoal organism *Leishmania donovani* in endemic areas of the Mediterranean, Africa, and Asia (see [Chapter 73](#)). Most documented cases in North America have been in dogs imported from endemic areas, but reports involving a closed research colony of English foxhounds in Ohio and Oklahoma indicated that once introduced, the agent can be transmitted in the United States.¹¹³ Leishmaniasis was diagnosed in a Maryland poodle that had not traveled outside the United States.³¹

986

Ocular and periocular lesions associated with leishmaniasis developed in 25% of 105 dogs in a study.⁹⁴ In 15% of the dogs in the study, ocular lesions were the only clinical sign. Clinical ocular disease, in decreasing order of frequency, included anterior uveitis, conjunctivitis, keratoconjunctivitis, periocular alopecia, diffuse blepharitis, posterior uveitis, orbital cellulitis, and a solitary eyelid nodule.

The diagnosis is made by histopathologic identification of the organism, serologic testing, PCR testing, or all of these. In dogs with conjunctivitis, scraping and cytologic examination have revealed the organism in some cases. The inflammation is mononuclear, and the organism is found within histiocytes.

Infectious Diseases of the Dog and Cat, 3rd Edition

Therapy is discussed in [Chapter 73](#). In addition to systemic antiprotozoal therapy, keratoconjunctivitis or uveitis should be treated with topical prednisolone acetate several times daily. Blepharitis can be treated with a topical ophthalmic antibiotic-dexamethasone ointment that is rubbed into the skin several times daily, whereas posterior uveitis should be treated with oral prednisolone at a dose of 1 to 2 mg/kg/day.

93.2.2.10 Other Bacterial Infections of Dogs

Septicemias caused by various bacteria may affect the eyes. Infections such as bacterial endocarditis, urinary tract infection, pyometra, and dental infection may cause uveitis through hematogenous spread of bacteria to the eye. Simultaneously cleaning teeth and performing intraocular surgery should be avoided to minimize the risk of bacteria localizing in injured ocular tissue. Contagious bacterial infections such as tuberculosis and salmonellosis may also manifest with ocular lesions.

93.2.2.11 Mycoses of Dogs and Cats

The systemic mycoses in North America are frequently associated with a granulomatous posterior uveitis. Anterior uveitis accompanies chorioretinitis in a large number of cases. With the exception of cryptococcosis, systemic fungal infections are less common in the cat than the dog; however, when they develop, ocular lesions are often present. In many animals, the ocular signs are the primary symptom.

In indigenous regions of the Mississippi and Ohio Rivers and the central Atlantic states, *Blastomyces dermatitidis* is common in dogs (see [Chapter 59](#)). Ocular involvement occurs in up to 52% of the cases.⁶ Ocular lesions are from chorioretinitis, which may vary from a focal granuloma in the fundus to widespread subretinal infiltrates of organisms and granulomatous inflammation ([Fig. 93-15](#)).¹¹ Anterior uveitis is common with extensive posterior segment disease, although the organism is not usually found in these tissues or in aqueous humor aspirates; however, in cases with endophthalmitis and granulomas in the anterior segment, the organism is widespread within the eye ([Fig. 93-16](#)). Secondary glaucoma is a frequent complication.

Histoplasma capsulatum infection develops most commonly in the Ohio, Missouri, and Mississippi River valleys but has been reported in many states in North America (see [Chapter 60](#)). As evidenced by published reports, ocular involvement with histoplasmosis is relatively rare in dogs.⁴⁸ In the cat, systemic histoplasmosis causes nonspecific clinical signs such as weight loss, anorexia, fever, and anemia. Ocular lesions occur in a fairly high percentage of affected cats and include granulomatous chorioretinitis, retinal detachment, anterior uveitis, and secondary glaucoma.⁴³

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 93-16 Endophthalmitis caused by blastomycosis in a cat. Note granuloma in anterior chamber. (Courtesy Sheryl Krohne, West Lafayette, Ind.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Coccidioides immitis is endemic in the southwestern United States, Mexico, and Central and South America (see [Chapter 62](#)). Ocular lesions are similar to those of blastomycosis, namely granulomatous chorioretinitis, retinal detachment, anterior uveitis, and secondary glaucoma. Organisms are found predominantly in the choroid. Limited data exist regarding the prevalence of ocular lesions in dogs and cats with coccidioidomycosis. Ocular lesions may be the presenting sign in up to 42% of dogs, and in 80% of dogs the lesions are unilateral.⁴ One study found that 13% of 48 cats had ocular lesions.⁴⁶

Cryptococcus neoformans is the most commonly reported feline mycotic infection and enters the body through the respiratory tract (see [Chapter 61](#)). This mycotic infection is common in dogs as well.

Chorioretinitis with granulomatous inflammation and retinal detachment is the most common manifestation; anterior uveitis is less common. The appearance of chorioretinal lesions is often somewhat different than the other mycotic infections. Tapetal lesions are usually dark gray in color, in contrast to the whitish appearance of most fungal granulomas ([Fig. 93-17](#)). Optic neuritis may also develop, particularly if the CNS is involved. A feline case of adnexal cryptococcus without intraocular or systemic lesions has been described.⁷³

Fig 93-17 Multifocal subretinal granulomas in a dog with cryptococcosis. Larger lesions are producing small bullous detachments.

Bilateral granulomatous chorioretinitis or endophthalmitis should suggest the possibility of systemic mycoses. Associated systemic signs of fever and respiratory, skeletal, dermatologic, or CNS involvement are often present. The specific diagnosis is often made by finding the organism in tissue aspirates. Vitreal centesis in an eye with endophthalmitis may be the best method of diagnosis if other sites are unyielding.

Therapy for ocular involvement with the systemic mycoses includes appropriate systemic antifungal therapy as discussed in [Chapter 57](#). In many instances the ocular inflammatory reaction continues to worsen with systemic therapy because of the immune reaction to the dying organisms. The use of oral prednisolone at a dose of 1 to 2 mg/kg/day has been extremely valuable in halting this vision-threatening inflammatory response. Oral prednisolone should be continued until fundic lesions completely resolve, which may take

Infectious Diseases of the Dog and Cat, 3rd Edition

several weeks to months.⁵⁹ If anterior uveitis is present, topical prednisolone acetate should be used several times daily, tapering once the overall disease is in remission.

Enucleation of blind eyes has been proposed as a means of eliminating a nidus of infection that may cause relapses. Although it is justifiable to remove a blind, painful eye (such as one with glaucoma), no rationalization can be made for removing an eye that has been affected by blastomycosis but is comfortable.

93.2.2.12 Protothecosis in Dogs and Cats

Prototheca species are ubiquitous algae in soil and water and occasionally pathogenic in dogs and cats (see [Chapter 69](#)). More than 50% of affected dogs have ocular involvement,⁷⁸ whereas ocular lesions have not been reported in cats. Most dogs with ocular lesions also have systemic signs such as diarrhea, but in some instances the systemic signs are inapparent or missed. Lesions include a granulomatous posterior uveitis, often with retinal detachment, that is similar in appearance to those associated with fungal infections like blastomycosis. Anterior uveitis is often present as well. Definitive diagnosis is usually made by finding the organism in aspirates, urine sediment, or biopsy samples. Vitreous centesis often yields the organism in dogs with ocular protothecosis. No efficacious therapy has been reported.

93.2.2.13 Toxoplasmosis in Cats and Dogs

Generalized toxoplasmosis has been associated with ocular inflammation in cats and dogs (see [Chapter 80](#)). The most prominent lesion is choroiditis with extension into the retina.²⁰ These lesions typically appear as multifocal dark gray infiltrates in the tapetal fundus and fluffy white infiltrates in the nontapetal fundus. Anterior uveitis also occurs, and *T. gondii* bradyzoites and tachyzoites have been identified histopathologically in the iris and ciliary body of systemically affected cats.²⁸

The ability of *T. gondii* to cause ocular disease without systemic disease is poorly understood. The fact that many cats have positive serum antibody titers to *T. gondii*, particularly IgG, makes it difficult to correlate uveitis alone with toxoplasmosis. It is possible that *T. gondii* may incite an immune-mediated uveitis without systemic disease. Several mechanisms have been proposed, including homing of activated immune cells to ocular tissues, molecular mimicry, circulating antigens or immune complexes from nonocular sites of parasite replication, and a nonspecific increase in immune response.^{20,23} In kittens experimentally infected in utero or in the early neonatal period, chorioretinitis and anterior uveitis developed without other evidence of clinical illness.⁹⁷

Serologic testing for *T. gondii* should include IgM and IgG. IgM increases and decreases for 3 months after infection, whereas IgG stays elevated for years. Cats coinfecting with FIV and *T. gondii* may develop a positive IgM titer, whereas the IgG titer remains negative.⁶⁵

T. gondii-specific antibodies can be measured in aqueous humor. Antibody levels can be compared with serum levels through use of the Witmer-Goldman coefficient, or C-value. C-values of greater than 8 suggest intraocular antibody production and may be more helpful than serum titers alone in diagnosing ocular toxoplasmosis. Aqueous humor can also be evaluated by PCR for the presence of *T. gondii* DNA.⁷⁴

Treatment of ocular toxoplasmosis in cats and dogs should include clindamycin at a dose of 12.5 mg/kg every 12 hours for 21 to 30 days.⁶⁴ The uveitis should also be treated with antiinflammatory agents such as

Infectious Diseases of the Dog and Cat, 3rd Edition

topical prednisolone acetate or a nonsteroidal ophthalmic preparation several times daily for anterior uveitis. Chorioretinitis should be treated with oral prednisolone at a dose of 1 to 2 mg/kg/day until resolution.

93.2.2.14 Feline Immunodeficiency Virus

Ocular inflammation has been associated with FIV in experimentally and naturally infected cats (see [Chapter 14](#)). Anterior uveitis is the most commonly reported ocular abnormality. Conjunctivitis, pars planitis, and chorioretinitis have also been reported. Ocular inflammation may be caused by direct viral damage to tissue, initiating immune-mediated disease, or allowing opportunistic infections to develop.¹²⁵ Other common feline pathogens, such as herpesvirus, *C. felis*, and *T. gondii*, that can cause ocular disease should be considered in FIV-positive cats. In an experimental study of chlamydial conjunctivitis, coinfection with FIV markedly prolonged the duration of clinical signs and led to chronic conjunctivitis.

Serologic evidence of coinfection with *T. gondii* was present in 28 (57%) of 49 FIV-positive cats in one study.⁹⁰ Approximately 43% of cats coinfecting with FIV and *T. gondii* had positive *T. gondii*-specific IgM serum antibody titers without a positive *T. gondii*-specific IgG titer.

987

If another infectious disease can be identified in an FIV-positive cat, it should be treated as specifically as possible. Uveitis caused by FIV can be expected to be a chronic problem. Treatment should be symptomatic and include topical antiinflammatory agents such as prednisolone acetate or a nonsteroidal agent such as flurbiprofen. For long-term use, a topical nonsteroidal drug is preferred because of the risk of exacerbating ocular herpesvirus with glucocorticoids. Oral prednisolone may be required for chorioretinitis. The author's experience in treating pars planitis has been poor.

988

93.2.2.15 Feline Infectious Peritonitis Virus

The most common ocular manifestation of infection with feline infectious peritonitis virus (FIPV) is bilateral granulomatous anterior uveitis, often accompanied by chorioretinitis (see [Chapter 11](#)). Frequently, large keratic precipitates and a fibrinous exudate are found in the anterior chamber ([Fig. 93-18](#)). The nature of the disease is a vasculitis, and it is common to see a pyogranulomatous exudate sheathing the retinal vessels ([Fig. 93-19](#)). Retinal hemorrhages and detachments may also develop.

Ocular disease is more common with the noneffusive, or dry, form of FIPV infection and may be the initial presenting sign. Diagnosis of FIPV-associated ocular disease is difficult because of the nonspecific nature of available coronavirus serum antibody tests. Rising serum antibody titers in the presence of characteristic ocular lesions is suggestive.

Because no effective treatment exists for FIPV infection, treatment of ocular disease is symptomatic. Topical glucocorticoids such as prednisolone acetate should be used several times daily for anterior uveitis. Systemic prednisolone should be used for chorioretinitis. Ocular disease may be temporarily ameliorated, but it usually recurs if the systemic disease worsens.

93.2.2.16 Feline Leukemia Virus

The predominant ocular manifestation of feline leukemia virus infection is lymphosarcoma (see [Chapter 13](#)).⁹ The uveal tract is a common site for metastasis of neoplastic lymphocytes via hematogenous spread. Cats with ocular lymphosarcoma may initially show signs of mild uveitis, including miosis, aqueous flare,

Infectious Diseases of the Dog and Cat, 3rd Edition

and keratic precipitates. As the disease progresses, the iris becomes greatly thickened and distorted with the infiltration of tumor cells. Glaucoma is a common sequela because tumor cells infiltrate the iridocorneal angle. Aqueous centesis may be helpful in making the diagnosis, because neoplastic lymphocytes readily exfoliate into the aqueous humor. In addition to intraocular involvement, invasion of the orbit by lymphosarcoma may occur. Aggressive treatment of cats with ocular lymphosarcoma with topical glucocorticoids, such as prednisolone acetate, as well as systemic therapy with glucocorticoids and other chemotherapeutic protocols can result in improvement.

Fig 93-18 Anterior uveitis with large keratic precipitates in a cat with feline infectious peritonitis.

93.2.3 Diagnosis

93.2.3.1 Aqueous Centesis

Aqueous centesis can be performed using heavy sedation or general anesthesia. A 27- to 30-gauge needle on a tuberculin syringe should be used with the “seal” broken so that movement of the plunger is smooth. The site of centesis is usually at the dorsal or lateral limbus because it is the most accessible. Topical proparacaine should be used even with sedation. A cotton-tip swab soaked in proparacaine and held at the site of centesis for 60 seconds before insertion of the needle facilitates the procedure. Forceps applied to the conjunctiva close to the limbus should be used to fixate the globe and apply counter pressure to the needle. The needle enters the cornea just rostral to the limbus and parallel to the plane of the iris (Fig. 93-20). The operator must be careful to avoid the iris, lens, and corneal endothelium. The procedure may be more hazardous in the diseased cornea because the needle point is obscured, and the increased corneal thickness results in a longer, beveled tract before the needle enters the anterior chamber. Unless the anterior chamber is collapsed, the volume that can be removed from the dog is about 0.3 ml and from the cat is about 0.5 ml. A culture swab is saturated with a portion of the aspirated aqueous, and the remaining aliquot is prepared for

Infectious Diseases of the Dog and Cat, 3rd Edition

cytology by centrifugation. If fibrin is present or iris adhesions of less than a few days' duration are present, 25 µg of tissue plasminogen activator (tPA) may be injected to dissolve clots and break synechiae.⁷²

93.2.3.2

Vitreous Centesis

Centesis of the vitreous cavity has more potential complications than aqueous centesis and is usually reserved for eyes that have lost considerable visual function. Choroidal hemorrhage and retinal tears are the two most likely complications. A 25- to 22-gauge needle with a 3-ml syringe should be used. The site of entry is 6 mm caudal to the limbus in the dorsolateral quadrant. Forceps are used to apply counter pressure, and the needle point is aimed posteriorly away from the lens and toward the center of the vitreous cavity (Fig. 93-21). The needle should be short (0.5 inch) so that it does not inadvertently pass completely across the vitreous humor and tear the opposite retina. Approximately 0.5 ml of vitreous humor can be removed for culture and cytology. If fluid cannot be obtained, minor positioning changes of the needle point should be attempted.

988

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 93-20 Aqueous centesis in a dog. A 27- to 30-gauge needle enters at limbus, avoiding iris and corneal endothelium.

Fig 93-21 Vitreous centesis in a dog. Needle enters 6 mm posterior to limbus and is directed slightly posterior and toward center of globe.

93.2.4 Therapy

The therapeutic routes available for treating ocular infections and inflammations are topical, subconjunctival, intraocular, and systemic. The routes selected depend on the location, severity of the infection, and the drug being administered. The eye has three barriers to drug penetration: the intact cornea for topical penetration and the blood-aqueous and blood-retinal barriers for systemic drug penetration. In general, drugs with a differential solubility in water and lipids and small molecular size are better able to penetrate these barriers. Inflammation or ulceration weaken these barriers to variable degrees and allow better penetration. The ability of antibiotics to penetrate into the normal eye varies by drug and route ([Table 93-6](#)).⁵³ The vitreous humor is a large, rather inert

Infectious Diseases of the Dog and Cat, 3rd Edition

structure, resulting in low drug levels by any route of drug administration except direct intravitreal injection, in which the vitreous humor acts as a depot for the relatively slow release of the drug.

93.2.4.1

Topical

Depending on the drug and whether the cornea is intact, topical therapy may provide adequate drug levels only on the surface or as deep as the iris and ciliary body. Epithelial defects of 25% to 50% increase drug penetration into the corneal stroma and aqueous by nine times, but larger defects do not produce an additional increase.⁵⁶ Other variables influencing drug concentrations via topical administration are the frequency of application, drug contact time, and drug concentration. Solutions are generally easier to apply to a painful eye and therefore are preferred in terms of compliance. To a point, a higher drug concentration increases the absorption. However, concentrated drugs may increase reflex lacrimation and become diluted by osmotically drawing fluid from the tissues.

When solutions are used, one drop (about 30 to 50 μ l) of a preparation is adequate. Multiple or rapidly repeated instillations of the same or different preparations simply increase the rate of loss via the NL duct or mutually dilute each preparation, thereby reducing the availability of each drug. Waiting an interval of at least 5 minutes between instillation of multiple drugs is preferred to allow reflex tearing to subside and prevent dilution of the previous drop.

Treatment of routine surface infections of the conjunctiva or prophylactic antibacterial therapy of corneal ulcers should include topical broad-spectrum antibiotics such as neomycin-polymyxin-bacitracin that are not applied systemically. This rationale is based on minimizing bacterial resistance to antibiotics that are beneficial in systemic therapy and avoiding sensitization of a patient by a topical antibiotic that might have potential in systemic therapy.

Reports have begun to emerge of anaphylactic reactions in cats after administration of topical bacitracin-neomycin-polymyxin B preparations.⁹⁶ Most cases have been fatal, thus it would be best not to use this formula in cats.

93.2.4.2

Subconjunctival

Subconjunctival administration of antibiotics or antiinflammatories is used primarily for anterior segment disease and can achieve therapeutic intraocular levels of medication. The major limitations of subconjunctival injections are drug irritation and ocular manipulation. The means by which a subconjunctivally injected drug reaches the interior of the eye are controversial, but direct diffusion through the sclera, which has no epithelial barrier as the cornea does, and leakage through the needle hole with topical absorption have been demonstrated. Except for long-acting drugs, most others must be readministered at 12- to 24-hour intervals to maintain therapeutic levels. Typically a single injection of a subconjunctival drug is administered, followed by topical agents, systemic agents, or both.

Drugs should be injected under the bulbar conjunctiva, not the palpebral conjunctiva. The dorsal 12 o'clock position is easiest to access. Adequate topical anesthesia is required. A proparacaine soaked cotton-tip swab should be held at the injection site for at least 60 seconds, followed by slow injection of drug with a 25-gauge needle. In many animals, this can be accomplished without sedation, although sedation may be required in some. In dogs and cats a volume of 0.2 to 0.5 ml can be administered, creating a bleb that resolves in a few hours.

Infectious Diseases of the Dog and Cat, 3rd Edition

Whereas significant posterior segment levels of drugs can be obtained when injecting near the equator of the globe, the subconjunctival route is *not* adequate for bacterial infections of the vitreous or optic nerve. Subconjunctival dosages vary by antibiotic (see [Appendix 9](#)).

989

990

Table 93-6 Intraocular Penetration of Antibacterial Agents in the Uninflamed Eye

AGENT	PENETRATION BY ROUTE

93.2.4.3

Intraocular

Intracameral or intraocular injection of antibiotics is a heroic and an extremely effective means of obtaining high levels of intraocular antibiotics for the treatment of bacterial endophthalmitis. If vision is to be preserved, the decision to use the intracameral route must be made early to avoid rapidly devastating inflammation to delicate intraocular structures. Because culture and susceptibility testing results are not available for a few days, a broad-spectrum bactericidal antibiotic is usually administered.

The use of intravitreal vancomycin is common in human medicine for the treatment of bacterial endophthalmitis following injury or intraocular surgery. Dosages of 1 mg (0.1 ml) of vancomycin have been injected into the vitreous, along with 2.25 mg (0.1 ml) ceftazidime or 0.4 mg (0.1 ml) amikacin.^{34,38,99} Typically, vancomycin is also administered intravenously. The intracameral injection of the drug combination can be repeated 3 to 4 days later.

93.2.4.4

Systemic

The systemic route of therapy is indicated in cases of chorioretinitis and optic neuritis, because topical or subconjunctival application does not result in therapeutic levels of drug in these tissues. Many drugs are

Infectious Diseases of the Dog and Cat, 3rd Edition

unable to cross the blood-retinal or blood-aqueous barrier, although some agents have good ocular penetration (see [Table 93-6](#)). However, in animals with inflammation, most drugs administered systemically do penetrate the eye. Antiinflammatory agents such as prednisolone, carprofen, and aspirin reach therapeutic levels in inflamed ocular tissue. Likewise, most antibiotics reach therapeutic intraocular levels when the blood-aqueous and blood-retinal barriers are disrupted by inflammation. Of the systemically administered antifungal azole compounds, fluconazole penetrates the eye and CNS best. Itraconazole has also been effective in many animals for treating systemic mycoses such as blastomycosis with ocular involvement.

In some cases, administration of a systemic medication may have an adverse effect on the eye. Systemic fluoroquinolones penetrate normal ocular tissue and have the potential to damage the retina. Some cats receiving systemic enrofloxacin (oral or injectable) have developed acute retinal degeneration and permanent blindness.^{39,123} This has been most notable in cats receiving greater than the recommended dose of 5 mg/kg/day. However, even lower doses may cause retinal degeneration in some cats, particularly older or debilitated animals, and all systemically administered fluoroquinolones should be viewed as potentially retinotoxic.

93.2.4.5

Adjunctive

In addition to specific antimicrobial therapy, standard nursing care involves cleansing of the ocular surface and lids with warm, moist swabs or using hot packing if lid and orbital swelling is evident. Systemic nonsteroidal agents such as carprofen or aspirin (for dogs only) are analgesic and lessen the inflammatory reaction. Topical atropine minimizes ocular pain from ciliary muscle spasms and helps prevent synechia; however, atropine should not be used if KCS, glaucoma, or iridocorneal angle compromise are present. Injection of 25 µg of tPA into the anterior chamber is an effective and dramatic means of breaking down adhesions and dissolving fibrin clots if given within 3 to 7 days of formation. Once the clot is organized, the efficacy is lost. If active or recent bleeding has occurred in the eye, intraocular rebleeding may occur after injection of tPA. Injections may be repeated if necessary. Injection of tPA into the vitreous humor is not as safe because of retinal toxicity.

94 CHAPTER 94 Environmental Factors in Infectious Disease

Craig E. Greene

94.1 MEANS OF TRANSMISSION

The reservoir of an infectious disease is the natural habitat of its causative agent. Organisms such as *Clostridium* and *Salmonella* can survive and multiply in inanimate reservoirs such as soil and water. Animate reservoirs, known as carriers, can be clinically or subclinically infected with and shed microorganisms that cause disease. Reservoirs and carriers are distinguished from the source of infection, which can be any vertebrate, invertebrate, inanimate object, or substance that enables the infectious agent to come into immediate contact with a susceptible individual. In many cases, the source is the reservoir.

The transmissibility or communicability of an infection refers to its ability to spread from infected to susceptible hosts. *Contagion* and *transmissibility* have been used interchangeably; however, the former implies spread after intimate contact. Transmission can occur between members of the same population (horizontal) or succeeding generations through the genetic material (vertical). Spread of infection to offspring by the placenta, from genital contact at birth, or in the milk is actually horizontal transmission. Not all infectious diseases are transmissible (e.g., systemic mycotic infections originate from soil rather than spreading between individuals).

Direct contact transmission is probably the most frequent and important means of spread of infection. This transmission involves direct physical contact or close approximation between the reservoir host and the susceptible individual. Venereal transmission of *Brucella canis* between dogs and bite transfer of feline immunodeficiency virus (FIV) between cats are examples of direct physical contact transmission. Aerosol droplets from respiratory, fecal, or genitourinary secretions of dogs and cats generally do not travel farther than 4 or 5 feet; therefore droplet spread can be considered a form of direct transmission. The spread of infection under such circumstances can usually be limited, as long as fomite transmission is prevented, by ensuring adequate distance between affected and susceptible animals.

Vehicle, or indirect, transmission involves the transfer of infectious organisms from the reservoir to a susceptible host by animate or inanimate intermediates known as vehicles or fomites. Indirect transmission is dependent on the ability of the infectious agent to survive temporarily adverse environmental influences. The most common animate fomites involved in indirect transmission in veterinary practice are human hands. Inanimate fomites can include anything by which an agent indirectly passes from infected to susceptible individuals, such as food dishes, cages, and surgical instruments. Canine and feline parvoviruses are often spread in this manner because of the short shedding period in infected animals and the relatively long period of environmental persistence of these viruses.

Common-source transmission involves the simultaneous exposure of a significant number of individuals within a population to a vehicle contaminated by an infectious agent. The vehicles of common-source infections are usually blood products, drugs, food, and water. Food-source outbreaks of *Salmonella* gastroenteritis have been observed in small animal practice.

Airborne spread of infection depends on the ability of resistant microorganisms to travel for relatively long distances or to survive in the environment for extended periods until they encounter susceptible hosts. Freshly aerosolized particles containing microbes rarely remain airborne for more than 1 minute unless they are smaller than 5 μm in diameter. Droplet nuclei, which are desiccated aerosolized particles containing resistant microbes, may also be carried alone or on dust particles by air currents for extended periods and distances. Resistant

Infectious Diseases of the Dog and Cat, 3rd Edition

respiratory pathogens such as *Mycobacterium tuberculosis* and *Histoplasma capsulatum* are commonly spread by this means. In human hospitals, nosocomial infections with *Staphylococcus aureus*, *Bordetella pertussis*, and *Streptococcus pyogenes* can be spread by these means.¹⁶³ *S. aureus* infections have been a concern because antimicrobial-resistant strains of *S. aureus* have been transmitted from people to dogs and cats (see [Chapters 35](#) and [99](#)).

Vector-borne disease may be considered a specialized form of vehicular or indirect contact spread whereby invertebrate animals transmit infectious agents. Vectors are generally arthropods that transmit infection from the infected host or its excreta to a susceptible individual, to its food and water, or to another source of immediate contact. Vectors such as flies may transfer organisms externally, or mechanically, on their feet or internally within their intestinal tracts. The ability of organisms to survive in the vector without further propagation has been demonstrated with *Shigella* and *Salmonella* infections. Propagative transmission means that the infectious agent multiplies in or on the vector before transfer. Transmission of the plague bacillus, *Yersinia pestis*, by fleas occurs in this manner. Transovarial transmission results when the vector transfers the organism to its progeny, as in the case of ticks transmitting *Rickettsia rickettsii*, the agent of Rocky Mountain spotted fever. Transtadial transmission, the transfer of infection only between molting stages in the life cycle of the vector, occurs in canine ehrlichiosis. True biologic (developmental or cyclopropagative) transmission by arthropod vectors involves an obligate developmental stage in the life cycle of the vector. Some of the protozoal pathogens of the dog and cat (e.g., *Hepatozoon*, *Trypanosoma*, *Leishmania*) have a developmental life cycle in the vector.

A pathogenic organism must evolve a mechanism that enables it to spread from one infected animal via the reservoir or carrier to other animals to perpetuate the cycle of infection. Generalized spread of the infection to many body tissues results in contamination of many body secretions. Acute localized respiratory and gastrointestinal (GI) infections usually result in heavily contaminated secretions or excretions, such as aerosols produced during coughing and sneezing or diarrhea and vomitus, respectively. Genitourinary infections are transmitted in urine, uterine or vaginal discharges, and semen. Occasionally, infectious organisms may be shed from open, draining wounds.

Clinical illness is not always encountered in animals that are shedding. Many subclinical carriers exist; they are usually in the chronic or convalescent stage of disease. Latent carriers may shed organisms intermittently in association with reactivation of infection. Infection potential, however, generally varies inversely with the length of time over which a disease is communicable. Acute, severe illnesses are usually associated with highly contagious secretions because transmission occurs over a short time.

94.2 ENVIRONMENTAL CONTROL OF MICROBES

The health of both humans and domestic animals depends on the ability to control microorganisms that cause or have the potential to cause disease. Destruction of the organisms occurs when the microenvironment is changed adversely by physical or chemical means. Several levels of microbial disinfection are recognized ([Table 94-1](#)). Good decontamination always requires initial cleaning to remove organic residues and debris. With prior cleaning, most of the organisms are removed and disinfectants are more effective.

Sterilization is the process by which microorganisms are destroyed by chemical or physical means. All life forms, including heat-resistant spores, are killed. Sterility is an absolute condition; no partial sterilization process is possible.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-1 Levels of Microbial Disinfection

LEVEL OF DISINFECTION	DESCRIPTION
High	Free of all microorganisms, including spores; equivalent to sterilization
Intermediate	Free of all vegetative bacteria, fungi, and most viruses
Low	Free of most vegetative bacteria, fungi, and enveloped viruses

Disinfection is the destruction of most pathogenic microorganisms, especially the vegetative forms, but not necessarily bacterial spores. Although disinfection may be brought about by physical agents, as well as chemical agents, a disinfectant is usually a chemical used on inanimate objects. Antisepsis, a special category of disinfection, is the inhibition or destruction of pathogenic microbes on the skin and mucous membranes. The assumption holds that all pathogenic vegetative microbes are destroyed; however, resident flora may persist. Importantly, the antiseptic must not be toxic to animal tissues. To reduce tissue toxicity, chemicals must be either diluted or applied for a shorter period than would be necessary to produce sterility.

Sanitation is the reduction of the number of bacterial contaminants to a safe level. A sanitizer is not concentrated enough, nor is it in contact with the organisms long enough, to effect disinfection.

In practice, in the absence of bacterial spores, sterilization and disinfection produce identical results. However, when spores are present, only the harshest of measures can ensure sterility. Unless the item to be treated can withstand sterilization procedures via autoclave or ethylene oxide (EO), either physical or chemical disinfection must be relied on to reduce the number of microorganisms to a safe level.

Protozoal cysts, mycobacteria, and bacterial spores are highly resistant to disinfection and sanitation. Prions, the proteinaceous agents that cause transmissible degenerative encephalopathies (see [Chapter 84](#)), are the most resistant infectious agents known. Some loss of infectivity of prions occurs at 100° C; however 130° C for 30 to 60 minutes is required for their inactivation. Prions are not affected by sterilizing levels of radiation, formalin, nonpolar organic solvents, burial for years, or passage through 0.1-µm filters. Their infectivity is destroyed by 1 M sodium hydroxide at 55° C or sodium hypochlorite (household bleach) diluted 1:1.

94.2.1 Physical Agents

94.2.1.1 Heat

Use of either moist or dry heat is one of the oldest physical controls of microorganisms. Of the two, moist heat, especially under pressure, is more efficient, requiring shorter exposure at a lower temperature than is needed for disinfection by dry heat. When used correctly, steam under pressure is the most efficient means of achieving sterility. The recommended temperature-pressure-exposure time to produce sterilization with an autoclave is 121° C at 15 pounds per square inch (psi) for 15 minutes or 126° C at 20 psi for 10 minutes. Steam heat is also most effective for eliminating resistant protozoal cysts, such as *Toxoplasma* and coccidia. Hot-air ovens are the most common dry-heat sterilizers, but to be effective, they must provide a consistent heat source. Dry-heat sterilization can be assumed if objects are maintained at 160° ± 10° C for a minimum of 1 hour but preferably 2 hours. Microwave oven sterilization times of dry materials are similar to those of dry ovens once the sterilization temperature is reached. The only advantage of the microwave is the shorter time it takes to achieve these temperatures. Dry heat is recommended for sterilizing cutting instruments and glassware or items that might be damaged by moisture, such as glass syringes and reusable needles.

992

993

Infectious Diseases of the Dog and Cat, 3rd Edition

94.2.1.2 Radiation

Ionizing or high-energy radiation can be produced by radioactive elements, which are sources of γ -rays, or by a cathode-ray tube that produces x-rays. γ -rays and x-ray radiations induce ionization of the vital cell components, especially nuclear DNA. Because of the cost and dangers of handling this equipment, this type of microbial control has found practical application chiefly in the industrial field. Pharmaceuticals, plastic disposables, and suture materials are generally sterilized by the manufacturer by means of ionizing radiation. Foodstuffs can be sterilized or disinfected of pathogenic microbes by using ionizing radiation. This process is safe and efficient but has met with resistance by the public. An unfounded misconception exists concerning residual radioactivity in treated foods. Nonionizing, or low-energy, radiation in the form of ultraviolet (UV) light has found practical application in the destruction of airborne organisms. Because low-energy rays do not penetrate well, they are used primarily as surface-active agents. The bactericidal range of UV light is 240 to 280 nm. UV lamps usually produce radiation in the range of 254 nm and work at maximal efficiency at temperatures of 27° to 40° C. They depend on air convection currents to circulate airborne organisms. Germicidal lamps must be positioned above eye level to prevent retinal burns. For best efficiency, the lamps can also be placed in air conditioning or heating ducts. (See Air-Borne Contaminants, under Prevention of Nosocomial Infections.)

Table 94-2 Antimicrobial Properties of Common Classes of Chemical Disinfectants

CLASS OF DISINFECTANT	BACTERIA				FUNGI		VIRUSES

Infectious Diseases of the Dog and Cat, 3rd Edition

94.2.2 Chemical Agents

Biocides (germicides) denote chemical agents having antiseptic, disinfectant, or preservative properties. In addition to the environmental control of infection, many of these agents are used to preserve food, pharmaceuticals, and medical supplies. Typically, biocides lack selective toxicity to microorganisms. The antimicrobial properties of various chemical disinfectants are summarized in [Table 94-2](#). [Table 94-3](#) describes the uses of the compounds to disinfect hospital equipment.

94.2.2.1 Alcohols

Ethyl and isopropyl alcohol are rapidly bactericidal against vegetative bacteria but have little effect against spores. Alcohols can be virucidal, provided that exposure time is adequate. Ethyl alcohol is more effective against the nonenveloped viruses than is isopropyl alcohol, whereas the reverse is true for the enveloped viruses. Ethyl alcohol is effective against *Proteus* and *Pseudomonas*, whereas isopropyl has a broader antibacterial spectrum. Alcohol is effective only as long as it remains in contact with the item to be disinfected. Because it evaporates readily, repeated applications may be needed to ensure adequate effect. Alcohol is applied primarily on viable tissues as an antiseptic agent but only on intact skin. Alcohols inactivate hexachlorophene but are used as a diluent for iodine to enhance its disinfection properties. 993

Alcohol has often been used as a rinse for povidone-iodine or chlorhexidine in skin decontamination. 994
Because water is essential for the antimicrobial action, absolute (100%) alcohol has no disinfecting qualities. Concentrations found to be most bactericidal are between 50% and 95% by volume. The two most widely employed concentrations are 70% and 85%. The alcohols are inactivated by organic soil, and they are ineffective if diluted to less than 50%. Alcohols are not effective for cold sterilization of instruments, and they dissolve lens-mounting cements, blanch asphalt tiles, and harden plastics on long-term exposure.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-3 Treatment Time Required for Chemical Disinfection of Hospital Equipment

EQUIPMENT	TYPE OF DISINFECTION ^a	DISINFECTANT ^b	EXPOSURE TIME
Objects with smooth hard surfaces	H	17	3–12 hrs
	H	18–10	15–18 hrs
	H	11	5 hrs

Rubber tubing (completely filled) and catheters	L		5 min
	H	17	3–12 hrs
	I	6, 10, 12	30 min
	L	7, 13, 14–16	10 min
Polyethylene tubing (completely filled) and catheters	H	17	3–12 hrs
	H	8–10	15–18 hrs
	I	1, 2, 6, 10, 12	30 min
	L	1, 7, 13–16	10 min
Thermometers (wiped thoroughly clean)	H	8–10	10–12 hrs
	I	2, 5, 10	30 min
	L	6	10 min
Lens instruments	H	9–11	10–12 hrs
	I	9, 10	30 min
	L	7, 13–16	10 min
Hinged instruments (free of organic material)	H	9, 10	10–12 hrs
	I	2, 8–10	20 min
	I	6, 12	30 min
	L	8–10	10 min
	L	1, 7, 13–16	20 min
Inhalation, anesthetic, and endoscopic equipment	H	9, 11	10 hrs
	H	17	3–12 hrs
	I	2, 10	20 min
	L	1, 14–16	20 min
	L	10, 11	5 min
Housekeeping (floors, furnishings, and walls)	I	3, 6, 12	20 min
	L	4, 7, 13–16	10 min

a H, High-level disinfection (free of all microorganisms; equivalent to sterilization); I, intermediate-level disinfection (free of all vegetative bacteria, fungi bacilli, and most viruses); L, low-level disinfection (free of vegetative bacteria, fungi, and most enveloped viruses).

b 1, 70%–90% ethyl or isopropyl alcohol; 2, 70%–90% ethyl alcohol; 3, hypochlorite (1000 ppm); 4, hypochlorite (100 ppm); 5, 0.2% iodine + alcohol; 6, iodophors (500 ppm); 7, iodophors (100 ppm); 8, 20% formalin + alcohol; 9, 20% formalin aqueous; 10, 2% activated glutaraldehyde aqueous; 11, 0.13% activated glutaraldehyde + phenate complex; 12, 2% phenolic aqueous; 13, 1% phenolic aqueous; 14, quaternary ammonium compounds; 15, amphoteric; 16, chlorhexidine; 17, ethylene oxide.

94.2.2.2

Halogens

These compounds are ineffective or unstable in the presence of organic material, soap, or hard water. Halogens are active against a wide variety of viruses and resistant bacteria, such as *Proteus* and

Infectious Diseases of the Dog and Cat, 3rd Edition

Pseudomonas. Table 94-4 summarizes the disinfectant activity of chlorine and iodine, which are described in greater detail.

Household bleach, a 5.25% sodium hypochlorite solution diluted to a maximum of 1:30 (vol/vol), is a common form of chlorine for disinfection. Bleach is sold with a pH of 12 to prolong its shelf life. To increase its germicidal activity, especially against spores, the bleach is diluted with water to increase the available chlorine and acetic acid to change the pH of the solution to 7.0.¹⁵¹ Increasing the temperature of the solution decreases the exposure time needed. Other than aldehydes, this chemical is one of the few that will inactivate parvoviruses. Dilution and acidifying bleach solutions reduces their stability, and bleach is also deactivated by light. Therefore bleach should be kept in opaque containers and diluted fresh daily.

Chlorine dioxide, a halogen, is superior to chlorine in the destruction of bacteria, including spores and viruses. It has high solubility and no odor, and it is unaffected by pH in the range of 4 to 10 and is nonreactive with ammonia compounds. Unlike bleach, chlorine dioxide is noncorrosive even at high chlorine concentrations. It must be generated from on-site synthesis or can be ordered in a stabilized form. Chlorine dioxide has high penetration of environmentally resistant bacterial biofilms and has been used to treat air conditioning cooling systems to remove pathogenic bacteria.

994

995

Table 94-4 Disinfectant Activity of Chlorine and Iodine^{7, 188}

CHEMICALS	CONCENTRATION (mg/L)	TEMPERATURE (°C)	TIME (min)
Chlorine			
Gram-negative bacteria	0.1	5	0.16
<i>Campylobacter</i>	0.3	25	0.5
<i>Giardia</i> cyst	2.5	60	5
<i>Cryptosporidium</i> oocyst	10	20	720
<i>Bacillus anthracis</i> spores	2.3	22	60
Unenveloped virus		5	30
Iodine			
Gram-negative bacteria	1.3	2–5	1
<i>Giardia</i> cyst	4	5	120
Unenveloped virus	0.5	5	30

Iodine is only slightly soluble in water; therefore disinfectant solutions are made by dissolving it in alcohol or combining it with organic compounds. Iodine is sporicidal, fungicidal, protozoacidal, and somewhat virucidal, depending on exposure time and concentration of free iodine. Destruction of bacterial spores requires moist contact for more than 15 minutes. Unlike chlorine, iodine exerts its effect over a wide range of pH.

Iodophors are iodine solutions complexed with surfactants or polymers, which help increase the contact of the iodine with the surface to be disinfected while limiting the concentration of free iodine. The advantages of iodophors over iodine are that they are nonstaining and produce minimal tissue damage. Organic matter may reduce their activity, especially with dilute solutions, but the effect is less marked than it is with hypochlorites. Rinsing with alcohol will reduce these solutions' residual antibacterial activity. Povidone-iodine is a complex of polyvinylpyrrolidone and iodine (Betadine solution, Purdue Frederick, Norwalk, Conn.). Such iodine compounds have been used for presurgical preparation, topical wound therapy, and joint or body cavity lavage. Solutions of 10% (undiluted) to 1% (1:9) povidone-iodine have been applied for skin and wound disinfection. Dilutions (1:4 to 1:100) of 10% stock solution result in increased bactericidal activity owing to increased concentrations of free iodine more so than in the undiluted stock solution. A 1:50 dilution of povidone-iodine is recommended as an ocular surface

Infectious Diseases of the Dog and Cat, 3rd Edition

disinfectant in presurgical situations.^{125,126} A 7.5% scrub containing an anionic detergent damages tissues and should be used only on intact skin. Bacterial concentrations are reduced on canine skin for up to 1 hour after scrub application.¹²⁵ Polyhydroxydine is a potent iodine-containing wound and skin antiseptic (Xenodine, Squibb Animal Health Division, Princeton, NJ.). It has been effective in treating canine wounds when used undiluted (100%) or as a 1:9 dilution (10%). As long as the iodophor solution maintains its color, it is effective.

Systemic absorption of iodine may result in transient reduction in serum thyroxine or bicarbonate concentrations. Contact dermatitis that persists for several hours may occur in dogs.^{125-127,142} The skin irritation may lead to inactivation of the iodine through weeping proteins and increased postsurgical infection. Iodophors are also damaging to deeper tissue fibroblasts and must be diluted to 0.001% to be applied as wound or body cavity rinses.⁹⁸ Concentrations of 0.5% to 1% have been effective but may be too strong for lavage of contaminated peritoneal cavities. Peritoneal lavage with 10% povidone-iodine can be fatal to dogs if 8 ml/kg is infused with intact peritoneum or 2 ml/kg with peritonitis. Concentrations of greater than 0.1% should not be used in joint irrigation.

94.2.2.3

Aldehydes

Aldehydes have been employed as gaseous sterilants, as well as chemical disinfectants. The exposure time needed for formaldehyde to effect sterilization is long because the gas does not penetrate well and has been replaced by more efficient gases. A 100% formalin solution is approximately 40% formaldehyde in water. A 20% formalin solution (8% formaldehyde) is a high-level disinfectant (sporicidal), and its biocidal activity can be increased by the addition of 70% alcohol, but the solution is irritating to tissues and mucous membranes.

Glutaraldehyde is chemically related to formaldehyde but is more reactive, even in the presence of organic materials, soaps, and hard water. A 2% aqueous alkaline solution is equivalent to 20% formalin in alcohol in biocidal activity. The alkaline solution is much more biocidal but less stable. Stability is maintained for approximately 2 weeks at pH 7.5 to 8.5. At the dilution at which it is used, glutaraldehyde is slightly irritating to the skin and mucous membranes and very irritating to the eyes. Both glutaraldehyde and formalin are high-level disinfectants for cold sterilization of instruments that are unable to withstand steam or EO gas, including lens instruments, such as endoscopes, and plastic tubing and catheters. After disinfection, items should be rinsed thoroughly with sterile distilled water. A glutaraldehyde-phenate complex (Sporicidin, Sporicidin International, Washington, DC) has been shown to be as effective at 1:16 dilution as is undiluted glutaraldehyde and as stable and less irritating.

Ortho-phthalaldehyde (OPA), a clear pale liquid of pH 7.5, and a working solution contains 0.55% OPA. Unlike glutaraldehyde, OPA is stable over pH of 3 to 9 and is more potent compared with glutaraldehyde, even against mycobacteria. Furthermore, OPA requires no activation and is not a tissue irritant. OPA is compatible with many materials; however, it stains proteins gray, including unprotected skin, and must be handled with protective clothing. High-level disinfection at 20° C varies from 5 to 12 minutes, depending on the country.

995

996

94.2.2.4

Phenolics

Phenolics are good housekeeping disinfectants because they remain stable when heated and, after prolonged drying, will redissolve on contact with water. They remain active in the presence of organic soil, soap, and

Infectious Diseases of the Dog and Cat, 3rd Edition

hard water and are usually the disinfectant of choice in treating fecal contamination, such as with *Salmonella*. Phenolics must be thoroughly rinsed from areas contacted by cats because of greater toxicity in this species, and they are irritating to the skin and mucous membranes.

Hexachlorophene, a phenolic derivative commonly formulated with hand soap, is used as a degerming agent for the skin and mucous membranes because it causes little tissue irritation. Used only once, hexachlorophene is no more effective than soap is in eliminating microorganisms. Hexachlorophene takes longer than chlorhexidine or povidone-iodine to be effective. Its activity is reduced by organic material, and it is inactivated by alcohol. Hexachlorophene is also neurotoxic when absorbed from the skin, and it should be avoided over extensive areas and in neonates and animals with severely abraded skin.

Diphenol hydroxybenzene complex (Citricidal® Nutribiotic Co., Lakeport, Calif.), a quaternary compound from grapefruit seed bioflavonoids, is a nontoxic, biodegradable, noncorrosive disinfectant. This compound comes as a liquid or powder concentrate and was virucidal for enveloped viruses such as feline herpesvirus but was not effective against feline calicivirus or feline parvovirus.⁵¹

94.2.2.5

Hydrogen Peroxide

This common irrigant has been advocated for flushing directly into contaminated or infected wounds. Because its lack of antibacterial activity and potential cytotoxicity, hydrogen peroxide is recommended as an initial flush in wounds for its effervescent action and increased oxygenation, which retard anaerobic bacteria. It works best as a disinfectant for nebulizer and anesthetic equipment.

Potassium monopersulfate, a water-soluble complex salt, is an oxidizing disinfectant that can be used in a wide variety of environmental cleaning purposes and in oral hygiene solutions. Potassium monopersulfate has been commonly used for nonchlorine oxidation and disinfection of swimming pools and spas. A 1% solution is not corrosive for finer surgical instruments. The chemical is highly bactericidal and virucidal and has efficacy against resistant organisms such as foot-and-mouth disease virus.

94.2.2.6

Surface-Active Agents

These agents are chemicals that alter the surface tension of the organism and are classified as cationic or anionic. The quaternary ammonium compounds (QUATs) are cationic detergents that have been used for disinfection and antiseptic purposes, although their activity as disinfectants may have been overrated. They are inactivated by organic material, soap, and hard water. They should not be used in preparation of skin for surgery because they are inactivated by detergents in surgical scrubs. QUATs are algicidal, fungicidal, bactericidal, and virucidal (against some enveloped viruses) at medium concentrations. Virucidal activity of newer QUATs such as dodecyl dimethyl ammonium chloride or *N*-alkyl dimethyl benzyl ammonium chloride is incomplete against viruses (even herpesviruses) in contrast to the claims of manufacturers.⁹¹ When properly used, QUATs are effective bactericides against both gram-positive and gram-negative bacteria; however, they display greater activity against gram-positive organisms. They have an unusual ability to kill *Giardia* cysts at refrigerator and room temperatures (see Prevention, [Chapter 78](#)). QUATs are ineffective against mycobacteria, *Proteus*, *Pseudomonas*, bacterial spores, and nonenveloped viruses even at high concentrations. When the temperature is increased from 20° to 37° C, the concentration of the solution can be reduced by one half. Benzalkonium chloride is the most common compound of this group.

As an environmental or skin disinfectant, concentrations of 0.001% to 1% benzalkonium chloride are generally used. Benzalkonium chloride has also been employed in medicine as an antiseptic and in flushing

Infectious Diseases of the Dog and Cat, 3rd Edition

infected wounds at very low (no more than 0.007%) concentrations. QUATs are thought to form a film over the skin, with the inactive part of the compound directed toward the skin, possibly trapping bacteria but not killing them. The germicidal part is directed toward the environment, preventing further contamination. Degerming the skin with a more effective antiseptic before applying a QUAT may overcome the problem. Care must be taken not to allow undiluted QUATs to contact exposed tissues. Chemical burns occurred after applying undiluted (10% to 17%) benzalkonium chloride on skin surfaces or 0.1% to 0.5% on conjunctivae or mucosae of dogs and cats. Cats also developed oral and esophageal ulcerations after licking treated skin areas, and oral ingestion should be avoided. Concentrations as low as 0.002% to 0.007% must be used on wounds, but other agents such as chlorhexidine or povidone-iodine are preferred.

Anionic surfactants or amphoterics, organic acids that have the detergency of anionic compounds, are effective against both gram-negative and gram-positive bacteria and are reported to be fungicidal but not sporicidal. Unlike QUATs, they are effective against *Proteus* and *Pseudomonas*. Amphoterics are effective in one application and are not inactivated by serum or hard water, although soaps and detergents affect them adversely. Similar to QUATs, amphoterics leave a film on the skin that will block the transfer of organisms from unwashed to washed hands. Amphoterics are nontoxic to tissues and noncorrosive to moist surfaces, and they have a deodorizing ability. They can greatly reduce the total number of bacteria on hospital floors.

94.2.2.7

Biguanides

Chlorhexidine, the most common disinfectant of this class, has gained popularity for surgical skin preparation and as a wound antiseptic because of its low tissue toxicity.¹²⁶ It is effective against *Proteus*, *Escherichia coli*, staphylococci, and *Pseudomonas*. In the skin, chlorhexidine binds to stratum corneum, giving up to 2 days residual activity after a single application. It has been shown to be an effective and nonirritating antiseptic for irrigating canine wounds. Concentrations of chlorhexidine of 0.5% in water, saline, lactated Ringer's solution, or alcohol have been shown to reduce bacterial contamination in canine wounds or as a surgical antiseptic, but they retard granulation tissue formation and epithelization. Lower concentrations of chlorhexidine (0.05% to 0.1%) were less antiseptic but can be used as a lavage for tissues or joints and did not inhibit wound repair. Chlorhexidine has not been effective in treating dermatophytosis (see [Chapter 58](#)). Because of irritation, even low concentrations should never be placed in the eye or in the ear canal with a damaged tympanum, although use with a damaged tympanum has been shown to be safe in dogs.⁹⁸ These compounds retain some activity in the presence of organic material and hard water but are inactivated by soaps. They are more effective at an alkaline pH.

Surfacine® (Surfacine Development Co., Tyngsborough, Mass.) is composed of a water-insoluble antimicrobial, silver iodide, and a surface coating of a polyhexamethylenebiguanide. The biguanide is attracted to the lipid in the bacterial cell outer membrane and transfers and accumulates the silver halide into the organism, causing bacterial cell death. Animate or inanimate surfaces can be treated with this

996

997

solution followed by drying leading to a persistent antimicrobial activity.¹⁴⁸ It is not toxic to mammalian cells and can be applied to inanimate and animate surfaces without prior surface treatment.

94.2.2.8

Ethylene Oxide

When properly applied, this gas is the most effective chemical sterilant. As with other chemical disinfectants, EO is subject to limitations imposed by temperature, moisture content, concentration, and exposure time. Recommendations are that routine sterilization be performed at 30° to 55° C. If the

Infectious Diseases of the Dog and Cat, 3rd Edition

temperature is not properly maintained, the gas may condense; or if the exposure time is too short, sterility failures can occur. Most EO sterilizers in hospitals are designed to produce 50% to 60% relative humidity; it must not fall below 30% or sterility failure will occur. Biologic indicators are available that monitor the efficacy of EO sterilization.

EO sterilization is not recommended for some plastics and pharmaceuticals or for animal feeds and beddings. The gas reacts with or is absorbed by these items. Solutions in sealed glass containers cannot be sterilized because the gas cannot penetrate glass. Instruments and other items should be clean, dry, and as free of contamination as possible before EO sterilization. Items are placed in semipermeable plastic wraps. After the sterilization process, articles must be aerated to allow the residual gas to dissipate because the absorbed gas is irritating to skin and mucous membranes. In *in vivo* and *in vitro* studies, ethylene oxide has been effective in inactivating feline leukemia virus (FeLV) infection in bone allografts for transplantation.^{29,30} Recommended routine aeration procedures are as follows: at room temperature, 48 to 168 hours, depending on the items sterilized and their use or with forced-air cabinets, 8 to 12 hours, depending on the cabinet temperature.

94.2.2.9

Hydrogen Peroxide Plasma

Temperature-sensitive equipment can also be sterilized using hydrogen peroxide plasma sterilizers. This gas vapor is able to sterilize equipment in times of up to 72 minutes. Devices with small lumens can be effectively treated in this manner. This process leaves no toxic residues and can be used for endoscope or other immersible instruments.

94.3

NOSOCOMIAL INFECTIONS

Nosocomial (hospital-acquired) infections can arise endogenously from the spread of indigenous microflora or exogenously from contact with organisms on external sources (Table 94-5). Exogenous sources of infection commonly include other animals and fomites such as human hands, rodents, arthropods, food dishes, catheters, and hospital cages. Transmission can occur by airborne, contact, or vehicle routes. Many nosocomial infections result from opportunistic spread of the normal microflora rather than newly acquired agents. The prevalence rate of nosocomial infections in humans and probably veterinary hospitals is 5% to 10% of hospitalized patients.

Not all infections that develop in the hospital environment are nosocomial in origin. Infections that are present or incubating at the time of admission are excluded. Moreover, nosocomial infections may not become clinically evident until after the patient has been discharged from the hospital. Hospitalized animals are more prone to infection because of increased exposure to pathogens, concurrent immunosuppressive illness, and the increased stress imposed by technologic advances in medical practice (Table 94-6). Excessive antimicrobial therapy may increase the risk of colonization with antimicrobial-resistant pathogens. Nosocomial pathogens are either naturally resistant to antimicrobial drugs or develop resistance during hospital therapy. Attention to hand hygiene (Table 94-7), alcohol-based hand disinfectant (rubs), or use of gloves are ways that antimicrobial resistance has

been controlled in human hospitals.¹⁸⁶ Of the disinfectants, alcohols have the most rapid microbicidal activity of all antiseptics. Furthermore, alcohol-based hand rubs have excellent spreading quality and rapid evaporation.

They are not irritating to the hands after repeated use as is a complication of frequent hand washing. Health care workers complied best with hand disinfection when dispensers containing alcohol-based hand rubs were available at each patient.²² In the veterinary hospital ward or intensive care, dispensers can be suspended on the outside of each cage or run to facilitate hand hygiene. These measures reduce the spread of pathogenic organisms between animals and the zoonotic risk of infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-5 Nosocomial Opportunistic Infections in Companion Animal Veterinary Hospitals

ORGANISM(S)	OUTBREAK CIRCUMSTANCES
<i>Klebsiella</i> spp.	Intensive care infection in 23 dogs and 1 cat. Most common in surgical wounds, urinary tract and blood. ⁶⁹
<i>Serratia marcescens</i>	Contaminated IV catheters and respiratory and genitourinary tracts and skin of hospitalized animals as a result of contaminated benzalkonium chloride. ⁶⁰
<i>Enterobacter cloacae</i>	Contaminated cleansing solution causing infection in four dogs and a cat. ¹²
<i>Staphylococcus intermedius</i>	Methicillin-resistant infection in 11 dogs following postsurgical or traumatic wounding or with recurrent pyoderma. ¹⁸¹
<i>Acinetobacter baumannii</i>	Nosocomial infection in 17 dogs and 2 cats an intensive care unit over 2.5-year period. Isolates were made from the urine, indwelling catheters. ⁶³
<i>Acinetobacter baumannii</i> , <i>Enterococcus faecalis</i> , <i>Enterococcus faecium</i> , <i>S. intermedius</i>	Surgical wounds and other wound infections, urinary infections. One <i>A. baumannii</i> isolate was transferred to an equine patient in the same hospital. ²⁰
<i>Serratia</i> spp., <i>Acinetobacter anitratus</i> , <i>Citrobacter freundii</i> , <i>S. intermedius</i> , <i>Klebsiella</i> spp., <i>Escherichia coli</i>	IV catheter in dogs with parvoviral enteritis. Organisms were variably drug-resistant. Only one dog developed signs of catheter-related infection. ⁹⁹
<i>E. coli</i>	Hospital-acquired infections in intensive care and other wards and also found in environment of the hospital. ¹⁵²
IV, Intravenous.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-7 *Methods for Hand Disinfection*^{122,123}

Hand Washing

1. Completely wet hands and wrists in a running stream of warm water.
2. Keep hands lower than elbows to avoid recontamination.
3. Apply soap over front and back of hands.
4. Rub all surfaces of hands, and interlace fingers and lather for 15 minutes.
5. Thoroughly rinse hands in clear running water.
6. Turn off faucets with a paper towel.
7. Dry hands thoroughly with new disposable paper towels.

Hand Disinfectants

1. Place hand disinfectant dispenser in a readily available place on each animal cage.
2. Squeeze the disinfectant on hands, and rub all surfaces.
3. Let disinfectant dry thoroughly before handling objects.

94.3.1 Development of Antibacterial Resistance

Microorganisms have evolved means of overcoming the effects of antimicrobial drugs. Most resistance mechanisms are under genetic control. Spontaneous chromosomal mutations are relatively rare in bacterial populations; extrachromosomal transfer of genetic material or plasmids is more important. Plasmid transfer occurs most frequently during bacterial conjugation, although alterations in bacterial nucleic acid may also occur through bacteriophages (via transduction), acquisition from naked nucleic acid (via transformation), or exchange between bacterial and host DNA (via translocation). Plasmid transfer also commonly occurs between bacteria of different genera.

Genetic acquisition of bacterial resistance to antimicrobials may be demonstrated in a wide variety of ways, including changes in permeability to the drug, in receptors for the drug, or in metabolic pathways. Plasmid resistance is frequently associated with cross-resistance among a large number of structurally related antimicrobials.

The prevalence of antibiotic resistance commonly increases in proportion to the frequency of use. Resistance often develops with streptococci, staphylococci, *E. coli*, *Salmonella*, *Proteus*, and *Klebsiella*. Suppression of normal enteric flora and proliferation of antimicrobial-resistant strains occur with partially absorbed antimicrobials or those that are excreted in the bowel in active form, such as tetracycline, chloramphenicol, ampicillin, metronidazole, furazolidone, amoxicillin, and cloxacillin. Antibiotic resistance in fecal coliform bacteria has been documented in domestic pets in association with the increased use of antibacterial drugs in such animals. Heightened antibacterial resistance among pets in rural environments was correlated with the increased use of antibiotics in livestock feeds. These findings should caution veterinarians against indiscriminate administration of antimicrobials. Moreover, similar resistance patterns have been identified in human contacts of both types of animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

Antimicrobial resistance in human medicine has been shown to be more of a problem in hospitalized patients, in whom antibiotic usage is widespread, than it is among patients in general.¹⁵⁸ Similar findings probably exist in veterinary practices. Transmission of opportunistic multidrug-resistant pathogens has been observed in veterinary teaching hospitals.²⁰ *Acinetobacter baumannii*, *Enterococcus faecalis*, *Enterococcus faecium*, and *Staphylococcus intermedius* were involved (see Table 94-5). The drug-resistant *A. baumannii* infection was traced to a contaminated intensive care unit in a veterinary teaching hospital.⁶³ The *S. intermedius* strains were not similar, suggesting that they were a result of infection of resident organisms in individual hosts. This contrasts with nosocomial and community-acquired infections with drug-resistant *S. aureus* between humans and from humans to dogs, which likely represents an anthroponosis. Several different strains were found; however, identical typing in some indicated spread among the hospitalized animals. Localized and systemic infections were found. All animals had intravenous (IV) or other types of indwelling catheters or tubes placed during their hospital stays. Surveillance and improved practices will be required in intensive care units to reduce the future risk of such events. Unfortunately, the development of new antibacterial drugs has just barely kept ahead of evolving resistance patterns. Widespread or indiscriminate usage of gentamicin, trimethoprim-sulfonamide, and fluoroquinolone by veterinarians may threaten the efficacy of these antibiotics in the near future. The availability of a large number of antibacterial drugs should not give the veterinarian a sense of security because many drugs have become obsolete as a result of evolving bacterial resistance.

Development of bacterial resistance can be prevented by certain adjustments during antimicrobial therapy. Measures include restricted prophylactic drug therapy, fully effective doses at adequate intervals, narrow-spectrum antibacterials specific for the isolated organisms, isolation of animals receiving long-term antibacterial therapy, selection of antibacterials against which the isolated organisms are not prone to develop resistance, changing of antibacterials after an effective treatment period, restriction of indiscriminate use of antibacterial drugs, and topical or local rather than systemic therapy whenever possible.

998

999

94.3.2 Biofilms

Microorganisms adhere to inert or living tissues by producing extracellular polymers that allow for adhesion and produce a structural framework for their support and protection. These microbial biofilms develop in all types of indwelling or external medical devices within the hospital environment (Table 94-8).^{43,44} Biofilms are a health risk because organisms involved are often highly resistant and have ready access to the body via the implant site (Table 94-9). The resistance occurs because antimicrobial agents must diffuse into the matrix, the organisms in biofilms have reduced metabolic requirements and growth rates, and the immediate environment provides further conditions protecting the organism. Plasmid resistance can also be shared between bacteria within a biofilm. The extracellular matrix of a biofilm is composed of polymeric compounds that are primarily polysaccharides surrounding the microorganisms in sheets or strands of amorphous material. Bacteria colonize indwelling medical devices such as catheters shortly after they are implanted. The rate of bacterial cell adherence depends on the property of the body fluids bathing the device, the rate of fluid flow over the surface and the composition of the biosynthetic device.

94.3.3 Conditions Associated with Nosocomial Infections

In human and probably veterinary hospitals, the most common nosocomial infections are urinary tract infections, followed by pneumonias, surgical site infections, and bacteremias.⁵⁴ For surgical and wound related infections, see Chapter 55.

94.3.3.1 Urinary Catheterization

This procedure is probably the most common cause of nosocomial infection in veterinary practice. Fluid washout from urine flow is a primary defense mechanism of the urinary tract. Catheters upset this barrier by permitting entry of organisms at the urethral meatus and catheter junction. The distal urethra and prepuce or vagina are normally inhabited by commensal organisms. When catheters are left in place, these bacteria can migrate in retrograde fashion and infect the rest of the urinary tract, which is normally sterile, generally occurring in 1 to 3 days. Transient bacteremia also may occur after manipulation of urinary catheters in infected patients. To prevent infection, the external genitalia must be thoroughly cleansed, after which catheterization must be performed under strict aseptic conditions. A short-term, repeated, nontraumatic catheter is preferable to placement of a long-term indwelling catheter. Prophylactic topical or systemic antimicrobial therapy does not reduce the prevalence of infection unless the catheter is left in place for

Infectious Diseases of the Dog and Cat, 3rd Edition

fewer than 4 days. Treatment with prophylactic antibacterial drugs may increase the risk of urinary or systemic infection with resistant bacteria or with fungi such as *Candida*⁸¹ (see Indwelling Urinary Catheters, [Chapter 91](#), and *Candida* infections, [Chapter 65](#)). Antimicrobial therapy should not begin until the catheter is removed. At this time, the urine can be cultured, the sediment examined, and the animal started on therapy, which should be modified when the culture results are received. Antimicrobial therapy instituted while the catheter is in place merely selects for resistant infections. Periodic instillation of a disinfectant such as hydrogen peroxide into closed urinary drainage systems has not been effective in preventing catheter-associated bacteriuria in people.

94.3.3.2

Intravenous Catheterization

IV infusions are both essential and lifesaving in veterinary practice. Since the development of flexible plastics, IV catheters are maintained in the patient for longer periods; however, the possibility that the infusion system can become contaminated is greater. The improper use of indwelling catheters has resulted in a high prevalence of nosocomial bacteremias and some fungemias.⁸¹ IV catheter-related infections are more common than is realized in veterinary practice. Organisms originate from contaminated infusates, the patient's skin, or from health care personnel. Although uncommon, infusion bottles, bags, or administration sets can become contaminated from hairline cracks produced during the manufacturing process. Organisms may enter infusion systems when the administration set is inserted into the bottle, allowing the influx of room air when the vacuum is released or when medicaments are added. Organisms can also be introduced at the connection of the infusion set with the hub of the IV catheter. Antimicrobial lock solutions have been used to reduce the frequency of associated infections.³

Finally, and most commonly occurring, is the migration of skin organisms at the insertion site into the cutaneous catheter tract and subsequent colonization of the catheter tip. Bacteria have a greater chance of gaining access when skin preparation is inadequate before catheter insertion because bacterial microflora density at the catheter insertion site is a major risk factor. Povidone-iodine has been the most widely used antiseptic for cleansing IV catheter sites, although cleansing with 70% alcohol or 2% chlorhexidine gluconate scrub has been comparable. A 2% tincture of chlorhexidine preparation has become available and needs further evaluation. In dogs, a 1-minute, 4% chlorhexidine gluconate scrub produced lower cutaneous bacterial counts than no disinfection when measured before catheter insertion or before withdrawal.²⁸

999

Uncleaned legs also had more microscopic dermatitis when the catheter was placed for 77 hours. Thrombus formation and phlebitis was observed microscopically in all dogs regardless of skin management. Interestingly, no difference was observed in the colonization rate of the catheter tip between the two groups. Catheter colonization rates are likely high as dogs with parvovirus infections had a 22% rate of bacterial isolation.⁹⁹ Organisms were generally gram-negative, multidrug resistant, and were of environmental or GI origin. Colonization rate of catheters from dogs in the same veterinary hospital with other conditions was not available.

1000

Although they can enter the lumen of the catheter at the hub, bacteria usually enter the IV infusion system at the site of penetration of the catheter tip by migrating between the catheter and skin surfaces. The prevalence of local infection is greatly increased when IV cutdown sites are used and catheters are in place for longer than 24 to 48 hours. Organisms producing localized infection at the catheter site can be infused systemically during the administration of fluid or during flushing of clogged catheters. Bacteria can also migrate in retrograde fashion, even against gravity flow, from the contaminated catheter to the infusion bottle.

Infectious Diseases of the Dog and Cat, 3rd Edition

Organisms such as coagulase-negative staphylococci have been shown to adhere to plastic catheters with subsequent replication and production of catheter-associated infections.⁷¹ Some investigators believe that the slime-producing strains of bacteria are more effective in catheter colonization. Inserted catheters readily develop biofilms containing large numbers of organisms.^{43,44} This layer may offer a physical barrier to host defenses or antibiotics in eliminating the bacteria. Several measures have been investigated to reduce biofilm formation given that the number of organisms in the catheter tip is directly related to the occurrence of bacteremia. Adding antimicrobial solutions to the heparin flush solutions (using antibacterial-impregnated catheters), sterile placement technique, and local application of antibacterial ointments at catheter insertion sites have been beneficial in reducing catheter-associated contamination.^{32,43,44} Changing catheters is also important because biofilms become more resistant to antimicrobial therapy with time. If organisms with acquired resistance are present in the biofilm, the chance of transfer of resistant plasmids to other colonizing organisms can increase with time as long as the catheter is in place. Results from in vitro studies reveal that polyvinyl chloride or polyethylene catheters are less resistant to the adherence of microorganisms than are catheters made of Teflon® (Dupont, Wilmington, Del.), silicone elastomer, or polyurethane.⁶

With the intent of preventing bacterial migration along the external IV catheter surface, IV catheters have been made with silver-chelated collagen cuffs or silver impregnation (Table 94-10).³⁴ Although these systems have had variable efficacy in people, animal studies have not been conclusive. In contrast, silver iontophoretic catheters and those coated with silver sulfadiazine-chlorhexidine have been effective in preventing IV catheter-related infections in animal studies.³⁴ Silver coating of medical devices or topical silver creams applied to the point of catheter insertion may have benefit in reducing infection rates; however, systemic silver toxicity has been reported in people when leaching of surfaces occurs.

To help reduce the prevalence of IV catheter-related infections, tunneling under the skin before the venous penetration site has been used. Keeping such sites free of moisture or contamination is still important in maintaining sterility and avoiding moisture on, or contamination of, the end-cap or penetration site (Fig. 94-1).⁴²

Organisms of the family Enterobacteriaceae, such as *Klebsiella*, *Enterobacter*, and *Serratia*, as well as *Citrobacter*, proliferate readily at room temperature in 5% dextrose and can reach concentrations of 10^5 and 10^6 organisms/ml without producing obvious clouding of the solution. Many other common contaminants, such as *Staphylococcus*, *Pseudomonas*, *E. coli*, and *Proteus*, do not survive or proliferate in 5% dextrose, although *Candida* can grow very slowly. *Serratia marcescens* has been incriminated as a common cause of medical device-related infections in small animal and human medical practice.¹²⁴ Benzalkonium chloride solutions should not be used for skin preparation because these antiseptic solutions can support the growth of *S. marcescens* and other microorganisms. In one instance, this organism was isolated from alcohol-soaked cotton balls used for skin decontamination.⁸³ *Pseudomonas* can grow in distilled water, normal saline, and even iodophors.⁷¹ *Candida* grow well in protein hydrolysates, whereas *Candida* and *Malassezia* proliferate in lipid emulsions.

Lactated Ringer's solution, normal saline, other isotonic fluids, and hypertonic saline solution have been less commonly incriminated as the sources of nosocomial bacteremia than have dextrose solutions; however, they can support the growth of a variety of organisms. Parenteral hyperalimentation fluids and other hypertonic solutions readily support the growth of *Candida*. Blood products, even when stored at refrigerated temperatures, can become contaminated and support the growth of cold-growing microorganisms such as *Pseudomonas* and some coliforms such as *S. marcescens*. *S. marcescens* was responsible for contaminating feline blood units.⁸³ Bacterial growth in the blood units caused slight brown discoloration of the blood.

1000

1001

Infectious Diseases of the Dog and Cat, 3rd Edition

Clinical signs of catheter-associated infection include localized swelling and warmth at the insertion site and venous cording. The systemic spread of infection is characterized by fever, hypotension, tachycardia, and GI and central nervous system signs. Overwhelming infections associated with endotoxemia are more likely to occur when gram-negative organisms are involved and in immunosuppressed patients. Clinical signs in such cases are shock, collapse, coma, and death. In cats receiving blood contaminated with *S. marcescens*, vomiting, collapse, diarrhea, icterus, panting, fever, and death were variable findings.

Diagnosis of IV infusion-associated infection is frequently made when the clinical signs improve suddenly after terminating fluid therapy. However, because bacteremia may seed many organs, clinical signs can persist after the infusion is discontinued. Culture or Gram's staining of catheter tips has been recommended and is a more rapid and practical means of determining presence of infection. After removal, the IV or intracutaneous segment of the catheter is rolled across an agar plate, and the resultant colonies that grow are counted. A count greater than 15 colony-forming units is often associated with bacteremia.⁷¹ However, this finding alone may not always confirm the presence of bacteremia. When blood cultures are performed, isolated organisms should correspond to those found at the catheter site. Pseudobacteremia may also occur when the infected catheter site locally seeds the venous effluent being sampled. At least two to three blood samples should be taken from different sites at intervals of at least 10 minutes once the catheter has been removed. Once catheter-related infection is suspected and the catheter tip or blood cultures are taken, the offending catheter should be removed. The animal should be started on antimicrobial therapy. Most infections can be eliminated with a 10- to 14-day course of antibacterials if the appropriate drug is selected.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-11 Recommended Procedures to Reduce the Risk of Intravenous Catheter–Related Infections

CONTROL MEASURE	RECOMMENDATIONS	BENEFIT OF REDUCING INFECTION
Catheter site	Peripheral veins versus jugular or femoral	Unknown
Catheter material	Teflon® or polyurethane versus polyvinyl chloride or polyethylene	Yes
Hand hygiene	Washing hands before catheter placement and each time it is handled. Wearing clean gloves is superior and acceptable versus sterile gloves.	Yes
Skin preparation	Povidone iodine (10%), chlorhexidine gluconate (2%–4%), tincture of chlorhexidine (2%)	Yes
Catheter dressing replacement	Transparent or gauze, the latter if leaking blood. Replace dressing if damp, loosened, or soiled.	Unknown
In-line filters	Use to reduce phlebitis but not infection	No
Antimicrobial impregnation	Chlorhexidine-silver sulfadiazine superior but very expensive for veterinary use.	Yes
Topical antimicrobial ointment	Povidone iodine reduces bacterial but not fungal contamination or antimicrobial resistance.	No
Anticoagulants	Heparin flush	No
Catheter replacement timing	Replace no more frequently than 72–96 hrs because bacterial colonization and phlebitis increases.	Yes
Administration set replacement	Replace intravenous tubing no more frequently than 72 hrs unless blood or lipids, in which case 24 hrs replacement is recommended.	Yes
Hang time for parenteral fluids	No timing of intravenous fluids; lipid emulsions should limit to 24 hrs and blood products for 4 hrs.	Yes
Tunneled catheters	Used for central venous catheters or when placed longer than 96 hrs.	Yes
Based on recommendations for humans as published in O'Grady, ¹²¹ Guidelines for the prevention of intravascular catheter-related infections, <i>Clin Infect Dis</i> 35:1281–1307, and <i>MMWR</i> 2002, 51:1–26; Slaughter SE. 2004. Intravascular catheter-related infections, <i>Postgrad Med</i> 116:59–66.		

IV catheter–associated infections can be prevented with adequate precautions (Table 94-11). Adequate skin preparation and antisepsis at the collection sites are essential. Hands should be washed before catheter placement. A large area of fur at the catheter site should be removed by careful clipping to avoid microabrasions of the skin. Gentle mechanical cleansing of the skin with an iodophor or with soap and water for 2 to 5 minutes should be followed by alternate disinfection using 70% alcohol and 1% to 2% tincture of iodine or iodophor solutions or, preferably, 2% chlorhexidine-gluconate.¹⁰² Iodine-containing antiseptics are effective against most bacteria and fungi, with the exception of spores. Tincture of iodine preparations, superior to iodophors for the final application, is frequently too irritating for repeated application.

1001

1002

Infectious Diseases of the Dog and Cat, 3rd Edition

To restrict movement, catheters should be firmly stabilized with adhesive tape. A small amount of a broad-spectrum antimicrobial ointment, such as one containing organic iodine or neomycin-bacitracin-polymyxin, should be applied at the point of catheter penetration through the skin, and the site should be covered with a sterile occlusive dressing. If only tape is to be used, it must be sterile. The date and time of catheter insertion should be recorded. No catheter should be left in place longer than 72 hours. If the catheter must remain in place for longer periods, the IV site should be inspected and dressed with a new sterile dressing at 48- to 72-hour intervals. Disconnecting the IV catheters for sampling or administering medicines should be minimized. Concurrent administration of antibiotics does little to prevent IV catheter-associated infection but causes the development of an antimicrobial-resistant infection.

When long-term IV catheterization is required, special catheters such as the Broviac or Hickman type (C. R. Bard, Inc., Murray Hill, NJ.) should be considered.^{19,71} These catheters have been designed to reduce migration of bacteria toward the implanted portion by a built-in cuff and subcutaneous tunneling of the proximal portion. These catheters are made of more flexible and nonreactive silicone, which is less irritative and thrombogenic, reducing the chance for a nidus of infection. Unfortunately, these catheters do not overcome the less common hematogenous seeding of bacteria on the catheter tips, which may occur from distant sites of infection.

Table 94-12 Polymicrobial Infections and Sites in Dogs and Cats

DISEASE	AGENTS	COMMENTS
Gastroenteritis or intraabdominal infection	Gram negatives and anaerobes	Usually, give at least two drugs simultaneously to cover both spectra; however, can consider third-generation cephalosporins or penicillins.
Stomatitis, periodontitis	Gram positives and anaerobes	Treat anaerobic flora with drugs such as clindamycin, metronidazole.
Chronic otitis externa	<i>Staphylococcus</i> , <i>Pseudomonas</i> , <i>Proteus</i>	May need bone-penetrating or central nervous system-penetrating antibacterial.
Chronic rhinitis with osteolysis	Variety of opportunistic nasal flora including <i>Aspergillus</i>	Systemic antibacterials may offer temporary improvement; may need curettage or topical infusions (or both) of antifungal drugs for recurrent cases.
Canine tracheobronchitis	Viruses and bacteria	In dogs, antibiotics not usually used; more widely used in cats. Usually a single broad-spectrum drug is used.
Pyothorax	Variety of anaerobic bacteria and some facultative anaerobes	Requires drainage and lavage; critical for recovery.
Aspiration pneumonia	Aerobic and anaerobic bacteria	Usually, coverage with two antimicrobials.
Necrotizing fascitis	Gram-positive streptococci or staphylococci and anaerobes	Clindamycin of choice but may need surgical drainage or amputation.
Indwelling catheter- or tube-related infections	Variety of organisms in biofilms; see intravenous catheter infections	Recommended not to treat until device is removed.
Abscesses or necrotic soft-tissue infections	Variety of organisms, including anaerobes	Drainage is critical along with antimicrobial therapy.
Osteomyelitis	Variety of organisms, especially if the result of a compound fracture	Drainage and curettage along with antimicrobials that penetrate biofilms.
Burns	Variety of organisms from the environment	Always handle with gloves; use shower hydrotherapy versus whirlpools; and when extensive, use skin grafts.

Infectious Diseases of the Dog and Cat, 3rd Edition

When a small volume or slow infusion rate is required, multiple small infusion bottles are preferred to one large bottle. The rationale is that should the system become contaminated, the time for microorganism multiplication is minimized. Infusion bottles should be checked for turbidity and vacuum, and infusion bags should be squeezed before use to detect leaks. Infusion filters 0.22 µm in diameter are available to restrict the flow of microorganisms through the fluid catheter into the patient; however, they will not prevent passage of endotoxins and pyrogenic factors. Drugs should be added to infusion fluid containers in uncontaminated surroundings after proper disinfection of the site of addition to the infusion fluid.

Technologic advances have been made with catheters to prevent bloodstream infections in humans.

1002

Iodinated alcohol solutions within catheter hubs, chlorhexidine-silver-sulfadiazine or

1003

antibiotic-impregnated catheters, and antibacterial-impregnated sponges have all been evaluated.¹¹³

94.3.3.3

Polymicrobial Infections

Many polymicrobial infections arise from opportunistic growth and invasion by normal flora or organisms in biofilms in the environment. Because of their persistence, antimicrobial resistance, and collective experience, microorganisms in the biofilms have been exposed to many more antimicrobial insults than those that are solitary, and biofilm inhabitants may be more resistant to treatment and disinfection. For polymicrobial infections to occur, a complex interaction must take place between two or more microorganisms, allowing them to live in close association. For example, infections of the skin or mucosal surfaces, infection, underlying damage to the epithelium can lead to colonization and potential invasion by a variety of surface bacteria or fungi. A list of common sites and types of polymicrobial infections is in [Table 94-12](#). Opportunistic commensal or environmental fungi such as *Candida* often interact with bacteria in these sites producing co-infections. Polybacterial disease is common in osteomyelitis, abscesses, vaginitis, periodontal diseases, chronic rhinitis with osteolysis, and necrotic soft-tissue infections.

94.3.3.4

Respiratory Infections

The upper respiratory tract passages have anatomic defense mechanisms that prevent most inhaled particles from reaching the lower airways. However, invasive procedures such as tracheostomy, fiberoptic endoscopy, transtracheal catheterization, nebulization, and endotracheal intubation bypass these defense mechanisms and expose the respiratory tract to increased numbers of organisms, especially gram-negative organisms. The occurrence of nosocomial pneumonias was *much* higher in endotracheally intubated human patients receiving histamine H²-receptor antagonist. Retrograde contamination of the oropharynx with gram-negative bacteria from the stomach was thought to be responsible.

Decreased respiratory clearance function has also been associated with an increased risk of nosocomial respiratory infections. Decreased clearance activity can occur with CNS depression, neuromuscular paralysis, chronic obstructive lung disease, and impairment of pulmonary alveolar macrophage function. Inhalation anesthesia, nebulization, humidification, and ventilatory support increase the risk of nosocomial infection resulting from cross-contamination. Appropriate disinfection protocols for the equipment in these procedures are discussed later (see Prevention of Nosocomial Infections).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-13 Practices to Reduce the Nosocomial Threat of Infections in the Hospital

Use of gloves when touching any body fluid, secretions, or excretion

Hand washing or hand disinfection before and after handling each patient

Face or eye shields and mask during procedures likely to generate aerosols

Disinfection of environmental surfaces or inanimate objects contaminated with body fluids using 1 : 100 dilution of household bleach

Soiled linens placed in leak-proof bags; can be decontaminated in an autoclave or incinerated; can be laundered in a normal hot-water cycle with bleach

94.3.3.5

Gastrointestinal Infections

Enteric pathogens, such as parvoviruses, coronaviruses, *Salmonella*, and *Giardia*, may spread among dogs or cats in a veterinary hospital or animal-holding facility. Outbreaks are usually the result of poor sanitation, inadequate disinfection, and crowding of animals. Wards, treatment areas, waiting rooms, cages, exercise runs, thermometers, and feeding utensils are all sources of infection. All outbreaks of gastroenteritis among recently hospitalized patients should be investigated as to the cause and possible source of infection. Fecal examinations and cultures for protozoa and parvovirus should be performed when economically feasible.

Prevention of GI infections requires intense cleaning and disinfection procedures. All feces within the hospital should be removed as soon as possible, and the contaminated surface should be thoroughly disinfected with a diluted (1:32) chlorine bleach solution. Smooth, impervious floor and cage surfaces will facilitate disinfection and cleaning. Crowding of animals in waiting rooms and in hospital wards should be avoided. Use of gloves and hand washing should be enforced. Hospitalized animals should not be moved from cage to cage, but each should be assigned to one cage. Animals having episodes of acute vomiting or diarrhea either before or after being admitted to the hospital should be isolated.

94.3.3.6

Decubital Ulcers

These types of ulcers are the most common nosocomial skin infections to develop in incapacitated animals maintained in immobile or recumbent positions on unpadded surfaces. Abrasion and continuous pressure over bony surfaces cause devitalization of skin and secondary bacterial invasion. Immunosuppressed animals may develop septicemia as a result of decubital sores. *Pseudomonas* commonly contaminates these wounds. Identification of the invading microorganism and antibacterial therapy are usually of little benefit unless the primary cause is eliminated. Prevention is easier than cure; it involves frequent turning of recumbent patients and placing padding in their cages. Open drains in whirlpool or other baths used for rehabilitation of recumbent patients have been found to harbor *Pseudomonas* and cause outbreaks of nosocomial infection.¹⁵ In such instances, *Pseudomonas* can persist in biofilms within the plumbing system despite the use of disinfectants such as chlorine or bromine.

Infectious Diseases of the Dog and Cat, 3rd Edition

94.3.4 Prevention of Nosocomial Infections

Most nosocomial pathogens, whether acquired endogenously or exogenously, do not produce disease by themselves. The risk of nosocomial infections is greatest for immunocompromised or surgery patients and for newborns. Prevention of these infections can be achieved only by strict monitoring of the known predisposing causes. Attempts should be made to reduce the contact of high-risk patients with potential pathogens by segregating them from the general hospital population or minimizing their hospital stay. Additional measures include placing indwelling catheters only when necessary, minimizing surgical procedures, and practicing routine disinfection. Chemical disinfection procedures in veterinary hospitals are reviewed in the following section and are summarized in [Table 94-3](#). Other procedures to control the threat of nosocomial infections are listed in [Table 94-13](#).

94.3.4.1 Antimicrobial Prophylaxis

Prophylactic antimicrobial drugs are controversial. The unnecessary use of antibiotics has caused justifiable concern because of the increased prevalence of resistant microorganisms. Antibiotics alter the patient's microflora and allow infection by resistant bacteria. For many years, microflora were thought to be responsible for bacterial superinfections after prophylactic administration of antimicrobial drugs; however, invasion by exogenous-resistant organisms is more likely. Prolonged antibiotic administration may not lessen an animal's susceptibility to infection but may merely alter the microbial flora that causes the problem.

1003

1004

Certain justifications exist for instituting treatment with antimicrobial drugs before documenting that an infectious process exists. Immunosuppressed hosts that have been exposed to disease may require antimicrobial therapy; however, most clinicians would argue that close monitoring of the patient should be followed by IV administration of antimicrobials only if fever or other signs of infection appear. High-risk conditions associated with immunosuppression and with secondary infection include diabetes mellitus, persistent neutropenia, Cushing's disease, immunosuppressive or cancer chemotherapy, and chronic bronchopulmonary disease. Traumatic or contaminated wounds and burns may require topical or systemic chemotherapy. For information on antimicrobial prophylaxis in wounds, burns, and surgical procedures, see [Chapter 55](#).

94.3.4.2 Isolation Precautions

Restricting animal movement and contact within a veterinary hospital is important in controlling spread of nosocomial infections. As a general rule, animals entering the hospital should be currently vaccinated (see [Chapter 100](#)) or should be vaccinated if their status is uncertain. Any animal infested with ectoparasites should be dipped on admission if its condition permits. Immunosuppressed patients should not be housed in the hospital or, if admitted, should be moved to a separate area. If an infection is identified in an animal, four categories are proposed for which isolation precautions are indicated ([Table 94-14](#)).

Class 1 infections have little chance of spread between individuals, and the zoonotic potential is low. Systemic mycotic and algal infections are contracted primarily by environmental exposure. Systemic herpesvirus infection is a threat only to young neonates, and dogs showing only neurologic signs with canine distemper are unlikely to spread disease. No additional precautions are needed, and routine cage cleaning, hand washing, and disinfection of hospital equipment are all that is necessary.

Infectious Diseases of the Dog and Cat, 3rd Edition

Class 2 infections are of greater risk of transmission compared with class 1. Close contact is required between animals with papillomatosis or FeLV or feline infectious peritonitis. Many of these infections can be spread by contact with infected body fluids. Most other infections in this group are vector transmitted so that proper arthropod control will minimize the risk of spread from infected individuals. Most of the organisms cannot survive outside the host and are susceptible to routine disinfectants.

Class 3 infections are spread by close or direct contact with infected individuals or their excreta, but the risk of transmission via body fluids and excreta can be minimized by sanitary measures. These animals can be admitted to the general hospital population, but they should remain in their cages so as to restrict the contact of their urine and feces with other animals. Their cages should be identified as to the particular illness. Hand washing and cage cleaning must be critically practiced between animals, and feces or diarrhea, urine, and vomitus should be removed immediately. Dilute (1:30) bleach for viruses and phenolic compounds for bacteria should be used for disinfection. *Toxoplasma* and *Cryptosporidium* oocysts are inactivated by 10% ammonia solutions or by boiling water or steam cleaning. *Giardia* cysts are most susceptible to some dilute (1:100 or greater) QUAT disinfectants.

Animals with *Class 4* infections should be strictly isolated in a separate ward and should not be admitted to the general animal population. Infections in this category have a high degree of zoonotic risk, with potentially serious complications, or they are rapidly spread between susceptible animals. Animals with upper respiratory tract infections are preferably not admitted to the hospital and should be treated as outpatients. These highly contagious diseases are spread by air or contact. The animal's body exudates or secretions are highly infectious or the organisms are too resistant to enable control of spread. Persons handling these animals should wear protective outer garments, shoe covers, and rubber gloves. Contaminated wastes from these areas should be double-bagged in plastic and disposed of separately. Cages should be thoroughly disinfected once the animal is discharged. If the patient had *Salmonella*, the treated cage surface should have negative culture results before being used again.

94.3.4.2.1

Hands

Hands are the most common reservoirs or fomites for microorganisms associated with nosocomial infection, and hand disinfection is probably the *single most important* and immediate way of reducing its hospital-acquired infections (Table 94-15). Alcohol hand rinses have become widely available for hand hygiene purposes. They have rapid and broad-spectrum microbicidal activity with little risk of emerging resistance.⁹⁷ Alcohol hand rinses should be used immediately before and after contacting patients or handling contaminated fomites. Because frequent hand washing of skin can cause dermatitis and secondary bacterial colonization, its recommended use has become more limited. In the cases in which washing is needed, hands should be washed routinely with water and mild, noncaustic soap or detergent after handling blood, secretions, and excretions or before surgical procedures and gloving. The mechanical effect of soap and water cleansing is most important in reducing the numbers of transient bacteria on the skin surface (Fig. 94-2). Frequent use of antiseptics should be avoided because they can burn or dry the skin. Preexisting dermatitis will result in the persistent carriage of large numbers of microorganisms, which negates the effect of hand washing. Bar soaps, allowed to dry between uses, appear to have a lower prevalence of contamination than liquid soaps. Liquid soap canisters can become contaminated and must be routinely emptied, cleaned, and disinfected before being refilled.

Iodine-containing soaps are superior as scrubbing agents before surgery; however, they may produce dermatitis in sensitive individuals. A comparison of the available hand-washing soaps and antiseptics

Infectious Diseases of the Dog and Cat, 3rd Edition

appears in [Table 94-16](#). Hand-washing sinks and bathing tubs in all areas of a veterinary hospital can be disinfected with chlorine bleach to reduce contamination with organisms such as *Pseudomonas*. Rubber gloves may be used as an adjunctive means of reducing spread of infection when hand washing must be done so frequently as to prove impractical or irritating to the skin.

94.3.4.3

Airborne Contaminants

These contaminants can be reduced by having impervious floor coverings and using wet mops or filtered vacuums throughout the hospital. Air conditioning systems should be electronically filtered if possible and should be designed to reduce turbulent airflow. The best ventilation systems have air inlets near the ceiling and air outlets near the floor, allowing air to travel downward toward the heavily contaminated floor region. Air exchange rates of 6 to 10 times per hour have been shown to reduce the number of airborne microorganisms efficiently in animal-holding facilities while producing minimal air turbulence. Electronic purification and reduction in airborne bacteria can be achieved with installation of ozone-producing devices that are mounted in a given room or in the supply air plenum (Aqua-Mist Inc, Winston-Salem, NC.). A UV radiation decontamination device that is effective in inactivating environmentally resistant organisms, such as *P. aeruginosa* and *Mycobacterium tuberculosis*, in air ducts is commercially available (Sterilite, AB-medica, Milan, Italy).²

1006

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-14 Classification and Guidelines for Management of Infectious Diseases Based on Risk of Nosocomial or Laboratory Exposure and Zoonotic Transmission

TRANSMISSION	DISEASE	PRECAUTIONS FOR HANDLING
Class 1. Acquired from the Environment or Limited Shedding or Susceptibility Period		
Soil reservoir, vector transmitted, blood transfusion	Histoplasmosis, ^a cryptococcosis, ^a coccidioidomycosis, ^a blastomycosis, protothecosis, neurologic canine distemper, haemobartonellosis, ehrlichiosis, ^a anaplasmosis, ^a trypanosomiasis, ^a borreliosis, ^a RMSF, ^a leishmaniasis, ^a nontuberculous mycobacteriosis ^a	No need for isolation. Transmission risk is low unless insect vectors are present. Some infections can spread to people or other animals if inadvertent inoculation of body fluids or tissues occurs. Always use gloves when performing procedures. Mycotic agents pose a high risk from laboratory cultivation of mycelial phases.
Dermal or transcutaneous contact	Dermatophytosis, ^a sporotrichosis, ^a dermatophilosis, L-form infection	Use gloves and protective clothing when handling animal and body fluids. Disinfect all instruments contacting animals. House animal separately, and disinfect surfaces with halogens.
Class 2. Close Contact or Vector Transmission Required of Environmentally Nonresistant Organisms		
Bite transmitted	Rabies, <i>Babesia gibsoni</i> infection	Animals should be quarantined separately. With zoonoses, such as rabies, no direct human contact should occur without protective equipment.
Class 3. Zoonotic Potential with Direct Transmission to People		
Close salivary or genital contact for transmission, urinary transmission; zoonotic spread through mucosae or cuts in skin	Leptospirosis, ^a feline leukemia, canine herpesvirus infection, canine viral papillomatosis, canine brucellosis ^a	Provide no-contact housing. Disinfect hands between handling of patients. Wear protective clothing when handling urine or genital secretions from animals with zoonoses.
Fecal-oral transmission, low contagion; risk of spread enhanced by diarrheic feces	Giardiasis, ^a cryptosporidiosis, ^a salmonellosis, ^a campylobacteriosis, ^a feline coronavirus infections, toxoplasmosis ^a	Animal should remain in a designated cage. Clean and disinfect all cages and litter boxes, and dispose of all feces in sanitary containers. Protective clothing is recommended because most are zoonoses.
Class 4. Transmission by Infected Body Secretions with Organism of Moderate Environmental Resistance and Zoonotic Potential		
Aerosol transmission, high contagion	Feline herpesvirus infection, calicivirus infection, bordetellosis, ^a tuberculous mycobacteriosis, ^a canine respiratory viruses, canine distemper, feline chlamydiosis, plague, ^a tularemia ^a	House in separate facilities if infection is acute and active. Wear protective clothing, including headgear, when handling patient with zoonoses, and wash hands between patients.
Fecal-oral transmission, high contagion	Canine parvoviral infection, feline panleukopenia, canine distemper (multisystemic), infectious canine hepatitis	Strict isolation in separate facility. High risk of transmission and severe often fatal disease.

^a Zoonotic potential with direct transmission to people.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-15 *Indications for Hand Hygiene in the Veterinary Hospital*^a

Hand Washing or Disinfection

1. At the times of arrival or leaving the hospital
2. Between direct contact with each patient
3. After touching likely contaminated inanimate objects (catheters, drapes, cages, soiled surgical or bedding linens)
4. After handling patients likely colonized with multiple or resistant bacteria
5. Before preparing food or medications for patients
6. After removing gloves because of potential leak
7. After inadvertent contact with urine, feces, blood, or other body fluids or secretions
8. After personal body functions, including urination, defecation, sneezing, coughing, or nose blowing

Wearing Latex Gloves

1. Before and after handling open wounds
2. Before performing surgical, endoscopic procedures, or placing indwelling catheters
3. Before handling particularly susceptible patients (immunosuppressed or with indwelling tubes or catheters)
4. Gloves should not be rinsed before removing because of potential leaks

a Adapted from recommendations from Osborne CA. 2000. Are your patients in safe hands? *DVM Newsmagazine* Mar-Apr: 24–26 and other sources.

Table 94-16 Comparison of Commonly Used Topical Soaps and Antiseptics

AGENT	ADVANTAGES	DISADVANTAGES
Hand soap	Noncaustic, inexpensive	Liquids and moist bars support bacterial growth
Hexachlorophene (phenolic)	Good for <i>Staphylococcus</i>	Must use daily, central nervous system toxicity with absorption, minimal effect on gram-negative bacteria and fungi
Benzalkonium chloride (QUAT)	Inexpensive	Ineffective, harbors opportunistic bacteria (e.g., <i>Serratia</i>)
Alcohol	Relatively inexpensive, need 70% aqueous, ethanol Superior, rapid microbial killing, added moisturizers reduce irritation	Volatile, flammable, drying, bacterial resistance common
Iodine (halogen)	Good for viruses, fungi, and vegetative and sporulated bacteria; most effective as tincture; sustained germicidal action	Irritating, hypersensitivity, stains skin, drying
Iodophors (halogen)	Water soluble, low irritation, less staining	Reduced potency compared with iodine, drying
QUAT, Quaternary ammonium compound.		

Infectious Diseases of the Dog and Cat, 3rd Edition

94.3.4.4 Surgical Equipment

Surgical equipment should be appropriately sterilized with steam autoclaves or EO rather than cold disinfection, and it should be stored in dust-free, enclosed cabinets. Cold disinfection should be avoided when possible because it may be associated with the increased risk of infections from soil saprophytes such as *Clostridium tetani*. All surfaces in operating rooms that do not come in contact with the patient should be routinely disinfected with phenolic compounds. Floors can be washed with disinfectants and wet mopped or polished. Wet mops or vacuums with filtered exhaust elements can pick up excess disinfectant and loosening debris. Built-up disinfectant films can be removed with a solution of 0.12 L (one half cup) of vinegar in 3.8 L (1 gallon) of water. Dry mops and brooms should never be used to clean hospital floors because they disseminate microorganisms in dust. Personnel should wear facemasks to minimize aerosol contamination in surgery areas. Hand washing and gloving for surgery are superior to hand washing alone in minimizing the spread of skin microflora to the patient. Antisepsis of the skin at the incision site is similar to that in preparing IV catheter sites, but a final application of tincture of iodine or iodophor solution takes place just before the animal is draped.

1006

1007

Fig 94-2 Proper hand-washing technique using soap and water. (Courtesy University of Georgia, Athens, Ga.)

94.3.4.5 Anesthesia and Nebulizer Equipment

Anesthesia and nebulizer equipment should be washed with water and detergents. This equipment may be heat sensitive, and it may need to be sterilized with EO gas or soaked in 2% glutaraldehyde for 30 minutes, followed by aeration or sterile water rinse, respectively. All equipment should be completely dry before it is used. Solid rubber facemasks that can withstand heat disinfection may be flash autoclaved at 56° C for 3 minutes.

Rubber anesthesia circuits can be disinfected by immersion in 80° C water for 15 minutes. Soda lime canisters should be completely emptied and disinfected by similar means when needed.

Infectious Diseases of the Dog and Cat, 3rd Edition

Nebulizers and humidifiers can be disinfected by flushing hydrogen peroxide (20% by volume in water) through the system. Acetic acid at a concentration of at least 2% has been used, but it is somewhat ineffective against the more resistant gram-negative bacteria. Chlorhexidine (0.02%) is better for this purpose, especially at a temperature of 50° C. Temperature-controlled nebulizers that can be maintained at 45° C have the lowest prevalence of contamination. Periodic disinfection of nebulizer chambers with chlorine bleach or sterilization with EO gas is also recommended.

94.3.4.6 Endoscopic Equipment

Endoscopic equipment should be cleaned with soap and water as soon as possible after each use to remove gross soil, rinsed thoroughly with clean water, then rinsed with a disinfectant solution. Iodophors and bleach are corrosive to metal parts. Flexible endoscopes should be effectively disinfected or sterilized between uses whenever possible, particularly if they are employed to examine normally sterile areas such as the respiratory and genitourinary tracts. Nosocomial outbreaks of *Pseudomonas* infections has been associated with incomplete cleaning of the biopsy channel of flexible bronchoscopes.¹⁷⁰ Flexible endoscopes can be sterilized by soaking in alkaline glutaraldehyde for 10 minutes and then rinsed with sterile water. Automated endoscope-reprocessing systems have also been developed that use performic acid as a sterilant.¹⁴⁹ Sterilization can be achieved with EO gas, but many endoscopes cannot withstand the 63° C aeration temperature that is commonly used and require more prolonged aeration at lower temperatures. Unlike rigid metal endoscopes, most flexible endoscopes cannot tolerate sterilization by steam autoclaving.

94.3.4.7 Cages

Animal-holding facilities must receive adequate disinfection. Mere cleansing of cages with liquid disinfectants between uses is insufficient. High-pressure cleaning will help remove organic residue (Fig. 94-3). Steam cleaning on a monthly basis is the most effective means of ward and cage sanitation. Transient washing at 82° C is considered optimal for cage disinfection except against spores of *Bacillus*, which can be killed if the washing is prolonged for a minute or more. Lower temperatures may be effective in destroying vegetative bacteria (Table 94-17).

Fig 94-3 Spraying walls with water as a cleaning practice to reduce dust and debris that can harbor microorganisms. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

94.3.4.8 Clothes and Dishes

Disinfection of these articles requires higher temperatures that can be achieved with automatic clothes washers, and dishwashers are preferred to manual rinsing (see [Table 94-17](#)). At high temperatures, most organisms will be killed; bacterial spores are the exception. Low-temperature (22° C) washing using laundry chemicals and bleach followed by drying is as effective as high-temperature (71° C) washing is for eliminating pathogenic bacteria.

94.4 CONTROL OF FREE-ROAMING ANIMALS

Free-roaming animals constitute a major reservoir for infectious diseases. Trapping, neutering, and returning animals to their environment has been done for free-roaming cats in many areas.^{128,154} Zoonotic diseases transmitted by free-roaming cats include plague, rabies, toxoplasmosis, *Bartonella henselae* infection, and *Salmonella typhimurium* infection. Feral cats can also transmit these and other nonzoonotic infections such as FeLV and FIV to native wild felids. Animals should be identified, and many female cats are pregnant during the course of infection. Euthanasia of debilitated cats is usually required.

94.4.1 Quarantine to Reduce Spread of Exotic Infections

Restricting travel of infected dogs and cats is essential in some regions to control the spread of infections to nonendemic areas. The rapid speed and long distance of current international transportation of animals has a high risk of spreading infectious agents. Even quarantine may be insufficient to stop the entry of some persistent infections. Dogs infected with *Babesia*, *Ehrlichia*, and *Leishmania* have been detected in those imported into the United Kingdom under its new “Pet Travel Scheme” or conventional quarantine.¹⁶² This system replaces the 6-month quarantine for some specified countries and rabies-free islands. A shortened quarantine period may facilitate the movement of animals into the general population and the potential of establishing an endemic focus, should suitable vectors or reservoir animal hosts be available.¹⁶⁷ In contrast, 6-month quarantine periods may have some psychologic effects on pets and their owners.¹⁴³ Future efforts to implement genetic screening for insidious exotic infectious agents may allow for more rapid detection of containment of infectious diseases and reduce the need for extended quarantines. [Table 94-18](#) summarizes some infectious diseases of dogs and cats that require screening or quarantine for international travel.

1007

1008

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-17 Susceptibility of Bacteria to Heat Disinfection

		TEMPERATURE			
PROCEDURE	ORGANISMS KILLED	°C	°F	TIME	COMMENTS
Dishwashing					
Automatic wash	Most vegetative bacteria	60	140	20 sec	Add detergent
Sterilization	All vegetative bacteria, most spores	82	180	10 sec	Add detergent
Manual wash	Some vegetative bacteria	43–49	110–120	10–20 sec	Add detergent
Cage Cleaning	All bacteria but spores	76.5	170	30 sec	Add disinfectant
	Gram-negative rods, gram-positive cocci	49	120	2–4 min	Steam or hot water
	Gram-negative rods	40–60	120–140	Instantaneous	Steam or hot water
	Gram-positive cocci	71	160	2–4 min	Steam or hot water
	All but <i>Bacillus</i> spores	82	180	Instantaneous	Steam or hot water
	<i>Bacillus</i> spores ¹⁸⁸	100	212	5 min	Steam or hot water
Anesthetic Tube Cleaning					
Mild disinfection	Most vegetative bacteria	55	132	3 min	Hot water
Pasteurization	All bacteria but spores	80	176	15 min	Hot water
Clothes Washing					
(Automatic)	All bacteria including spores	>71	>160	25 min	Add detergent and bleach to increase cidal activity
Heat Inactivation (dry heat)					
	Gram-negative rods	60	140	5 min	No organic material
		65	149	3 min	
		70	158	1 min	
	Unenveloped viruses	56–60	133–140	20–40 min	No organic material
		80	176	1 min	
	Foot-and-mouth disease virus ³⁹	50	122	2 days	No organic material
		80	176	3.75 min	No organic material
	<i>Cryptosporidium</i>	64	147	2 min	No organic material
		72	162	1 min	No organic material
	<i>Giardia</i>	70	158	10 min	No organic material
	<i>Bacillus</i> spores ¹⁸⁸	150	302	10	No organic material

94.5 VECTOR-BORNE INFECTIONS

94.5.1 Fleas

The host is essential in the maintenance and propagation of fleas in the environment. After feeding on the host, mating occurs, and the female begins to lay eggs within 24 hours. Forty or more eggs are laid per day, and they drop off in the host's environment. Fleas must be permanently associated with the host for survival. Use of insecticides and insect growth regulators with convenient formulations have allowed for control of fleas because of enhanced efficacy and improved owner compliance. [Tables 94-19](#) and [94-20](#) summarize control measures for vectors of infectious diseases of dogs and cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

94.5.2 Ticks

A large number of infectious agents, including viral, bacterial, and protozoa, are transmitted by ticks ([Table 94-21](#)). Most are three-host ticks in which each stage feeds on a different stage after molting. Most ticks of medical importance to dogs and cats are hard bodied, belonging to the family Ixodidae. These ticks have a hard dorsal back plate known as a scutum. The larval tick hatches from the egg within days to months, depending on environmental temperature and humidity. The tick can be recognized by having six legs and generally feeds on small rodents or birds because it remains on or close to the ground or on short vegetation. After feeding on the host for several days and becoming engorged, it drops off and molts into an eight-legged nymph. Nymphs find a suitable host, feed to engorgement, and then fall off to molt into the adult tick. Nymphs and adults generally feed on successively larger hosts. Ticks require feeding for reproduction and development. They seek (quest) for hosts during time periods when environmental temperature and humidity are suitable for this process. Once on the host, ticks crawl on the host to find a suitable place to attach. After they penetrate the epidermis and insert their hypostome, they secrete a cement-like substance that affixes them to the host. They do not feed until after 24 to 36 hours after attachment. Females, larvae, and nymphs slow feed for a range of 2 to 14 days, with the females feeding for the longest period. Male ticks feed briefly, if at all. In females that mate, a rapid feeding phase of engorgement occurs within the last day of attachment. While feeding, blood is consumed by the tick as its salivary gland secretions enter the host. These secretions contain biologically active compounds that serve as anticoagulants and antiinflammatory agents to help the tick avoid host immune mechanisms. Infectious agents harbored by the tick can be inoculated into the host during the feeding period.

1009

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-18 Organisms Persisting in the Host That Require Potential Screening or Quarantine for International Transport

ORGANISM (CHAPTER)	SCREENING METHOD	VECTOR	GEOGRAPHIC DISTRIBUTION
Rabies virus (22)	RFFIT or FAVN http://www.vet.ksu.edu/depts/rabies/	Mammalian carnivore by bites, rarely aerosols	Worldwide except some insular and peninsular nations
<i>Ehrlichia canis</i> (28)	Single IgG titer	<i>Rhipicephalus sanguineus</i>	Worldwide except some insular nations
<i>Brucella canis</i> (40)	Single IgG titer	Venereal, aerosols	Americas; foci in other areas
<i>Leptospira</i> spp. (44)	Agglutination titers with high values	No vectors	Worldwide and focused in temperate and tropical regions around water sources
Lyme borreliosis (45)	C6 protein-specific IgG assay or PCR of connective or other tissue	<i>Ixodes</i> spp. (ticks)	Worldwide with specific foci in vector habitat
<i>Yersinia pestis</i> (47)	Cytology and culture	Fleas	Worldwide with specific foci
<i>Leishmania</i> spp. (73)	Single IgG titer as a screen ^a Identification of organism by cytology, biopsy, culture, or PCR in blood, body fluids, or tissues	Phlebotomine sandflies	Worldwide with specific foci
<i>Babesia</i> spp. (77)	Serology as a screen ^a ; cytology of blood smears or PCR of blood cells	Various ticks, dog bites, transfusions, venereal, congenital	Worldwide; however, certain foci and variable by species
<i>Trypanosoma cruzi</i> (72)	Single IgG titer as screen ^a ; identification of organism by cytology or biopsy of blood or tissues	Reduvid bug	Americas in certain foci
<i>Trypanosoma</i> spp. (72)	Cytology of blood smears	Tse tse fly	Africa in certain foci
<i>Hepatozoon canis</i> (74)	Organism identification in blood smears; antibody titer performed	<i>Rhipicephalus sanguineus</i>	Worldwide foci in certain areas
<i>Hepatozoon americanum</i> (74)	Organism identification in muscle biopsy, rarely in blood smear	<i>Amblyomma maculatum</i>	Gulf Coast of North America
<i>Cytauxzoon felis</i> (76)	Organism identification in blood smears or as schizont in tissues	<i>Dermacentor variabilis</i>	Lower Eastern United States

^a Cross-reactivity within and between genera of protozoans can make this screening unreliable and may indicate transient infection or vector exposure; however, the presence of a antibody titer to one of these infections indicates further documentation should be considered.

Ticks can be removed manually using tweezers or forceps taking care using constant traction without twisting. Care should be taken so that mouthparts are not left embedded because foreign body inflammation will persist. Prevention involves periodic use of acaricides (see Tables 94-19 and 94-20).

Rhipicephalus sanguineus is one of the most ubiquitous tick species in the world. All three stages will feed on dogs, making it a domiciled pest wherever dogs are housed. As a result, the tick can be transported with dogs and establish infections in quarantine facilities and transmit infections to exposed dogs. Although previously

Infectious Diseases of the Dog and Cat, 3rd Edition

not found in the United Kingdom, live ticks have escaped detection and have been capable of propagating,¹¹ which may be caused by the change away from the 6-month quarantine as a result of reciprocity in the European Union. Live *R. sanguineus* have also been found in dogs living only in the United Kingdom that were exposed to automobiles or quarantine stations that housed imported dogs.

94.5.3

Sandflies

Flies of the genera *Lutzomyia* and *Phlebotomus* are important in the transmission of leishmaniasis. Control of these vectors should involve spraying the environment, most commonly with pyrethrin-based insecticides. Safer topical insecticides should also be applied to the skin and clothing of the human inhabitants and on animal fur. Because the dog is considered a potential reservoir in some countries, topical therapy or avoidance of vectors, which often feed at night, is essential in reducing the public health risk.¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-19 Control Measures for Vectors of Infectious Diseases of Dogs and Cats

INSECT OR ARACHNID	AGENTS TRANSMITTED	CONTROL MEASURES	RECOMMENDED INSECTICIDES, REPELLENTS, GROWTH REGULATORS
Flies	<i>Leishmania</i> spp., <i>Anaplasma</i> sp., <i>Bacillus anthracis</i> , <i>Francisella tularensis</i>	Hair clipped around wound Pick larvae out of wound Sanitation Elimination of larval food Use of screens with small mesh size Use of light traps, baited jar traps	Host-DEET Environment-chlorpyrifos
Mites	<i>Rickettsia tsutsugamushi</i>	Skin scrape to detect Control environment and maintain sanitation	Amitraz, phthalimide dip, selamectin, ivermectin
Fleas	<i>Yersinia pestis</i> , <i>Rickettsia felis</i> , <i>Francisella tularensis</i> , <i>Rickettsia typhi</i>	Sanitation Treat infested animals with appropriate flea control Treat outdoors with sprays and elimination of rodents Treat indoors with use of vacuum and baseboards	DEET, permethrin, fipronil, imidacloprid, lufenuron, selamectin, nitenpyram, methoprene, pyriproxyfen, organophosphates
Ticks	<i>Ehrlichia</i> spp., <i>Borrelia</i> spp., <i>Francisella tularensis</i> , <i>Hepatozoon</i> spp., <i>Rickettsia rickettsii</i> , <i>Cytauxzoon felis</i> , <i>Anaplasma phagocytophilum</i> , <i>Babesia</i> spp.	Remove leaf litter, landscape barriers, deer fencing, bait box placement, host treatment, biologic control (chitin-synthesis inhibitors)	DEET, fipronil, organophosphates, amitraz, permethrin, selamectin
Mosquitoes	Equine encephalomyelitis, West Nile virus	Avoiding infested habitats Wearing protective clothing Using insect repellent Draining of swamps Cleaning ditches Treating of streams and ponds Management and cleaning of storm water-retention structures	DEET, citronella, Skin-So-Soft Bath Oil®

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 94-20 Some Chemicals Used in the Control of Arthropod Vectors of Infectious Diseases of Dogs and Cats

CHEMICAL (BRAND NAME, COMPANY; PREPARATION)	AFFECTED VECTOR	DOSE (DURATION)	SPECTRUM
Organophosphates (Paramite™, Vet-Kem; topical sponge-ons)	<i>Ixodes scapularis</i> eliminated rapidly with environmental damage ¹⁸⁹	11.6% active ingredient; 1 oz/gal of water (kills adult fleas 16 days)	Ticks, fleas, mites (adulticide)
Amitraz (PREVENTIC™ collars, Virbac; impregnated collar)	<i>I. scapularis</i> did not transmit <i>Borrelia burgdorferi</i> 7 days after collar placed ⁵²	9% amitraz (one collar effective for 3 mos)	Ticks, mites (preventative: inhibits mouth parts)
Permethrin (Proticall®, Defend®, EXspot®, Schering-Plough; topical spray and spot-on)	<i>I. ricinus</i> , ¹⁴⁰ <i>I. scapularis</i> , <i>Rhipicephalus sanguineus</i> , <i>Dermacentor variabilis</i> , <i>Ctenocephalides</i> spp.	1 cc/30 lb (effective against <i>Ixodes</i> , <i>C. felis</i> 4 wks, <i>Dermacentor</i> 3 wks)	Ticks, fleas (adulticide)
Fipronil (Frontline®, Merial; topical spray and spot-on)	<i>Ctenocephalides felis</i> , <i>Ixodes</i> , <i>Dermacentor</i> , <i>R. sanguineus</i> , <i>Amblyomma</i> , <i>Haemophysalis</i> , ¹⁶¹ <i>Otodectes</i> ⁴⁰	Contains 9.7% fipronil 7.5–15 mg/kg (every 30 days but can control fleas for up to 3 mos)	Ticks, fleas (adulticide, ovicide, larvicide)
Permethrin-imidacloprid (K9Advantix®, Bayer; topical spot-on)	<i>R. sanguineus</i> 98.5% efficacy after 3 days, ⁹³ <i>D. variabilis</i> , <i>Ctenocephalides</i> spp., <i>I. ricinus</i> (product insert)	8.8% imidacloprid, 44.0% permethrin (every 30 days, kills ticks up to 4 wks)	Fleas, ticks, mosquitoes (adulticide, larvicide)
Imidacloprid (Advantage®, Bayer; topical spot-on)	<i>Ctenocephalides</i> spp. (product insert)	9.1% imidacloprid 10–20 mg/kg (every 30 days) <10 lb = 0.4 ml tubes, 11–20 lb = 1.0 ml, 21–55 lb = 2.5 ml, >50 lb = 4.0 ml	Fleas (adulticide, larvicide)
Lufenuron (Program®, Sentinel®, Novartis; oral)	<i>C. felis</i> on cats treated with 30 mg/kg produced nonviable eggs for 14 days; larvicidal activity for 32 to 44 days (product insert)	Injectable: 10 mg/kg (every 6 mos); oral suspension: 30 mg/kg (every 30 days); tablet: 10 mg/kg (every 30 days)	Fleas (larvicide, ovicide)
Lufenuron/milbemycin oxime (Program Plus®, Novartis; oral)	<i>C. felis</i> , <i>Dirofilaria immitis</i> , <i>Ancylostoma caninum</i> , <i>Toxocara canis</i> , <i>Trichuris vulpis</i> (product insert)	0.5 mg/kg milbemycin oxime, 10 mg/kg lufenuron every 10 days	Fleas (larvicide, ovicide); anthelmintic
Nitenpyram (Capstar™, Novartis; oral)	<i>C. felis</i> ¹⁶¹	2–4 mg/kg (daily)	Fleas (adulticide)
Selamectin (Revolution™, Pfizer; topical spot-on)	<i>R. sanguineus</i> , <i>D. variabilis</i> , ¹⁴⁰ <i>Ctenocephalides</i> spp., sarcoptic ascariasis ⁴⁰	Dog: 6 mg/kg (every 30 days)	Fleas, ticks, mites (adulticide, larvicide, ovicide)
Permethrin/methoprene (Zodiac FleaTrol®; topical spot-on)	<i>Ctenocephalides</i> spp. (product insert)	Permethrin 45%; methoprene 2.9% (every 30 days)	Fleas (ovicide)

Infectious Diseases of the Dog and Cat, 3rd Edition

95 CHAPTER 95 Immunodeficiencies and Infectious Diseases

Urs Giger

Craig E. Greene

Immunodeficiencies are a large heterogeneous group of hereditary and acquired disorders of host immunity that can be associated with an increased risk of infection ([Table 95-1](#)).^{40,77,92,102} They can arise through disturbances in antigen-specific defense mechanisms mediated by lymphocytes, the nonspecific defense system (which includes phagocytes, plasma proteins, and physical barriers), or both. Although the exact pathogenesis of many canine and feline immunodeficiencies remains unknown, the molecular defects for some forms have been elucidated. Because many effective preventive and therapeutic measures are now available to control infectious diseases in individuals with intact host defense mechanisms, animals with persistent, antimicrobial-unresponsive infections likely suffer from an immunodeficiency disorder. A few hereditary immunodeficiency disorders are prevalent within certain breeds of dogs and cats, whereas others have been described once and may currently exist only in research animal colonies.

Some major clinical features suggest that a patient has an impaired immune system ([Table 95-2](#)). Specific organisms and medical conditions often implicated in immunocompromised hosts are listed in [Table 95-3](#). A definitive diagnosis often requires specific immune testing in addition to routine laboratory tests, and therapeutic interventions are limited. Immunodeficiencies can be divided into primary or secondary forms depending on whether they are inherited or acquired.

95.1 PRIMARY OR HEREDITARY IMMUNODEFICIENCIES

Many genetically determined immune defects have been described in the dog, whereas only a few are known in cats. They occur rarely and are summarized in [Table 95-4](#); some are discussed next in more detail in the Specific Primary or Inherited Immunodeficiencies section of this chapter. They can be broadly classified according to defects of the specific or nonspecific immune system as well as combinations thereof.⁷² The nonspecific immune system, also known as *innate* or *natural immunity*, should be functional at birth and available on short notice to protect the host from invasion by all sorts of organisms. It includes physicochemical barriers, phagocytes, complement and other plasma proteins, and natural killer cells. Congenital barrier defects particularly involve the skin and mucous membrane surfaces and are associated with infections of particular organs. The Ehlers-Danlos syndrome, causing fragile, hyperextendable skin in many dogs and cats as well as the myxedematous skin and immunodeficiencies of Shar-peis, predisposes the animals to pyoderma, whereas ciliary dyskinesia in dogs increases the susceptibility to rhinosinusitis and pneumonia. Disorders of the phagocytic system involve defects of neutrophils and monocytes as well as the complement system and can lead to pyogenic and granulomatous infections. The granulomatous reaction can occur when neutrophils malfunction and mononuclear cells are recruited. A wide variety of pyogenic bacteria (e.g., staphylococci, *Escherichia coli*, *Klebsiella*, *Enterobacter*) are usually involved, most of which are normal microflora or pathogens of relatively low virulence. Recurrent infections of the skin, respiratory tract, and oral cavity are common, and intermittent bacteremia and overwhelming sepsis are also seen. Multisystemic amyloidosis, vasculitis, and immune complex disease are complications that can occur as a result of chronic recurrent or persistent infection. Cyclic hematopoiesis and leukocyte adhesion deficiency (LAD) are examples of quantitative and qualitative phagocytic defects, respectively.

1014

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 95-1 Features of Immunodeficiency Diseases Based on the Underlying Defect

DEFECT	SUSCEPTIBILITY TO SPECIFIC INFECTIONS	DIAGNOSTIC TESTS TO CONFIRM DEFECT
Physical barrier Ciliary dyskinesia Ehlers-Danlos syndrome	Respiratory infections Skin injury and infections	Electron microscopy of cilia Histopathology and electron microscopy of skin
B cell	Pyogenic bacteria, <i>Giardia</i> spp.	Globulin, serum electrophoresis, tetanus antibody response
T cell	Bacterial sepsis, mycobacteria, <i>Candida</i> and <i>Pneumocystis</i> spp.	Thymic radiographs, skin testing delayed hypersensitivity, CD4 and CD8 lymphocytes
Granulocyte	Bacteria; streptococci; <i>Pseudomonas</i> , <i>Candida</i> , <i>Nocardia</i> , and <i>Aspergillus</i> spp.	Neutrophil count, phagocytosis assays
Complement	Pyogenic bacteria	CH ₅₀ assay

Table 95-2 Major Clinical Signs of Immunodeficiency Disorders

1. Recurrent infections, chronic and protracted course of infection, or both
2. Infection with common nonpathogenic (opportunistic) or aberrant infectious agents
3. Severe and often atypical infectious disease manifestations
4. Delayed, incomplete, or lack of response to antimicrobial therapy
5. Adverse reactions to modified-live virus vaccines

The specific immune system can be divided into humoral and cell-mediated immune systems and includes B and T lymphocytes, immunoglobulins, and cytokines.⁷² Deficiencies of B lymphocytes or humoral immunity affect the production of immunoglobulins and lead to increased susceptibility to pyogenic bacterial infections. Deficiencies of T lymphocytes or cell-mediated immunity (CMI) are associated with viral and fungal infections, but intracellular bacterial infections may also occur. Animals with cellular immunodeficiencies may have smaller thymic and tonsillar tissues as well as intestinal and peripheral lymph nodes and decreased numbers of circulating lymphocytes.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 95-3 Organisms and Medical Problems Commonly Implicated in Immunocompromised Hosts

Opportunistic Organisms

Viruses: Feline herpesvirus, feline infectious peritonitis virus, feline calicivirus, canine papillomavirus, canine herpesvirus

Mycoplasma: *Mycoplasma haemofelis*

Bacteria: *Citrobacter* spp., *Escherichia coli*, *Enterobacter* spp., *Klebsiella pneumoniae*, *Mycobacterium* spp., *Nocardia asteroides*, *Proteus* spp., *Pseudomonas aeruginosa*, *Serratia marcescens*, *Staphylococcus intermedius*

Fungi: *Aspergillus* spp., *Candida* spp., *Cryptococcus* spp., *Histoplasma* spp., *Blastomyces* spp., *Coccidioides* spp., *Mucor* spp.

Protozoa: *Pneumocystis* spp., *Toxoplasma gondii*, *Neospora caninum*, *Cryptosporidium* spp., *Giardia* spp., *Tritrichomonas* spp., *Isospora* spp.

Metazoa: *Demodex canis*, *Otodectes notoedres*

Medical Problems

Recurrent skin infections

Recurrent mucosal infections

Neonatal sepsis and mortality

Reactive amyloidosis

Vasculitis, arteritis, polyarthritis

Recurrent bacteremia

Granulomatous infections

Chronic hypersensitivity reactions

Autoimmune diseases

Persistent intracellular rickettsial or bacterial infections

Disproportional leukocytosis

Persistent lymphopenia

The degree of immunodeficiency varies greatly between defects. Infections may be systemic or restricted to a particular organ system like the skin or respiratory tract. Some immunodeficiencies lead to overwhelming infections and death within the first few days to weeks of life, whereas others, such as morphologic leukocyte changes, are not consistently associated with any noticeable predisposition to infection. Chédiak-Higashi syndrome in smoke-colored Persian cats is characterized by abnormally large eosinophilic granules in polymorphonuclear leukocytes. It causes no immunodeficiencies but does cause a bleeding tendency resulting from a platelet storage pool disease.¹⁷¹ Similarly, Birman cats with acidophilic granulation of neutrophils and dogs and cats with various lysosomal storage diseases (e.g., mucopolysaccharidosis, gangliosidosis, mannosidosis) have granulation or vacuolation of leukocytes without being immunocompromised. The

1014

1016

Infectious Diseases of the Dog and Cat, 3rd Edition

Pelger-Hu't anomaly, which is characterized by hyposegmentation of granulocytes, causes no immunodeficiency, despite the fact that the leukograms of affected dogs and cats reveal the most severe left shift with a normal leukocyte count. In foxhounds, in vitro chemotactic response of these neutrophils was diminished, whereas in basenjis no functional abnormalities have been found.^{16,139-141}

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 95-4 Primary or Hereditary Immunodeficiencies of Dogs and Cats^a

DISEASE (SYNONYMS)	INHERITANCE ^b	BREEDS	DEFECT	CHARACTERIZATION
Dogs				
Ciliary dyskinesia ^{48, 68, 81, 142} (immotile cilia syndrome)	AR	Many breeds ^b	Functional and morphologic cilia abnormalities	Rhinosinusitis, bronchopneumonia with bronchiectasis, situs inversus
Complement component 3 ^{14, 248, 249} (C3 deficiency)	AR	Brittany spaniel	C3 deficiency	Pyogenic infections, lack of C-mediated phagocytosis in colony of dogs with neuromuscular disease
Neutrophil Defects				
Bactericidal neutrophil defect ¹⁷	U	Doberman pinscher	Unknown	Upper respiratory infections, reduced bactericidal activity, ciliary dyskinesia not excluded
Cyclic hematopoiesis ^{126, 151} (cyclic neutropenia)	AR	Collie (gray)	Hematopoietic growth factor defect	Severe neutropenia every 12–14 days, reactive amyloidosis
Chronic idiopathic neutropenia ¹³⁸	U	Rottweiler	G-CSF deficiency	Recurrent fever, sepsis, polyarthritis, pyoderma
Leukocyte adhesion deficiency ^c	AR	Irish setter, Red and white setter	CD11/18 deficiency β chain (CD18) deficiency	Severe leukocytosis, infection with limited pus formation, lack of neutrophil adhesion
Pelger-Huët anomaly ^{16, 140}	AD	Australian shepherd, foxhound, others	Unknown	No immunodeficiency, hyposegmented granulocytes
Selective cobalamin malabsorption ^{86, 87, 187}	AR	Giant schnauzer, border collie, beagle, Australian shepherd	Ileal cobalamin receptor defect	Weight loss, inappetence, leukopenia with hypersegmentation megaloblastic bone marrow, methylmalonic aciduria
Cell-Mediated Immune Defects				
Increased susceptibility to avian mycobacteriosis ^{41, 56, 107, 227}	U	Basset hound	Possible RAMP deficiency	Systemic avian tuberculosis (see Chapter 50), toxoplasmosis and neosporosis
Increased susceptibility to <i>Pneumocystis</i> pneumonia ^{15, 39, 70}	AR	Dachshund	Unknown	<i>Pneumocystis</i> pneumonia (see Chapter 68)
Susceptibility to fungal and rickettsial infections; pyoderma ^{29, 50, 173, 210, 250}	U	German shepherd	Possible macrophage or T-cell defect	Severe ehrlichiosis (see Chapter 28), Rocky Mountain spotted fever (see Chapter 29), disseminated aspergillosis (see Chapter 64), deep pyoderma

Infectious Diseases of the Dog and Cat, 3rd Edition

X-linked severe combined immunodeficiency (X-SCID) ^d	XR	Basset hound, Cardigan Welsh corgi	Common gamma chain of IL-2 and other cytokines	Severe bacterial and viral infections, no IgG and IgA, deficient lymphocyte blastogenesis
Severe combined immunodeficiency (SCID) ^d	AR	Jack Russell terrier	DNA-protein kinase catalytic subunit	Severe serum immunoglobulin deficiency, hypoplasia of lymphoid tissues
Combined immunodeficiency ²⁰⁶	U	Shar-pei	T-cell and B-cell defects, low IL-6 and IL-2	Skin, respiratory, and gastrointestinal infections
Immune vasculitis, amyloidosis ^e	U	Shar-pei	Elevated IL-6	Arthritis, amyloidosis, renal failure, hepatic rupture, hypoproteinemia
Lethal acrodermatitis ¹²³	AR	Bull terrier	Zinc metabolism defect	Zinc deficiency, hyperkeratosis
Increased susceptibility to parvoviral infection	U	Rottweiler, Doberman pinscher	Unknown	Parvovirus infection (see Chapter 8)
Vaccine-exacerbated immune disturbance ⁶⁶	U	Akita	Unknown	Variable meningitis, polyarthritis, amyloidosis (see Chapter 100)
Thymic abnormalities and dwarfism ^{211, 212}	U	Weimaraner	Unknown	Reduced growth, thymosin responsive
Humoral Immune Defects				
Recurrent infections ^{41, 56, 107, 227}	U	Weimaraner	Reduced IgG	Pyoderma, severe abscess, bleeding tendency (HOD, see Chapter 100)
Selective IgA deficiency ^{73, 89, 97, 175, 247}	U	Beagle, Shar-pei, German shepherd	IgA deficiency	Respiratory and GI infections
Cats				
Hypotrichosis congenital and thymic atrophy ²⁵	AR	Birman	Unknown	Nude kittens, neonatal death, no thymus
Leukocyte granulation ¹¹⁵	U	Birman	Unknown	No immunodeficiency, acidophilic granules
Pelger-Huët anomaly ¹⁴¹	AD	Domestic shorthair	Unknown	No immunodeficiency, hyposegmentation
Chédiak-Higashi syndrome ^{37, 135}	AR	Persian	Unknown	No immunodeficiency, large granules in phagocytes, bleeding tendency
Reactive (AA) amyloidosis ^{62, 63, 108}	U	Abyssinian	Unknown	Reactive (AA) amyloidosis, renal failure
Feline GM1 gangliosidosis ⁴²	U	Domestic shorthair	Unknown	Premature thymic involution

Although an increased susceptibility to opportunistic infections develops, the type of infection varies depending on the type of defect within the immune system. A few immunodeficiency disorders predispose animals to a restricted group of unusual infectious agents. Some male dachshunds appear predisposed to *Pneumocystis* pneumonia, and German shepherd dogs may be prone to systemic aspergillosis or rickettsioses. Doberman pinschers and Rottweiler dogs are more likely to develop parvoviral disease. Golden and Labrador retrievers that had high serum antibody titers to *Borrelia burgdorferi* were more likely to have glomerulonephritis.⁴⁷ Basset hounds and miniature schnauzers have an increased susceptibility to systemic avian mycobacteriosis, toxoplasmosis, and neosporosis. Foxhounds appear to be predisposed to developing leishmaniasis. Great Danes and Dobermans may be more susceptible to cryptococcal infections.¹⁵⁷ A genetic predisposition to demodicosis has been proposed in various canine breeds and families. Feline infectious peritonitis has also been suggested to have a genetic basis (see [Chapter 11](#)). The mechanisms predisposing particular animals to specific infections remain unknown in many breeds.

1016

1017

Fig 95-1 Two littermate Rottweiler pups. Pup on left has stunted growth from chronic recurrent infections. (Courtesy University of Georgia, Athens, Ga.)

The previously mentioned key signs of infection (see [Table 95-2](#)) develop in animals with a primary immunodeficiency generally early in life. Despite receiving colostrum, clinically affected animals may have illness during the neonatal to juvenile period and may develop recurrent and overwhelming infections that lead to severe debilitation and death before 1 year of age. Several animals, but typically not all, in a litter may be affected, whereas the parents are usually healthy. A genetic predisposition to infection is rarely noted after 1 year of age (e.g., avian tuberculosis in basset hounds). Furthermore, animals with primary immunodeficiencies may have other special clinical manifestations. Hypersensitivity reactions may occur and reflect an overall dysregulation of the immune system caused by a lack of one or more components or a chronic antigen stimulation from inadequate clearance of infections. Chronic systemic infections may also hamper the growth rate ([Fig. 95-1](#)). Characteristic coat color dilutions and increased tendency for surface bleeding are seen in collies

Infectious Diseases of the Dog and Cat, 3rd Edition

with cyclic hematopoiesis, Persian cats with Chédiak-Higashi syndrome, and Weimaraners with an incompletely defined immunodeficiency.

The mode of inheritance of primary immunodeficiencies has not yet been determined in all cases. Autosomal recessive transmission, with affected males and females born to healthy parents, is usual, but a few exceptions exist. The Pelger-Hu't anomaly is inherited as an autosomal dominant trait. A severe combined immunodeficiency from different mutations in the common γ -chain interleukin-2 (IL-2) receptor in basset hounds and Cardigan Welsh corgis is an X-linked recessive disorder, so only males are affected, and the dams and half of the female littermates are carriers. Thus the breed, gender, age of onset, type of infections, and other special characteristics may suggest a particular immunodeficiency.

95.2 SECONDARY OR ACQUIRED IMMUNODEFICIENCIES

All components of the immune system of animals with secondary immunodeficiencies are initially intact and functional but become transiently or permanently impaired during or after an underlying disease condition or exposure to certain agents. Thus secondary immunodeficiencies occur much more commonly than primary forms. They are associated with organ impairment and entrance of infectious agents into the body. This infection may cause additional damage to the particular organ or lead to systemic infectious diseases. Various barrier disturbances lead to surface infections, such as respiratory tract, urogenital, and gastrointestinal infections and dermatitis. Furthermore, certain infections, particularly viral diseases in cats, directly impair the immune system, predisposing the animals to secondary bacterial, fungal, or protozoal infections. For example, cats infected with the feline immunodeficiency virus (FIV) harbor more diverse fungal microflora on the hair and mucosal surfaces than noninfected cats,²¹⁸ which may predispose the FIV-infected cats to a greater prevalence of secondary fungal infections.

Puppies and kittens are particularly vulnerable to infections because of their incompletely developed immune systems. Colostrum intake during the first day of life transfers maternal immunoglobulins and provides protection during the first few weeks of life in small animals. Although colostrum deprivation has been shown in large animals to result in major neonatal losses, neonatal kittens and puppies kept in high-quality catteries or kennels do not seem to be predisposed to infections. However, a transient hypoglobulinemia after the decline of maternal antibodies in the plasma and before the immunocompetency of 2- to 4-month-old animals may increase the susceptibility to various infections.²¹⁷ Similarly, older animals may again become immunocompromised. Various drugs and chemicals as well as nutritional deficiencies may drastically impair the production and function of leukocytes. Known secondary immunodeficiencies in companion animals are listed in [Table 95-5](#), and some are discussed in detail at the end of this chapter.

95.3 DIAGNOSTIC STUDIES

Although an immunodeficiency may be suspected on the basis of clinical evidence, specific laboratory tests are generally required to reach a definitive diagnosis.⁹⁰ A minimum database of information, including results of a complete blood count, serum chemistry screen, and urinalysis, should always be obtained and may suggest a specific disorder. The differential leukocyte count is the most important test result. Leukopenia in the presence of an active bacterial infection is by far the most feared condition. It should be noted that generally, some breeds have low white blood cell counts. Neutropenia may be transient, as it is with cyclic hematopoiesis every 12 to 14 days, or persistent, as it is in animals with cobalamin deficiency or overwhelming infections (sepsis). Lymphopenia may be observed in dogs with a T-cell or severe combined immunodeficiency. Although leukocytosis is expected during periods of infection, defects in leukocyte adhesion and egress from blood

Infectious Diseases of the Dog and Cat, 3rd Edition

circulation at sites of infection may be associated with disproportionately high leukocytosis for the degree of infection as with hereditary LAD and glucocorticoid usage. Dachshunds with *Pneumocystis* pneumonia also have very marked leukocytosis. The erythrocyte count may be in the normal range even if the animals have active infections and during periods of treatment and remission. Careful review of a blood smear may reveal leukocyte abnormalities such as granulation and vacuolation resulting from lysosomal storage diseases or Chédiak-Higashi syndrome,¹³⁵ acidophilic granulation of leukocytes in Birmans,¹¹⁵ phagocytized microorganisms, or toxic leukocyte changes that suggest overwhelming infections.

Serum globulin concentrations are generally higher during chronic infections. Low or normal globulin levels in infected animals may suggest major external losses or diminished production from a humoral (B-cell) immune defect. Indeed, specific immunoglobulin deficiencies have been recognized in dogs. Serum protein electrophoresis may identify a γ -globulin deficiency, but immunoelectrophoresis is required to detect the class and degree of immunoglobulin deficiency. Maternal immunoglobulins can only be absorbed during the first day of life and influence the values during the first few weeks. IgM can be synthesized very early in life, whereas the development of IgA may be delayed for months. Thus it is important to compare values with data from age-matched controls. Titers against specific antigens can be measured, followed by evaluation of the antibody response to vaccination against particular agents. However, despite the antibody titer level, cellular immunity is not being assessed. Biopsy specimens of lymph nodes may reveal disorganization with loss of germinal centers and normal paracortical lymphocytes. Decreases in plasma cell populations may also be evident.

T-cell or combined immunodeficiencies cause defective CMI responses. The animal may have prolonged allograft rejection times and decreased delayed-type hypersensitivity to skin testing with viral vaccines,

Infectious Diseases of the Dog and Cat, 3rd Edition

tuberculin, or dinitrochlorobenzene (DNCB).¹⁸⁶ Reduced in vitro lymphocyte stimulation results may also be caused by a primary lymphocyte defect or the infection.

The identification of the agents infecting an animal is important for diagnostic as well as therapeutic reasons. (Appropriate cultures of tissues, body fluids, and excretions for microorganisms and antigen and serologic blood tests are addressed in the chapters on specific infectious agents.) Antibody titers may also be used to assess a response to vaccines and humoral immunity. For instance, Rottweilers appear to respond late to parvovirus vaccines and have an increased susceptibility to the infection.

Gross and microscopic histopathology and cytology may reveal certain microorganisms but are most helpful in characterizing the architecture, morphology, maturation, and function of the immune system, such as of the leukocytes, bone marrow, lymph nodes, thymus, and spleen, as well as other barrier systems. In ciliary dyskinesia, morphologic abnormalities of cilia may be identified by electron microscopy, but functional studies by imaging techniques or on respiratory epithelial biopsy specimens are also indicated.

For additional characterization of the immunodeficiencies, special leukocyte studies are often required. Surface marker studies by fluorescent-assisted cell sorters or flow cytometers can differentiate between T- and B-cells, determine T- and B-cell ratios, and determine the presence or absence of leukocyte adhesion proteins (CD11/18) or IL-2 receptors. Lymphocyte function studies include lymphocyte stimulation and plaque-forming assays for in vitro immunoglobulin production. Phagocyte function studies assess leukocyte adhesion, migration, chemotaxis, phagocytosis, “respiratory burst,” and bactericidal activity. All functional assays should be performed on fresh blood cells and compared simultaneously with an age- and breed-matched control. Furthermore, in vitro lymphocyte functions are generally impaired and phagocyte functions are enhanced during periods of active infection. Whenever possible, it is advisable to control the infection before studying leukocyte function.

95.4 TREATMENT AND PREVENTION

Successful control of infection in immunodeficient animals depends on the underlying disease as well as the type and severity of the immune defect. In immunocompromised patients, early and aggressive antimicrobial therapy is indicated even for mild infections with nonpathogenic agents. Because of the immunodeficient host's potential inability to kill bacteria, bactericidal antibiotics are recommended until bacterial infections are controlled. If the underlying disorder causing a secondary immunodeficiency can be corrected, the infection is often easily controlled. The underlying disorder should be treated and triggering agents such as drugs eliminated immediately.

1018

No practical treatments for primary immunodeficiencies exist. Immunocompromised animals with infection generally have a guarded to poor prognosis. Despite aggressive antimicrobial therapy, their infections are difficult to control, leading to overwhelming infections, protracted courses, and recurrences. Some leukocyte defects cause death before 1 year of age, whereas others may not lead to a markedly increased predisposition to infection. In experimental studies, bone marrow transplantation corrected several leukocyte defects.^{111,152} Granulocyte colony-stimulating factor (GCSF) has been used to increase neutrophil numbers and treat chemotherapy-induced and cyclic neutropenia (see [Chapter 2](#)).

1019

Fresh whole blood may be transfused repeatedly to animals with overwhelming infections and neutropenia or neutrophil dysfunction, but the effect is very transient. Plasma transfusions or immunoglobulin injections may temporarily support animals with humoral immunodeficiencies. However, these products should not be used in animals with complete IgA deficiency because they may experience anaphylactic reactions to the foreign IgA protein. No commercial canine γ -globulin is available, and the human γ -globulin preparations are exorbitantly expensive and may cause allergic reactions upon repeated use. No data support their use in immunodeficient

Infectious Diseases of the Dog and Cat, 3rd Edition

infected small animals, although they have been successfully treated immune-mediated diseases. Nonspecific immunostimulators have not been documented as being beneficial in animals with cell-mediated immunodeficiencies. However, immunocompromised animals with active infections should not be vaccinated. Furthermore, the use of modified live virus (MLV) vaccines should be avoided in animals with inherited or acquired T-cell defects, because they may develop clinical disease from the vaccine virus.

Owners must consider the potential zoonotic risks involved with keeping an immunodeficient animal with infections that may be contagious to humans, particularly immunosuppressed humans (see [Chapter 99](#)).

95.5 SPECIFIC PRIMARY OR INHERITED IMMUNODEFICIENCIES

95.5.1 Dogs

95.5.1.1 Primary Ciliary Dyskinesia

Primary ciliary dyskinesia, also known as *immotile cilia syndrome*, is caused by various functional and ultrastructural ciliary abnormalities, including lack of outer or inner dynein arms, abnormal microtubular pattern, random ciliary orientation, and electron-dense cores in the basal body. Because of impaired mucociliary clearance, affected animals have recurrent bacterial rhinitis, sinusitis, and bronchopneumonia with bronchiectasis. Poorly motile or immotile live sperms lead to male infertility, and although evidence is lacking, dysfunction of ependymal cilia may cause hydrocephalus. Otitis media may also occur. The lack of coordinated cilia motility during embryogenesis is responsible for the 50% prevalence of concurrent situs inversus in some forms of primary ciliary dyskinesia. The clinical triad of rhinosinusitis, bronchiectasis, and situs inversus is known as *Kartagener's syndrome*.^{68,177,201}

Primary ciliary dyskinesia is inherited by an autosomal recessive trait. It represents a heterogeneous group of defects that have been described in more than a dozen breeds.²⁴⁴ Clinical signs typically begin at a young age, and recurrent respiratory infections lead to death or euthanasia before 1 year of age. However, a few dogs have remained nonsymptomatic for months to years.⁸¹ A diagnosis is reached by documenting an absence of ciliary clearance of a microaggregated albumin that is labeled with technetium 99 m (Tc 99 m) and placed through a catheter into the nasal cavity or the tracheal bifurcation and by tissue biopsy of ciliated mucosae with ultrastructural analysis and in vitro motility studies.^{33,48} Induction of ciliogenesis can also be determined by use of in vitro cell culture.³³

95.5.1.2 Rhinitis and Bronchopneumonia in Irish Wolfhounds

Chronic recurrent respiratory infections have been observed in related Irish wolfhounds from Europe and Canada.^{34,142} In puppies the disease begins with a serous rhinitis that later becomes catarrhal to hemorrhagic with turbinate ulceration and destruction. Pneumonia and generalized lymphadenomegaly are apparent in later stages. Although the disease is responsive to antimicrobial treatment, it may progress in intervening periods. Although a familial relationship exists, the exact mode of inheritance and the underlying defect are uncertain. A primary ciliary dyskinesia has been identified in some wolfhounds²⁴ but has not been a consistent feature of the disease. Serum IgA levels were reduced in some dogs, but bronchoalveolar lavage fluid had high IgA concentrations in tested dogs, which may relate to their inflammatory response to infection.³⁴

Infectious Diseases of the Dog and Cat, 3rd Edition

95.5.1.3 Neutrophil Bactericidal Defect with Respiratory Infection in Doberman Pinschers

Neutrophil dysfunction was described in a family of Doberman pinschers in which a young animal had chronic recurrent respiratory tract infections.¹⁷ Oxygen radical formation and bactericidal activity of neutrophils were reduced despite normal phagocytosis of bacteria. The specific defect has not yet been identified, and primary ciliary dyskinesia has not been completely ruled out. The ciliary morphology appeared normal, but no functional studies have been performed. Affected Doberman pinschers develop clinical signs of upper respiratory tract infections at a few weeks of age. They respond to antibiotics, but the prognosis is guarded.

95.5.1.4 Cyclic Hematopoiesis

Cyclic hematopoiesis is characterized by a periodic production and maturation defect of hematopoietic cells in the bone marrow.¹⁷⁸ In affected dogs, all blood cell counts cycle precisely at a 12- to 14-day interval, whereas in human patients the cycle is 21 days. Because of the short half-life of granulocytes, severe neutropenia (fewer than 1000 per microliter) is seen every 12 to 14 days and lasts for 3 to 4 days, thus the synonym *cyclic neutropenia syndrome*. Serial blood counts are used to reach a definitive diagnosis. During periods of severe neutropenia, dogs are highly susceptible to bacterial infections. Clinical symptoms appear at 6 to 8 weeks of age with regularly recurring bacterial infections (Fig. 95-2). The chronic exposure leads to systemic amyloidosis, and death may be result from organ failure (of the kidney and other organs) and sepsis before 1 year of age. Furthermore, gingival bleeding may occur from an associated platelet storage pool disease. Affected collies have a silver gray or light beige to tan coat color, and secondary hormonal cycling has been observed.^{126,151}

Cyclic hematopoiesis was the first reported canine immunodeficiency observed and has only been clearly described in collies that are hypopigmented, hence the term *gray collie syndrome*. It is inherited as an autosomal recessive trait, but no clinical case has been reported since the 1970s. The basic mechanism for the defect is still being determined. Experimentally, bone marrow transplantation completely corrects this syndrome, including the coat color dilution. Furthermore, administration of lithium carbonate at extremely high and otherwise toxic doses is known to induce leukocytosis and ameliorates the cyclic neutropenia in affected animals. Similarly, injections of GCSFs, alone or in combination with steel factor, abolish the cycling, suggesting a signaling defect in the proliferation and maturation of hematopoietic cells. Mutations in a leukocyte elastase have been identified in humans with a similar syndrome.¹⁷⁸ However, the defect in dogs is associated with a homozygous mutation of the gene encoding the dog adaptor protein complex 3 β -subunit that directs trans-Golgi export of transmembrane cargo proteins to lysosomes.^{11,129}

(Courtesy Teaching File, University of Pennsylvania, Philadelphia, Pa.)

Infectious Diseases of the Dog and Cat, 3rd Edition

95.5.1.5 Leukocyte Adhesion Deficiency

LAD has previously been described as *canine granulocytopathy syndrome* in Irish setters and is also known as *canine leukocyte adhesion deficiency (CLAD)*.²⁰³ It is known to be caused by the absence of a family of three leukocyte integrins.^{57,93,233,235} These proteins are heterodimers (CD11a-c/CD18) with a specific α -chain (CD11a-c) and a common β -chain (CD18). In LAD, the β_2 -subunit is missing (CD18 deficiency), resulting in a lack of surface expression and function of all three leukocyte integrins. The CD11b/18 is the most critical integrin because is the CR3 receptor that binds C3bi and ICAM-1 of activated endothelium, thereby mediating tight adhesion leukocytes. Because of this deficiency, granulocytes are unable to marginate, migrate randomly or by chemotaxis, and kill microorganisms, resulting in an impaired inflammatory response despite marked leukocytosis (Fig. 95-3, A). Furthermore, the in vitro lymphocyte stimulation response is reduced. A single missense mutation substituting a cystine with a serine has been identified in affected Irish setters, and the same mutation has been found in red and white setters.^{57,84,131-133} Hematopoietic stem cell transplantation of CD18+ donor cells reverses the defect.⁸

Affected dogs have a severely increased susceptibility to bacterial and fungal infections. Signs of pyogenic infections develop during the first weeks to months of life, are often recurring, and are poorly responsive to antibiotics. Omphalophlebitis and gingivitis are often the first infections and might be followed by pyoderma, pododermatitis, thrombophlebitis, pneumonia, pyometra, osteomyelitis (especially craniomandibular and metaphyseal), and fatal sepsis. Pups are often stunted or have poor body condition.^{43,232} The sites of infections exhibit only minimal inflammation and pus formation despite a most severe persistent leukocytosis of 25,000 to 500,000/ μ l (see Fig. 95-3, B). Regional lymphadenomegaly and poor wound healing are commonly noted. Long-term therapy with bactericidal antibiotics is required to keep affected animals alive.

LAD has been reported in Irish setters worldwide and is an autosomal recessive disease. The defect also has been documented in red Holstein cattle and in humans.¹³¹ The diagnosis is currently made by mutation-specific DNA testing,^{84,132,133} whereas in the past, demonstration of a lack of neutrophil adherence to glass, plastic, or wool and deficiency of leukocyte glycoproteins CD11/CD18 by flow cytometry analysis were used (see Fig. 95-3, C). A polymerase chain reaction (PCR) test is also available²³⁹ (see Appendix 6). Laboratories are available that can perform these assays commercially (see Appendix 5 for commercial laboratories). The same LAD mutation appears to be widespread in Irish setters and Red and White setters.^{84,124,133} Carrier dogs can be detected by genetic testing.⁵⁷ Mixed chimeric hematopoietic stem cell transplantation from a histocompatible littermate has been shown to reverse the clinical signs of illness in an affected dog.⁴⁴ At times, donor recipients were immunosuppressed with cyclosporine and mycophenolic acid mofetil during the 2 months after transplantation.

95.5.1.6 Complement C3 Deficiency

A C3 deficiency was found in a colony of Brittany spaniels with spinal muscular atrophy.^{14,248,249} C3 is a key factor of the complement system required in opsonizing bacteria. Affected dogs have defective chemotaxis and bacterial phagocytosis from a complete deficiency of C3 (0.1%) and less than 1% plasma complement activity. The immunodeficiency is generally mild and animals live until adulthood, but serious infections may occur, including pneumonia, pyoderma, sepsis, pyometra, and septic arthritis. Affected dogs

Infectious Diseases of the Dog and Cat, 3rd Edition

may develop renal failure with amyloidosis. This is an inherited autosomal recessive disorder, and a diagnosis can be reached by documenting a lack of serum complement activity.

95.5.1.7 Selective Cobalamin Malabsorption

Chronic neutropenia and megaloblastic anemia have been described in giant schnauzers, beagles, Australian shepherds, and border collie pups.^{85,87,187} Affected animals fail to thrive and show signs of lethargy, inappetence, and cachexia but are only rarely predisposed to infection accompanied by fever, lameness, or diarrhea. Blood smears show neutropenia with hypersegmented neutrophils. Affected animals have low serum cobalamin concentrations and methylmalonic aciduria. A cobalamin ileal receptor defect was documented in affected giant Schnauzers.⁸⁷ Treatment with parenteral administration of cobalamin once or twice monthly is highly effective.⁸⁵

95.5.1.8 Hereditary Neutropenia in Border Collies

Chronic neutropenia and recurrent bacterial infections has been found in certain lines of border collies in Australia and New Zealand.² This suspected autosomal recessive defect is characterized by stunted growth in pups by 2 weeks of age and fever, anorexia, diarrhea, and lameness by 2 months of age. Metaphyseal osteomyelitis is seen radiographically, and neutropenia (fewer than 3×10^9 cells/ μ l) is consistently found. Bone marrow cytology shows granulocytic hyperplasia with a shift to the right, suggesting that the developing cells cannot enter the systemic circulation. Fasting hypercholesterolemia is also observed. Pups respond poorly to antimicrobial therapy and eventually succumb to systemic infections.

95.5.1.9 Common Variable Immunodeficiency in Miniature Dachshunds with Pneumocystosis

Certain lines of miniature dachshunds are predisposed to developing *Pneumocystis* pneumonia by 1 year of age (see [Chapter 68](#)). This predisposition also occurs in Cavalier King Charles spaniels; however, additional immunologic studies in those dogs are not available. Affected miniature dachshunds have hypogammaglobulinemia, with decreased IgA, IgG, and IgM; decreased lymphocyte transformation to phytohemagglutinin and pokeweed mitogens; and absence of B cells and presence of T cells in lymphoid tissues (stained by CD3 and CD79a cell markers).¹⁴⁶

95.5.1.10 Miscellaneous Defects in Dogs

Increased susceptibility to avian mycobacteriosis has been recognized in basset hounds and miniature schnauzers (see [Chapter 50](#)). The underlying defect is unknown, but it may represent a defect in the resistance against mycobacterial protein. Similarly, English and American foxhounds in the United States are commonly infected with leishmaniasis^{88,188} and pit bulls and greyhounds with babesiosis (see [Chapter 77](#)), thus a genetic predisposition is suspected. Although the Pelger-Hu't anomaly has been observed in dogs, it has not been associated with clinical illness.¹³⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

95.5.1.11 German Shepherd Infections

German shepherds are more severely infected with *Ehrlichia canis* (see Chapter 28), *Rickettsia rickettsii* (see Chapter 29), and *Aspergillus* spp. (see Chapter 64). Some German shepherd dogs also are predisposed to pyoderma.^{29,50} These predispositions may involve separate defects that have yet to be undefined. Affected dogs have pruritus with a deep pyoderma over the lumbosacral region, which may spread to other regions.²¹⁰ Coagulase-positive *Staphylococcus intermedius* is most commonly cultured. Proposed mechanisms for this susceptibility include hypothyroidism, cell-mediated immunodeficiency associated with serum inhibitors or defective helper T cells, and bacterial hypersensitivity reactions to staphylococci.^{29,50,52,250} Although the inciting causes may be multivariate, the condition responds favorably to long-term administration of systemic antimicrobials. A German shepherd with familial cutaneous vasculopathy developed demodicosis after recovery from its vascular lesions.⁸⁰

95.5.1.12 X-Linked Severe Combined Immunodeficiency

X-linked severe combined immunodeficiency (X-SCID) is characterized by a failure of humoral immunity and CMI.^{72,75,78} It develops in various animal species when lymphocyte precursors fail to differentiate into mature lymphocytes because of mutations within recombina-activating genes 1 and 2 or within the genes encoding DNA-dependent protein kinase (DNA-PK). It also develops when differentiated lymphocytes are incapable of completing signal transduction pathways because of defects in cell surface receptors for ILs.¹⁹⁷ In dogs, defects in the γ^c chain lead to deficiency of several cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21).⁷⁴ Although profound deficiencies are found in T-cell function, some B-cell activities are preserved.¹¹⁰ For example, canine X-SCID B cells are capable of producing IgM but do not class-switch to the production of IgG after mitogen stimulation. The shared usage of a γ^c chain by these cytokines explains the profound immunologic abnormalities and the impaired IgG response.¹⁸⁹ The ability of lymphocytes to bind to IL-2 and proliferate is severely impaired, and the development of thymocytes is drastically reduced, with an increased proportion of CD4-/CD8-thymocytes.^{221,222} Serum IgG and IgA concentrations are low, but IgM values are normal.¹²² Because of the X-chromosomal recessive mode of inheritance, male dogs are affected, whereas females (the dams and some littermates of those affected) are carriers. The gene defect for this disease in dogs and people is on the proximal short arm of the X chromosome (Xq13). Two molecular mechanisms cause SCID in dogs. Jack Russell terriers have a mutation within the DNA-PKcs gene, whereas the Cardigan Welsh corgi and the basset hound have defects in the gene encoding the gamma chain that is common to the receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21.¹⁹⁷ Bassets with X-SCID have a deletion of four base pairs, which produces a frame shift and subsequent premature stop codon in exon 1.¹¹⁴ Affected Cardigan Welsh corgis have a cytosine insertion, resulting in a premature stop codon.^{113,199,220} Because of the variable genetic defect, the clinical spectrum of disease manifestations can differ among affected genetic lineages of dogs.

1021

1022

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 95-4 Basset hound puppy showing pyoderma and demodicosis from X-linked severe combined immunodeficiency. (Courtesy Peter Felsburg, University of Pennsylvania, Philadelphia, Pa.)

After the decline of maternal immunity, affected male dogs develop bacterial skin, gastrointestinal (GI), and respiratory infections (Fig. 95-4). Puppies fail to thrive and grow, and they die within a few months. The most characteristic clinical features are a lack of lymph nodes, tonsils, Peyer's patches, and thymus. Basset hounds develop vaccine-induced distemper when the dam has a loss of immunity. If they survive, they are poor doers and die by 5 to 6 months of age. Corgis have reduced serum γ -globulin concentration and often die by 5 months of age because of infections acquired from the environment or vaccinations. They can survive in germ-free environments; however, an increased prevalence of leukemia has been observed.⁷⁷ A diagnosis is reached by histopathology, immunologic testing, or a PCR-based test to identify the specific mutation in bassets and corgis; however, these mutations appear to have been eliminated from breeding populations other than those in research colonies.

Bone marrow transplantation from unaffected littermates was effective in reestablishing normal T- and B-cell function in affected dogs.^{76,109,111}

95.5.1.13 Autosomal Recessive SCID of Terriers

Affected Jack Russell terriers succumb to opportunistic and vaccine-induced infections within 2 to 4 months of age.¹⁷⁰ They experience severe lymphopenia, agammaglobulinemia, thymic dysplasia, and peripheral lymphoid aplasia. A faulty V(D)J recombination and complete deficiency of DNA-PK activity result from a reduced expression of the DNA-PK catalytic subunit.^{10,170} This defect is different from the X-linked disease in bassets and corgis but similar to the C.B-17 SCID mice and Arabian SCID foals.¹⁹⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

95.5.1.14 Selective IgA Deficiency

Various forms of selective IgA deficiency have been described in several breeds, including beagles,^{72,97} Shar-peis,¹⁷⁵ German shepherd dogs,²⁴⁷ and others,¹⁸² but the mode of inheritance remains unknown. The defect may be either an inherited primary defect of certain breeds or may arise secondary to pathologic changes within the intestinal mucosae. Serum IgA concentrations may be completely absent or markedly reduced and only very slowly developing over the first year of life. Complete deficiencies are found in Shar-peis, and partial deficiencies have been found in German shepherds.⁵⁴ Thus serum IgA concentrations need to be compared with those of age-matched controls. Reduced concentrations of IgA have been found in duodenal explant cultures of some German shepherd dogs that had serum IgA values within reference limits.⁸⁹ Therefore this measurement may be more reliable than serum concentrations. The serum IgG and IgM concentrations are consistently within reference values. Reduced secretory IgA concentrations have also been found in bronchial secretions of affected dogs.¹⁸² Affected juvenile dogs are predisposed to mucocutaneous infections such as chronic recurrent respiratory infections involving parainfluenza and *Bordetella bronchiseptica*, gastroenteritis, pyoderma, and otitis. IgA-deficient dogs may have a positive rheumatoid factor, anti-IgA antibodies, or both and may develop allergies and autoimmune diseases. IgA deficiency in German shepherds is not linked to their predisposition to develop disseminated aspergillosis.⁵³ Although affected dogs have large polyclonal increases in serum IgG concentration, it is not directed against *Aspergillus terreus*.

95.5.1.15 Immunodeficiencies in Weimaraners

At least two distinct syndromes of immunodeficiency have been observed in Weimaraners. In one syndrome, which has been reported only once, growth hormone deficiency has been associated with wasting and thymic hypoplasia.^{211,212}

The second syndrome, which is similar to the common variable immunodeficiency syndromes described in humans, involves recurrent bacterial infections and inflammatory conditions in young Weimaraners, which often become systemic.^{40,56,79,107,227} Some dogs may outgrow their condition and not show signs later in life. Clinical signs of those with recurrent disease generally start at a few months to 3 years of age and are characterized by lethargy, anorexia, intermittent fever, lymphadenomegaly, pyogranulomatous disease, large abscesses in muscle, stomatitis, osteomyelitis, surface bleeding, and coat color dilution. Some dogs have diarrhea or vomiting. Hyperesthesia of long bones or joints (Fig. 95-5), swelling at injection sites, and recurrent urinary infections or pyoderma have also been observed. Signs in many Weimaraners are precipitated at the time of their early vaccination series and are characteristic of hypertrophic osteodystrophy (HOD). These dogs respond most favorably to antiinflammatory doses of glucocorticoid therapy, and the syndrome may be caused by MLV distemper vaccines (see Chapters 3 and 100). Some dogs later develop polyarthritis or meningitis. Although the dogs respond favorably to antibacterial therapy, glucocorticoid therapy, or both, recurrence of systemic inflammatory disease can occur. Although an immunologic deficiency is suspected, inconsistencies exist in the immunologic studies performed on these dogs. Neutrophilia, which is often marked with a left shift, has been observed. Decreased neutrophil phagocytosis of opsonized bacteria and chemiluminescence as well as slightly low serum IgG and IgM concentrations have been reported in some dogs with increased amounts of circulating immune complexes (CICs).⁴¹ In other reports, reduced serum IgG, IgA, and IgM have been observed with no increase in CICs.⁷⁹ The lack of CICs in most reports suggests that primary decreased production rather than secondary

1022

Infectious Diseases of the Dog and Cat, 3rd Edition

1023

immunoglobulin consumption is responsible for the defect. No specific diagnostic tests are currently available. Despite antibiotic and supportive therapy (draining of abscesses), the prognosis remains guarded. Some Weimaraners also appear to have an increased tendency to develop HOD, which has been associated with a postvaccination reaction (see [Chapter 100](#)). Whether this predisposition is only involved with this reported immunodeficiency syndrome is uncertain, although similar postvaccination complications have been frequently noted in these immunoglobulin-deficient dogs.⁷⁹

Fig 95-5 Weimaraner puppy, with lameness from immunodeficiency.
(Courtesy Teaching File, University of Pennsylvania, Philadelphia, Pa.)

95.5.1.16 Immunodeficiencies in Shar-peis

In addition to the severely abnormal skin structure, which leads to a barrier failure, two distinct syndromes have been characterized in the Shar-pei dog—one involving combined antibody and CMI defects and the other involving renal amyloidosis and swollen joints.

The *combined immunodeficiency syndrome* may have been confused with the selective IgA deficiency described in this breed (see previous Selective [IgA] Deficiency section). Dogs 7 months to 7 years of age develop recurrent infections involving respiratory, skin, and GI systems.²⁰⁶ Chronic bronchitis, gastroduodenal or colonic ulceration, diarrhea and vomiting, adult-onset pyoderma, demodicosis, and bacterial and fungal otitis develop. In addition, the dogs have are predisposed to developing GI neoplasia, lymphoma, and other malignancies. Single or multiple immunoglobulin class deficiencies are observed in dogs, with IgM deficiency and decreased IL-2 synthesis predominating. Dogs with GI signs or malignancy usually had reduced IgM. Decreased lymphocyte stimulation test results were found in most of the dogs, suggesting a combined T- and B-cell defect.²⁰⁶ In addition, peripheral blood mononuclear cells had reduced IL-6 synthesis.

Recurrent fever of unknown origin and swelling of the tibiotarsal joints are the symptoms of another immune-based syndrome in Shar-peis, known as *Shar-pei fever* or *Shar-pei hock*.^{64,162,208} The lameness

Infectious Diseases of the Dog and Cat, 3rd Edition

can be monoarticular or involve multiple joints, usually affecting the tibiotarsal joints and occasionally the carpus. Predominant mononuclear cell polyarthritis and cellulitis, with or without synovial inflammation, can develop. Clinical signs of renal failure—a result of amyloid deposition in the kidney—and the nephrotic syndrome (proteinuria, hypercholesterolemia, and hypoproteinemia) eventually develop. Although a majority of the dogs have amyloid deposition in the renal medulla, glomerular involvement from amyloid or membranous glomerulitis occurs in only 60% to 80% of affected dogs.⁶⁴ Polydipsia, polyuria, weight loss, dehydration, ascites, and peripheral edema may occur. Thromboembolism may be a sudden complication in some dogs with the nephrotic syndrome. Radiographic changes are soft tissue swelling with periarticular bone erosion and bone production. Recurrent fever, joint pain, and swelling often resolve within 24 hours.¹⁶² Postpartum metritis has developed in intact females and may be another inflammatory feature of this illness.⁶⁴ Hyperglobulinemia and increased levels of IL-6 are found in affected dogs.²⁰⁷ This syndrome is similar to familial Mediterranean fever, a human hereditary disorder characterized by polyserositis and reactive amyloidosis. Treatment with colchicine early in the course of disease may reduce amyloid deposition in people and has been proposed for affected dogs.

95.5.1.17 Lethal Acrodermatitis in Bull Terriers

Also known as *zincers* among bull terrier breeders, the lesions of lethal acrodermatitis are similar to those of zinc deficiency in dogs. This syndrome is characterized by hyperkeratosis and parakeratosis and thymus and lymph node hypoplasia, leading to increased susceptibility to infection and failure to thrive.^{123,166} Growth retardation, hard and cracked footpads, pyoderma around body orifices, and aggressive to unresponsive behavior are hallmark features at a few weeks of age. The disease symptoms resembles zinc deficiency but are unresponsive to zinc therapy. Thus affected dogs die or are euthanized before 6 months of age. Affected dogs have lower plasma IgA concentrations than clinically healthy dogs.¹⁶⁵

95.5.1.18 Immunodeficiencies in Related Rottweiler Dogs

In one study, a litter of Rottweiler pups either died before 6 months of age from systemic inflammatory disease or subsequently developed chronic inflammatory skin disease.⁵¹ Serum IgA and IgG concentrations were low. Secondary lymphoid tissues had reduced numbers of CD3⁺ T cells, although some were found within foci of B-cell follicles. Irregularities were found in plasma cell development, and plasma cells were absent from all mucosal and cutaneous sites. In inflammatory lesions, macrophages expressing major histocompatibility complex (MHC) class II molecules were present. Related unaffected dogs had reduced serum IgA concentrations; however, the spectrum of the defect in affected dogs suggests a more complex underlying defect. Rottweilers are more susceptible to parvovirus infection, oral papillomatosis, and nasal and systemic fungal infections; however, it is uncertain whether these abnormalities are interrelated.

95.5.1.19 Susceptibility to Parvovirus Infection

Numerous purebred dogs have an increased prevalence rate of parvovirus infection. The breeds include Doberman pinschers, Rottweilers, American pit bulls, and Dalmatians, among others (see [Chapter 8](#)). The reason for this apparent susceptibility is unknown.

Infectious Diseases of the Dog and Cat, 3rd Edition

95.5.1.20 Akita Polyarthrititis

Akita polyarthrititis has been observed in related Akita dogs and is exacerbated by MLV vaccines (see [Chapter 100](#)).

95.5.2 Cats

95.5.2.1 Hypotrichosis Congenita with Thymic Aplasia

Hypotrichosis congenita with thymic aplasia is a defect that is characterized by the birth of nude athymic kittens with severe immunodeficiencies, kittens that are similar to the well-known nude mice in laboratories. This lethal syndrome has been recognized in the Birman breed and is an autosomal recessive inherited disorder ([Fig. 95-6](#)).²⁵ One author has observed a syndrome of unknown cause in ragdoll kittens characterized by fatal infections in the neonatal to weaning period. Use of MLV panleukopenia vaccine may have accelerated their death. Some kittens died of panleukopenia at a younger age. By weaning, others developed numerous systemic fatal infections. Thymic, splenic, and lymphoid hypoplasia were observed in these affected kittens.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 95-7 Pelger-Hu't anomaly in cat with hyposegmentation of nucleus. Despite morphologic changes, no clinical immunodeficiency was observed. (Courtesy Teaching File, University of Pennsylvania, Philadelphia, Pa.)

95.5.2.2 Other Defects

Neutrophil abnormalities have been observed in Birman cats with leukocyte granulation,¹¹⁵ Persian cats with Chédiak-Higashi syndrome,^{135,171} and domestic short-haired cats with the Pelger-Hu't anomaly (Fig. 95-7).¹³⁹ Clinical immunodeficiencies with these defects have not been recognized. Loss of thymic mass has been observed in cats with GM1 gangliosidosis.⁴² Other purebred cats have had more problems with viral respiratory (see Chapter 16) and coronavirus (see Chapter 11) infections, but specific defects have not been elucidated.

95.5.2.3 Reactive Amyloidosis in Abyssinians

Abyssinians are predisposed to developing reactive AA amyloidosis in many organs, but clinical signs are caused by renal dysfunction. A genetic basis is suspected, but the mode of inheritance is uncertain. This syndrome is similar to amyloidosis in Shar-pei dogs and familial Mediterranean fever in people. Splenic inflammatory diseases, often related to secondary infections from immunodeficiencies, are responsible for the amyloid deposition in reactive amyloidosis. However, in some affected cats, concurrent inflammatory disease is not detected.⁶³ Generalized amyloidosis has also been observed in Siamese and oriental cats, but clinical features and amyloid protein composition differ.^{179,237} Reactive amyloidosis has also been detected

Infectious Diseases of the Dog and Cat, 3rd Edition

in Siberian tigers (*Panthera tigris altaica*)²¹⁴ and cheetahs (*Acinonyx jobatus*)¹⁹⁰; it may represent a genetically based increased susceptibility to infectious disease.

95.6 SPECIFIC SECONDARY OR ACQUIRED IMMUNODEFICIENCIES

Acquired or secondary immunodeficiencies can develop at any time as a result of an interference with host defense mechanisms. Immune defects secondary to many infectious diseases, metabolic disturbances, intoxications, and drug therapies^{35,172} have been reported (see [Table 95-5](#)).

95.6.1 Infectious Diseases

95.6.1.1 Canine Distemper

Disseminated viral infections that involve replication in and damage to lymphoid tissue, such as canine distemper, are associated with depression of CMI. Persistent immunodeficiencies caused by canine distemper virus (CDV) usually develop when infection develops prenatally or within the first weeks of neonatal life, when full immunocompetence has not been established. Affected dogs frequently are stunted and may develop chronic infections with protozoans such as *Giardia* and with *Mycoplasma* (*Haemobartonella*). They can also be expected to be more susceptible to infection with viral and fungal pathogens, and they frequently have pronounced lymphopenia and hypogammaglobulinemia. Persistent suppression of CMI in neonatal puppies can be detected by decreased lymphocyte stimulation test results and decreased synthesis of T-cell–dependent antibodies (IgG and IgA). IgM levels are also reduced if thymic hypoplasia results from early in utero infection. Transient depression of CMI has been reported in older neonates that are infected with virulent CDV. Some of this suppression has been shown to be caused by lymphocyte immunoregulatory factors in serum. Depression of immunoresponsiveness after vaccination is minimal if it occurs at all (see [Chapter 3](#)).

95.6.1.2 Canine Parvovirus Infection

Canine parvovirus has an affinity for replicating in rapidly dividing cells and produces severe lymphopenia and immunosuppression in neonates (see [Chapter 8](#)). An increased risk of secondary infections, including greater susceptibility to encephalitis induced by canine distemper vaccine, has been reported in 3-week-old pups (see [Chapter 100](#)). Lymphocyte stimulation assay results were depressed in adult mongrel dogs that were shedding canine parvovirus in the feces.¹⁸⁵ Because of the concurrent leukopenia and intestinal mucosal disruption, parvovirus-infected dogs are at increased risk for developing secondary infections. Pups recovering from parvoviral infection have had a higher prevalence of urinary tract infections than age-matched control pups. Bacterial septicemia and disseminated candidiasis have been reported in animals with parvovirus.

1024

95.6.1.3 Canine Ehrlichiosis

Depression of in vitro lymphocyte stimulation and skin hypersensitivity with DNCB have been reported in dogs with ehrlichiosis several months after the initial infection, when hyperglobulinemia develops. The depression does not appear to alter the course of infection, although certain breeds (e.g., German shepherds) have more severe illness and greater CMI depression before and after infection than other breeds. No increased susceptibility to infection has been documented in dogs with acute ehrlichiosis as yet; however,

1025

Infectious Diseases of the Dog and Cat, 3rd Edition

they are susceptible to pyogenic infections during the chronic neutropenic phase of the disease (see [Chapter 28](#)).

95.6.1.4 Canine Leishmaniasis

Dogs with leishmaniasis are prone to developing secondary infections, presumably because their immune system is preoccupied with defending the body against a persistent intracellular organism. Generalized demodicosis has been described in dogs with leishmaniasis.¹⁷⁶ Immunoreactive CD3 lymphocytes were sparse in lesions, whereas MHC II class macrophage expression was abundant. Cell-mediated immunosuppression was suspected as a secondary complication.

95.6.1.5 Canine Demodicosis

Dogs with generalized demodicosis have decreased in vitro lymphocyte stimulation, T-lymphocyte deficiency, and random neutrophil movement.^{6,206} Serum proteins with apparent immunoregulatory roles are responsible for the findings. No increased susceptibility to infection has been documented in vivo, although many dogs do develop severe secondary pyoderma. Secondary bacterial infection rather than the mite *Demodex canis* has been thought to be responsible for the suppressed immune response, because neutrophilic chemotactic movement has been decreased in bacterial (staphylococcal) pyoderma in dogs. Histologically, mural folliculitis is a consistent lesion of active demodicosis. Histochemical studies indicate a preponderance of CD3⁺ and CD8⁺ infiltrating lymphocytes and a low CD4⁺/CD8⁺ ratio in follicular lesions and peripheral blood.^{26,29} These cytotoxic lymphocytes may induce the inflammatory lesions or be a deleterious response in dogs that develop this disease. Compared with dogs with localized demodicosis or clinically healthy dogs, those with generalized demodicosis had lower messenger ribonucleic acid (mRNA) expression of for interferon- γ and tumor necrosis factor- α (TNF- α) and higher expression of IL-5 and transforming growth factor- β . As in other studies of *Demodex* and pyoderma with successful antimicrobial therapy for pyoderma or antiparasitic treatment of demodicosis, the test results return to reference ranges with clinical improvement.

95.6.1.6 Feline Panleukopenia

Feline panleukopenia virus has a predilection for rapidly dividing cells and produces permanent cell-mediated immunosuppression and thymic atrophy in kittens infected in utero. Lymphoid depletion, mild depression of in vitro lymphocyte function, and neutropenia are characteristic in neonatally infected cats, which may have a transiently increased susceptibility to infection. Overwhelming sepsis from gram-negative enteric microflora, which accompanies feline panleukopenia, may be related to the immunosuppression caused by the virus ([Fig. 95-8](#)) (see [Chapter 10](#)).

95.6.1.7 Feline Leukemia Virus Infection

Immunodeficiencies in feline leukemia virus (FeLV) infection often develop before malignant transformation of T lymphocytes. A reduction in CD4⁺ and CD8⁺ lymphocyte subset ratios has been shown to develop in FeLV-infected cats, as it does in cats infected with the feline immunodeficiency virus (FIV).¹¹⁶ FeLV-infected cats have impaired T-cell-mediated immunity as characterized by reduced in vitro lymphocyte stimulation, prolonged retention of cutaneous allografts, and impaired response to delayed hypersensitivity skin testing. Secondary hyperglobulinemia and complement depletion have also been

Infectious Diseases of the Dog and Cat, 3rd Edition

found. Immune complex formation may also interfere with lymphocyte function, because immune complex removal has improved the clinical condition of infected cats. Infected cats that do not develop neoplasia have a high mortality rate and increased susceptibility to concurrent infection with other organisms, such as commensal bacteria, pathogenic fungi, *Mycoplasma (Haemobartonella) spp.*, and feline infectious peritonitis (FIP) virus. Certain forms of FeLV infection also result in severe neutropenia, which increases the risk of secondary bacterial infection. Persistent neutropenia may also develop in some cats latently infected with FeLV. A panleukopenia-like syndrome can develop in cats that are coinfectd with FeLV and FIV (see [Chapter 13](#)).¹⁵⁵

Fig 95-8 Queen and her litter of kittens, which were dying of panleukopenia. Kittens had thymic atrophy and neutropenia associated with neonatal infection with a parvovirus. (Courtesy University of Georgia, Athens, Ga.)

95.6.1.8 Feline Immunodeficiency Virus Infection

Cats naturally affected with FIV develop fever, variable neutropenia, and chronic infections of the skin and mucosal surfaces (see [Chapter 14](#)). Experimentally inoculated cats develop generalized peripheral lymphadenomegaly and transient neutropenia followed by a disease-free period. Alterations in the phenotype of CD8⁺ and other blood lymphocytes eventually leads to immunodeficiency.²¹⁶ In natural circumstances, opportunistic infectious agents, which are normally controlled by CMI, are also involved in producing disease. Calicivirus, FIP, *Toxoplasma spp.*, and systemic fungi are notable examples.^{49,205} Compared with uninfected cats, *Cryptococcus neoformans* and *Candida albicans* are isolated more frequently from the oropharyngeal mucosa of FIV-infected cats, and *Microsporium canis* are isolated more frequently from skin.¹⁵⁹ Defective natural killer cell cytotoxic activity has been detected.²⁵³ Incidental and opportunistic infections may accelerate the development of acquired immunodeficiencies in infected cats.²⁰⁴ During therapy, FIV-infected cats that were treated with the protease inhibitor TL-3 were protected from developing central nervous system (CNS) signs or the progression of already evident CNS signs.¹²¹ Cats with FIV must be vaccinated with killed vaccines (see [Chapter 100](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

95.6.1.9 Retroviruses Isolated from Diseased Dogs

Anorexia, depression, and multiple lymphadenomegaly have been described in a Rottweiler. A cell line from this dog contained an identifiable C-type retrovirus.¹³ Retroviral elements have been isolated from cells derived from canine lymphosarcoma and endogenous sequences from normal canine cells.^{223,224} A new canine lentivirus has been isolated from the buffy coat of a leukemic dog.¹⁹³ Clinically healthy dogs have also had positive PCR blood test results for FIV, although the accuracy of these assays has been questioned.¹² Whether canine retroviruses cause clinical illness in dogs remains to be determined.

95.6.1.10 Overwhelming Bacteremia

Severe endotoxemia or sepsis has been shown to impair CMI in dogs and decrease neutrophil bactericidal function (see [Chapter 38](#)). Neutrophilic phagocytosis was markedly deficient in a dog with systemic β -hemolytic streptococcal infection.³² Sera from dogs with pyometra inhibited lymphocyte activity.⁶⁹ It also contained higher concentrations of immunoglobulins and CICs.

95.6.2 Hemophagocytic Syndrome

Pathologic proliferation of the mononuclear phagocyte system can either result from infectious diseases or contribute to immunologic dysfunction and signs of debilitation, weight loss with anorexia, and relapsing fever in dogs or cats.^{225,243} Splenomegaly and hepatomegaly may be apparent. Viral or neoplastic diseases are commonly considered to be contributors to this syndrome. In dogs, parvovirus infection or lymphoid or myelomonocytic leukemia has been described. Immune aberrations are suspected to be responsible. The outcome of animals with this condition is guarded; in one dog, disseminated intravascular coagulation was reported as a complicating factor.²²⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 95-6 Acquired Defects in Phagocyte Function

DISEASE	MECHANISM	SITE OF INFECTION	INFECTING ORGANISMS	PREDISPOSING FACTORS
Uremia	Decreased phagocytosis	Catheter sites, lungs, urinary tract, blood	Staphylococci, aerobic gram-negative organisms	Peripheral vascular disease
Diabetes mellitus	Increased adherence, variable chemotaxis, decreased phagocytosis and respiratory burst	Lungs, urinary tract, catheter sites, eyes, bone	Staphylococci, Enterobacteriaceae, filamentous fungi	Hyperglycemia, total parenteral nutrition, skin ulcers, urinary catheterization
Hepatic cirrhosis	Increased adherence with decreased chemotaxis and phagocytosis	Urinary tract, lungs, blood, soft tissues	Staphylococci, Enterobacteriaceae, other enteric organisms	Urinary catheterization
Systemic lupus erythematosus	Increased adherence, decreased chemotaxis, decreased phagocytosis	Lungs, blood	Gram-positive bacteria, mycobacteria, opportunistic organisms	Immunosuppressive therapy
Burns	Decreased chemotaxis and phagocytosis	Wounds, urinary tract, blood, lungs	Staphylococci, aerobic gram-negative organisms, yeasts	Extensive burns, age extremes
Traumatic injuries	Decreased chemotaxis and phagocytosis	Wounds, urinary tract, blood, lungs	Staphylococci, aerobic gram-negative organisms	Old age
Modified from Engellich G, Wright DG, Hartshorn KL. 2001. Acquired disorders of phagocyte function complicating medical and surgical illnesses. <i>Clin Infect Dis</i> 33:2040–2048.				

95.6.3

Metabolic Disturbances

Many biochemical processes that occur in noninfectious disease states interfere with normal immune mechanisms. Failure of neonates to ingest colostrum and dysproteinemia are both associated with impaired humoral antibody function. Decreased complement concentration has been noted with endotoxemia, immune-mediated hemolysis, and malnutrition. Age has a marked influence on CMI. Newborn puppies and kittens experience a hypothermic state during the first week of life that suppresses T-cell function. A decline in CMI, which also develops in older dogs and cats, may explain their increased susceptibility to infectious and neoplastic disorders. Lymphocyte stimulation by various mitogens is depressed in older dogs, and male dogs were more profoundly affected. A decline in B-cell percentages was also noted.¹⁰⁰ Proper nutrition is also an important determinant of immunoresponsiveness. Protein and caloric restriction has resulted in premature thymic atrophy and decreased cell-mediated, humoral, and phagocytic responses in animals. In contrast, overfed, obese dogs have been more susceptible to infections and severe clinical illnesses.

Vitamin E and selenium deficiencies in dogs have been associated with decreased in vitro lymphocyte responsiveness, decreased serologic response to vaccination, and increased susceptibility to infection with opportunistic pathogens. The deficit can be accentuated by excessive intake of polyunsaturated fats (strong oxidants that counteract the effects of vitamin E). Vitamin E deficiency causes the animal to produce a suppressor serum factor capable of decreasing lymphocyte responsiveness to antigenic stimulation. Increased incidence of distemper infection has been noted in a kennel of dogs that developed “brown fat disease” as a result of a diet deficient in vitamin E.

Inherited granulocyte colony-stimulating factor deficiency ¹³⁸

Vitamin A deficiency can cause immunosuppression and opportunistic infections similar to those associated with vitamin E deficiency. In areas of the world where vitamin A deficiencies exist, human measles virus infection has a high mortality. A similar phenomenon might be expected to occur in dogs with canine distemper. Zinc deficiency during prenatal and neonatal periods can result in impaired CMI responses and thymic atrophy. Immunosuppression caused by dietary deficiencies can be relieved by adequate supplementation.

Infectious Diseases of the Dog and Cat, 3rd Edition

Depressed phagocyte function has also been reported in humans with diabetes mellitus, systemic lupus erythematosus, and renal failure (Table 95-6). Similarly, poorly regulated or untreated diabetic dogs had weaker neutrophil adherence than controlled diabetic and nondiabetic dogs. Diabetic dogs have an increased prevalence of urinary tract infections¹³⁴ and hepatic abscesses.¹⁰⁴ Any cause of permanent neutropenia, such as bone marrow aplasia, significantly impairs phagocyte function. Intestinal lymphangiectasia is associated with depressed CMI because of lymphocyte loss. Immunosuppression can be induced during treatment of immune-mediated diseases. Glucocorticoids, cytotoxic drugs, and cyclosporine are the most potent agents that can lead to secondary infections. Endogenous or exogenous hyperadrenocorticism is associated with a high prevalence of urinary tract infections. Use of gold salts, danocrine, or immunoglobulins to treat immune-mediated diseases has the most sparing effect on host immunocompetence. Splenectomies in humans are associated with a high risk of bacterial and protozoal infections; in dogs and cats, reactivation of babesiosis and haemobartonellosis is most notable.

95.6.4 Neutropenia

Neutrophils are important in a host's defense against bacteria. Neutropenia increases the risk of bacterial infection. Decreased production and increased use are basic mechanisms and can be subdivided into additional categories (Table 95-7).^{18,19,71} As mentioned previously, numerous infectious agents can result in neutropenia. Myelosuppression can be caused by cytotoxic drugs or infectious agents. Immune-mediated neutropenia has also been observed in dogs and cats.^{156,168,194} Animals with neutrophil deficiencies develop recurrent bacterial infections and have resolution of clinical signs after antibacterial administration but no increase in neutrophil counts. The prevalence of infection in animals with immune-mediated neutropenia is generally low compared with that in animals with cobalamin deficiency. Despite the circulating neutropenia, animals have adequate or high numbers of proliferating neutrophil precursors in the bone marrow. If antibody is directed against neutrophil precursors, precursors may be few or absent. No test exists to measure antineutrophil antibody, and diagnosis is usually made by a favorable response of increasing numbers of circulating neutrophils after institution of treatment. Rapid increases in neutrophil numbers, usually within 48 hours, are observed after immunosuppressive doses of glucocorticoids are given.

96 CHAPTER 96 Fever

Katharine F. Lunn

Fever is a common clinical finding in patients with infectious, parasitic, inflammatory, immune-mediated, or neoplastic disease. In many of these patients, fever is accompanied by other more specific or localizing clinical signs, and the cause of the fever is determined with simple diagnostic tests. In some cases, the cause of the fever is not readily apparent, but it resolves spontaneously or in response to empirical therapy, often with antibiotics. In a small subset of patients, the cause of fever is not easily determined and not therapeutically responsive, and the problem becomes persistent or recurrent. Such cases of fever of unknown origin (FUO) present a particular diagnostic challenge in both human and veterinary medicine.^{60,32} This chapter outlines the pathophysiology of fever and presents an approach to the small animal patient with FUO.

96.1 PATHOPHYSIOLOGY OF FEVER

Body temperature is determined by the set-point of the hypothalamic thermoregulatory center. Thermoregulation depends on sensory information from external and internal thermoreceptors and on physiologic and behavioral effector mechanisms that control heat production and heat loss. Body heat is lost through the skin and the respiratory tract and can be gained by transfer from the environment or generated by muscle activity or body fat catabolism. Body temperature is decreased by panting, cutaneous vasodilation, seeking shelter, and remaining inactive (Fig. 96-1, A). In a cold environment, body temperature is maintained by shivering, postural changes, piloerection, and cutaneous vasoconstriction (see Fig. 96-1, B). In a normal animal, these mechanisms balance heat loss and heat gain and keep the body temperature as close as possible to the normal hypothalamic set-point (Fig. 96-2, A).

Hyperthermia refers to any increase in body temperature above normal. In true fever, the hypothalamic set-point is elevated, and body temperature is increased by enhanced heat production and conservation. Heat gain and heat loss mechanisms now act to maintain body temperature at the new set-point (see Fig. 96-2, B). In nonfebrile hyperthermic conditions, the hypothalamic set-point is *not* altered, and elevated body temperature is the result of increased and unregulated heat gain or heat production or impaired heat loss (see Fig. 96-2, C). Examples of nonfebrile causes of hyperthermia include heat stroke, exercise-induced hyperthermia, malignant hyperthermia, seizure activity, and hypermetabolic disorders. Hyperthermia of this type can progress to multiorgan-dysfunction syndrome caused by an interplay among circulatory disturbances, hypoxia, increased metabolic demand, cytotoxicity of high temperature, and activation of inflammatory and coagulation cascades.⁷

Fever is mediated by the action of pyrogens. Exogenous pyrogens (infectious agents and their products, tumors, drugs, and toxins) stimulate inflammatory cells to release endogenous pyrogens (cytokines such as interferons, interleukin [IL]-1 and -6, and tumor necrosis factor [TNF]- α) that use the cell-signaling apparatus gp130. Exposure to these cytokines leads to induction of cyclooxygenase 2 activation of the arachidonic acid cascade, with enhanced synthesis of prostaglandin E₂ (PGE₂). PGE₂ is synthesized by hypothalamic vascular endothelial cells and acts on thermoregulatory neurons to raise the hypothalamic set-point. The thermoregulatory set-point is located in a rich vascular network called the organum vasculosum laminae terminalis in the preoptic-rostral hypothalamus that possesses little if any blood-brain barrier. Endothelial cells within this area are thought to release arachidonic metabolites themselves, and then metabolites of cyclooxygenase such as PGE₂ are thought to diffuse the short distance to the hypothalamic neurons and induce fever. PGE₂, which itself is not neurally active, may induce production of cyclic adenosine monophosphate (cAMP) or other neurotransmitters, which, in turn,

Infectious Diseases of the Dog and Cat, 3rd Edition

raises the temperature set-point of the body. Additional evidence suggests that the thermoregulatory center may also be stimulated via vagal fibers that respond to release of cytokines locally released in tissues.⁵⁸ The pathogenesis of fever is summarized in [Figure 96-3](#).

96.2 FEVER OF UNKNOWN ORIGIN

FUO in both human and veterinary medicine can be most usefully defined as fever that does not resolve spontaneously in the period expected for self-limited infection and the cause of which cannot be ascertained despite considerable diagnostic effort.² In veterinary medicine, this diagnostic effort typically includes a complete history and physical examination, complete blood (cell) count (CBC), chemistry, urinalysis (UA), and radiography. Also common is for veterinary patients to receive antibiotic therapy to address possible bacterial infection before it is determined that the origin of the fever is unknown.¹⁶

96.2.1 Etiology of Fever of Unknown Origin

Although fever is frequently associated with infectious diseases, the same response can be elicited by many inflammatory, immune, or neoplastic disorders. Because the list of differential diagnoses for FUO is extensive, grouping these causes into broad categories based on the underlying disease process is useful. [Table 96-1](#) shows the causes of FUO divided into infectious and parasitic diseases, [Table 96-2](#) summarizes inflammatory and immune-mediated causes of FUO, and neoplastic and miscellaneous causes are listed in [Table 96-3](#). In the human medical literature, the causes of FUO are typically distributed as follows: 30% to 40% are infectious, 20% to 30% are neoplastic, 10% to 20% are rheumatologic, 15% to 20% are miscellaneous, and 5% to 15% are undiagnosed. Broadly similar distributions have been reported in veterinary patients, but variation can be found among reported case series.⁴⁶ This variation may be caused by both the particular clinical interests of the authors and their geographic locations. Published case series are also exclusively or predominantly canine.^{46,23} Infection, immune-mediated disease, and neoplasia are the most common causes of FUO in the dog, whereas FUO in cats appears most likely to be infectious in origin.⁴¹

Table 96-1 Infectious and Parasitic Diseases Associated with Fever of Unknown Origin

TYPE OF INFECTION	EXAMPLES
Systemic bacterial	Infective endocarditis (D), bacteremia from inapparent focus (B)
Localized bacterial	Infective endocarditis (D), pyelonephritis (B), prostatitis (D), stump pyometra (B), pyothorax and lung infections (B), pancreatitis (D), hepatic abscess or cholangiohepatitis (B), peritonitis (B), septic meningitis (B), septic arthritis (B), osteomyelitis (B), diskospondylitis (B), tooth root abscess (B), other abscesses or cellulitis (B)
Specific bacterial	Leptospirosis (D), Lyme disease (D), brucellosis (D), mycobacterial infection (B), bartonellosis (B), plague (C), L-form infections (B)
Viral	Feline leukemia virus infection (C), feline immunodeficiency virus infection (C), feline infectious peritonitis (C), feline calicivirus infection (C), canine distemper virus infection (D)
Rickettsial and mycoplasmal	Ehrlichiosis (B), anaplasmosis (D), hemotropic mycoplasmosis (B), mycoplasmal infections (B)
Fungal	Blastomycosis (B), cryptococcosis (B), coccidioidomycosis (B), histoplasmosis (B)
Protozoal	Toxoplasmosis (B), neosporosis (D), hepatozoonosis (B), babesiosis (B), leishmaniasis (B)
D, Predominantly dog; C, Predominantly cat; B, both dog and cat.	

Table 96-2 Inflammatory and Immune-Mediated Diseases Associated with Fever of Unknown Origin

TYPE OF DISEASE	EXAMPLES
Immune-Mediated	Systemic lupus erythematosus (D, rare in C), idiopathic immune-mediated polyarthritis (B), rheumatoid arthritis (D), polymyositis (B), steroid-responsive meningitis-arteritis (beagles, boxers, Akitas, Bernese Mountain dogs, German shorthaired pointers), vasculitis (B)
Inflammatory	Nodular panniculitis (B), lymphadenitis (B), steatitis (D), pancreatitis (C), inflammatory bowel disease (B), granulomatous diseases (B), hypereosinophilic syndromes (B)
D, Predominantly dog; C, predominantly cat; B, both dog and cat.	

Table 96-3 Neoplastic and Miscellaneous Diseases Associated with Fever of Unknown Origin

TYPE OF DISEASE	EXAMPLES
Solid tumors	Several, including hepatic tumors, gastric tumors, lung tumors, bone tumors, metastatic disease, and any necrotic tumor (B)
Hematopoietic tumors	Lymphoma (B), leukemia (B), myeloma (B), malignant histiocytosis (B)
Miscellaneous	Metaphyseal osteopathy (D), panosteitis (D), portosystemic shunt (B), pansteatitis (C), drug reaction (B), Shar-pei fever (D)
D, Predominantly dog; C, predominantly cat; B, both dog and cat.	

Fever is rarely an isolated finding in these cases, given that the cytokines induce a large number of complex immunopathologic events. These events include increases in total or relative numbers of circulating immature

Infectious Diseases of the Dog and Cat, 3rd Edition

neutrophils and an increase in synthesis of a wide variety of acute-phase proteins from the liver. Other synthesized proteins are antiproteases, complement components, fibrinogen, ceruloplasmin, ferritin, and haptoglobin. In addition, even larger amounts of C-reactive protein and serum amyloid A protein are produced.¹⁹ This production occurs despite a dramatic reduction in the synthesis of albumin, lipoprotein lipase, and cytochrome P₄₅₀ by the liver. The presence of fever and concomitant changes in these serum proteins is referred to as an acute-phase response to infection. The ability of cytokines to suppress or alter gene expression for synthesis or suppression of commonly produced protein molecules accounts for the altered lipid, protein, and drug metabolism observed in patients with chronic infectious or inflammatory disease states. It may also result in the deposition of amyloid proteins in the syndrome known as reactive AA amyloidosis.

IL-1 and TNF also have dramatic effects on endothelial cells, causing the synthesis of prostaglandin I₂ (PGI₂, prostacyclin) and PGE₂. These arachidonate metabolites caused increased blood flow. IL-1 and TNF also stimulate the plasma membrane of endothelial cells by increasing the expression of intercellular adhesion molecule 1 so that they become more adherent and attract neutrophils, monocytes, and lymphocytes. IL-1 and TNF increase procoagulant activity on the endothelial cell surface at the same time that they induce plasminogen activator inhibitor. These effects lead to activation of factor VIII and thrombin and platelet aggregation in the initiation of coagulation. These events are similar and involve the same pathways as those in the body's response to endotoxin (see [Chapter 38](#)).

96.2.2 Development of a Diagnostic Plan for Fever of Unknown Origin

Although some patients with FUO may have uncommon infectious, inflammatory, or neoplastic diseases, many patients are ultimately found to have an unusual or early manifestation of a common disorder.² Therefore the clinician must approach these cases in a systematic fashion that allows for the detection of any potential cause of fever while avoiding unnecessary testing and minimizing patient discomfort. A diagnostic plan for FUO may be based on consideration of the disease process, as outlined in [Tables 96-1, 96-2, and 96-3](#). A complementary approach is summarized in [Table 96-4](#) in which the causes of FUO are grouped according to anatomic or body system location. This approach is helpful in selecting diagnostic tests, particularly when localizing clinical signs are absent or subtle. By combining a disease process and anatomic approach, the clinician can develop a comprehensive diagnostic plan for any FUO patient.

In addition to appropriate diagnostic tests, the diagnostic plan should follow a sequence that is both logical and flexible. The typical diagnostic plan will begin with tests that are safe, simple, inexpensive, and easy to interpret. A staged approach can be used to guide the selection of diagnostic tests, and examples are outlined in [Table 96-5](#).

The results of stage 1 tests in the FUO patient will then determine the tests to be performed at the next stage. If the fever has not been localized, more specialized procedures can also be introduced.

Stage 2 test results again require the repetition of earlier tests and introduce the need for advanced imaging and more invasive procedures. Ideally, the selection of these tests will be based on abnormalities detected in stages 1 and 2.

An important aspect of stage 3 test results in the FUO patient is the need to repeat the early, less invasive, and inexpensive tests frequently enough to detect new changes. The key is not to rigidly follow a predetermined and fixed diagnostic plan but rather to review and modify the plan as new results become available. For

Infectious Diseases of the Dog and Cat, 3rd Edition

example, if repeated CBCs demonstrate developing pancytopenia, a bone marrow aspirate and biopsy should be performed early in the diagnostic plan and not reserved for stage 3.

96.2.2.1

Client Communication

The management of the FUO patient demands flexibility, dedication, and patience from both the clinician and the client. By definition, patients with FUO will already have undergone several basic diagnostic tests, and some may have received one or more courses of antibiotic therapy. Clients may be frustrated by the failure to reach a diagnosis or the continuation of the patient's clinical signs. Good client communication is vital to the successful resolution of the FUO case. The clinician should explain that many diagnostic tests, including repeated tests, may be necessary to reach a diagnosis and that the process may be time consuming and expensive. However, clients should also be reassured that a diagnosis is reached in most cases, that many causes of FUO may be treatable or even curable, and that the fever itself is rarely harmful to the patient.

1031

1032

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 96-4 Causes of Fevers of Unknown Origin Grouped by Body System or Region

BODY SYSTEM OR REGION	APPROPRIATE DIAGNOSTIC TESTS	EXAMPLES
Blood and hematopoietic	CBC, blood film evaluation, bone marrow aspirate, urinalysis, ophthalmic fundic exam, bone marrow biopsy, serum protein electrophoresis, FeLV and FIV tests, other serology, blood culture	Leukemia, myeloma, bacteremia, drugs, ehrlichiosis, granulocytopenia, hypereosinophilic syndromes, hemotropic mycoplasmosis, metastatic neoplasia, walled-off hematomas
Lymphoid	Lymph node palpation, lymph node cytology and culture, lymph node biopsy, lymphangiography	Lymphoma, lymphadenitis, lymphangitis
Cardiovascular	Auscultation, radiography, angiography, electrocardiography, echocardiography, vascular biopsy, pericardiocentesis, blood culture	Endocarditis, pericarditis, vasculitis
Respiratory	Radiography, transtracheal or endotracheal wash, fine-needle aspiration, biopsy, ultrasonography, bronchoscopy, bronchoalveolar lavage, CT, thoracoscopy	Bronchial foreign body, fungal or bacterial pneumonia, neoplasia, pulmonary embolism
Nervous system	Fundic and neurological examination, radiography, myelography, CT, MRI, nerve or muscle biopsy, CSF analysis	Toxoplasmosis, fungal infection, steroid-responsive meningitis-arteritis, FIP
Musculoskeletal	Radiography, arthroscopy, blood culture, arthrocentesis, synovial membrane biopsy, bone biopsy, RF, ANA	Immune-mediated polyarthritis, myositis, panosteitis, diskospondylitis
Gastrointestinal	Radiography, barium contrast studies, ultrasonography, rectal examination, fecal cytology, rectal cytology, fecal culture, oral and dental radiographs, lipase and amylase activities trypsin-like immunoreactivity, endoscopy, laparoscopy, exploratory surgery, biopsy	Neoplasia or abscess anywhere in GI tract, pancreatitis, inflammatory bowel disease, fungal disease, portosystemic shunt, hepatobiliary, gastric, or splenic inflammation
Urogenital	Urinalysis, urine culture, prostatic wash and ejaculate cytology and culture, radiography, ultrasonography, IV pyelography, cystography, cystoscopy, vaginography, cytology, biopsy	Prostatitis, stump pyometra, pyelonephritis, orchitis
Endocrine	Biochemical profile, thyroid hormone	Hyperthyroidism
Pleural or peritoneal cavity	Radiography, ultrasonography, fluid analysis, cytology, microbial culture, biopsy	Pyothorax, FIP, peritonitis, neoplasia
Skin	Physical examination, cytology, biopsy, microbial culture, fistulography	Abscess, fungal infection, nodular panniculitis, vasculitis, actinomycosis, nocardiosis, mycobacteriosis

ANA, Antinuclear antibody; CT, computed tomography; MRI, magnetic resonance imaging; RF, rheumatoid factor; CBC, complete blood cell count; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; IV, intravenous; CSF, cerebrospinal fluid; FIP, feline infectious peritonitis; GI, gastrointestinal.

96.2.2.2

History

The patient history should include details of geographic location and environment, travel history, lifestyle (e.g., indoor versus outdoor, history of hunting), and exposure to ticks or other vectors. All of these factors

Infectious Diseases of the Dog and Cat, 3rd Edition

will influence exposure to specific microorganisms. The medical history should cover diet, vaccination, heartworm and other parasite treatment and prevention, the administration of any other medications, and previous medical or surgical problems. The response to past therapies used for the fever problem should be noted. Clients should be questioned about the patient's urination and defecation habits and the presence of clinical signs such as lameness; neck, back, or abdominal pain; skin lesions; masses or swellings; weakness; exercise intolerance; coughing; nasal discharge; and dyspnea.

Table 96-5 *Diagnostic Plan for Fever of Unknown Origin*^a

1. History
 - a. Detailed
 - b. Additional questions for other medical problems
2. Physical examination
 - a. System by system complete exam
 - b. Fundic examination
 - c. Neurologic examination
3. Laboratory testing
 - a. CBC, blood smear
 - b. Biochemical profile
 - c. Additional biochemistry: bile acids, lipase, amylase, CK, T₄
 - d. Complete urinalysis including sediment
4. Radiologic imaging
 - a. Thoracic and abdominal radiography
 - b. Abdominal ultrasonography, if other results negative
 - c. Echocardiography, if murmur
 - d. Spinal survey series
 - e. Long bone or joint survey
 - f. Dental radiography
 - g. Contrast radiography as indicated by system
 - h. Computerized axial tomography
 - i. Magnetic resonance imaging
 - j. Nuclear scintigraphy scans
5. Cytologic evaluation
 - a. Evaluation of any enlarged lymph nodes or masses
 - b. Synoviocentesis, especially with hyperesthesia
 - c. Bone marrow evaluation

Infectious Diseases of the Dog and Cat, 3rd Edition

- d. Bronchoscopy with bronchoalveolar lavage
- e. CSF analysis, especially with hyperesthesia
- 6. Serologic testing
 - a. For persistent pathogens
 - i. Dogs – Ehrlichia, Brucella, Bartonella, Neospora
 - ii. Cats – FeLV, FIV, FCoV, Toxoplasma
 - iii. Other persistent infections as indicated
 - b. Immunopathologic diseases
 - i. ANA, RH, and LE tests
 - ii. Anti-platelet, anti-erythrocyte, anti-leukocyte tests
- 7. Bacteriologic testing
 - a. Urine, blood, or joint-fluid cultures
 - b. Fecal cultures
- 8. Tissue biopsy
 - a. Bronchoscopy or thoracoscopy with biopsy
 - b. Exploratory laparotomy with biopsy buffet
- 9. Therapeutic trial
 - a. Selected antibacterial drugs
 - b. Antifungal drugs

CBC, Complete blood (cell) count; *CK*, creatinine kinase; *T₄*, thyroxine; *CSF*, cerebrospinal fluid; *FeLV*, feline leukemia virus; *FIV*, feline immunodeficiency virus; *FCoV*, feline coronavirus; *ANA*, antinuclear antibody; *RF*, rheumatoid factor; *LE*, lupus erythematosus

- a. Fever is not harmful. Many diagnostic tests are needed and may have to be repeated or this list recycled. Tests listed lower under each section generally have higher cost or risk, or less immediate indication and should be considered with successive work-ups. With persistence, a diagnosis is often made and there is a favorable response to treatment.

96.2.2.3

Physical Examination

All body systems should be examined in detail, and a complete physical examination should be repeated at each hospital visit for outpatients. Inpatients should be examined twice daily. The physical examination should include careful cardiac auscultation and regular examination of the oral cavity and rectum, bones and joints, lymph nodes, and skin. Repeated ocular examinations should not be overlooked because they may provide evidence of infectious, inflammatory, or neoplastic disease. Given that fever can often wax and wane in FUO, the pattern of fever in an individual patient should be determined by serial measurement

Infectious Diseases of the Dog and Cat, 3rd Edition

of body temperature. This measure is not of any value in elucidating the underlying cause, but it is important in monitoring the response to any subsequent therapy.

96.2.2.4 Complete Blood Count and Serum Chemistry Profile

The problem of fever is often accompanied by neutrophilia or a stress leukogram, and serum chemistry tests are frequently nonlocalizing in FUO patients. However, any abnormalities detected on these tests should be used to direct further testing. The CBC should always be accompanied by examination of a blood smear so as to determine blood cell morphology and look for microorganisms. Automated CBCs should be verified by manual counts.

96.2.2.5 Urinalysis and Urine Culture

Because FUO may be associated with focal urogenital infections (e.g., prostatitis, pyelonephritis), UA and urine culture are mandatory in the evaluation of fever patients. Urine samples should be obtained by cystocentesis and submitted for bacterial culture and susceptibility testing, regardless of the appearance of the urine sediment.

96.2.2.6 Radiography

Thoracic and abdominal radiographs should be obtained during the first stage of evaluation of the FUO patient. These radiographs are simple to obtain and may provide early evidence of neoplastic disease or suggest infectious disease such as bacterial or fungal pneumonia. In the second or third stages of diagnosis, long bone, joint, vertebral, and dental radiographs should be considered. Contrast radiographs (e.g., intravenous [IV] pyelography, barium series, cystography, myelography, fistulography) may be indicated in some cases.

96.2.2.7 Ultrasonography

Abdominal ultrasonography can be used to look for potential sources of fever in organs such as the liver, spleen, pancreas, gastrointestinal (GI) tract, urinary tract, prostate, uterus, lymph nodes, and adrenal glands. Other regions that can be investigated by ultrasonography include the thorax (particularly in the presence of effusions or masses), the retrobulbar area, and any other peripheral mass lesion or swelling. Ultrasonography is particularly useful in facilitating the minimally invasive acquisition of fine-needle aspirates or biopsies.

96.2.2.8 Echocardiography

Ultrasonographic examination of the pericardium, myocardium, endocardium, heart valves, and great vessels is essential in the evaluation of the patient with FUO and a heart murmur, particularly if the murmur is of recent onset. These findings are suggestive of infective endocarditis, particularly if a source of infection (e.g., gingivitis, prostatitis, an IV catheter) is also present. Although echocardiography is not 100% specific or sensitive for the diagnosis of infective endocarditis, the finding of vegetative aortic valve lesions is considered to be pathognomonic.⁷³ Mitral valve lesions can suggest a diagnosis of infective endocarditis if present together with other supportive findings. Therefore the results of echocardiography should be interpreted in light of the patient's signalment, clinical signs, and blood culture results. Infective endocarditis is much more common in dogs than it is in cats, and middle-age dogs of medium to large

1033

1034

Infectious Diseases of the Dog and Cat, 3rd Edition

breeds (e.g., German shepherd dogs, boxers, golden and Labrador retrievers) appear to be over-represented.⁷³

96.2.2.9 Computed Tomography and Magnetic Resonance Imaging

These advanced imaging modalities are now available to many clinicians in referral hospitals. These assessments should be regarded as third stage tests in the evaluation of the FUO patient and used when clinical signs have been localized to a particular body system. For example, computed tomography is useful for detecting certain pulmonary lesions and for examining the nasal cavity, tympanic bullae, and pharynx. Magnetic resonance imaging is often used in evaluation of the central nervous system (CNS).

96.2.2.10 Aspirates and Biopsies

Fine-needle aspirates are usually simple and safe to obtain, and touch preparations or impression smears can also be made from ulcerated lesions or discharge material. Cytologic examination of these samples is relatively inexpensive and, depending on the skill of the clinician, can sometimes be performed in-house. For example, if blastomycosis is suspected, repeated aspirates from lymph nodes or skin nodules can be examined for *Blastomyces* organisms because they are relatively easy to identify. Aspirates can also be obtained from lymph nodes, abnormal fluid accumulations, and from masses or abnormal organs detected with imaging such as ultrasound or radiography. Examples include aspiration of consolidated lung lesions, splenic aspirates if unexplained splenomegaly is detected, and aspiration and analysis of exudates and effusions. Aspirates of fluids such as pleural, pericardial, or peritoneal effusions; cerebrospinal fluid (CSF); synovial fluid; or bile should also be submitted for bacterial and other cultures. Aspiration of peripheral lymph nodes, even if palpably normal, is recommended in the second stage of diagnostic testing if the source of the fever has not been localized.

Specialized techniques such as CSF sampling, bronchoalveolar lavage, transtracheal or endotracheal lavage, prostatic wash and ejaculation, bone marrow aspiration, and arthrocentesis are used to obtain cytology and culture samples from specific locations. The use of bone marrow aspiration and arthrocentesis are discussed later in this chapter.

Tissue biopsies are often obtained in the second or third stages of the diagnostic evaluation, when the source of the fever has been localized to a specific organ or tissue. However, in some cases, specific localizing signs may be absent. When biopsies are obtained with an invasive procedure, for example exploratory laparotomy, obtaining tissue from multiple sites and in sufficient quantities is important to allow histopathology, special stains for infectious agents, and culture for organisms such as aerobic and anaerobic bacteria, mycobacteria, and fungi. If necessary, the diagnostic laboratory should be contacted in advance to discuss optimal tissue handling, preservation, and transport. Biopsies may also be obtained with techniques such as thoracoscopy, laparoscopy, endoscopy, or arthroscopy, or they can be obtained percutaneously, sometimes with guidance from ultrasound or radiography.

96.2.2.11 Bone Marrow Cytology and Histology

Bone marrow disease is a relatively common cause of FUO. Reported examples include myelodysplasia, lymphoid leukemia, myeloma, and disseminated adenocarcinoma.^{32,23} Bone marrow aspiration is indicated in the early stages of diagnostic testing if CBCs show unexplained cytopenias. Pancytopenia requires the evaluation of both cytology of a bone marrow aspirate and histopathology of a core biopsy. In cats, bone

Infectious Diseases of the Dog and Cat, 3rd Edition

marrow cytology slides should also be reserved for feline leukemia virus fluorescent antibody testing. Bone marrow aspiration is indicated in the third stage of the diagnostic plan if the FUO has not yet been localized.

96.2.2.12 Arthrocentesis

Immune-mediated polyarthritis is a common cause of FUO in published canine case series.^{46,23} The condition may be idiopathic (nondeforming and nonerosive), or it may be caused by rheumatoid arthritis or associated with other immune-mediated disorders such as systemic lupus erythematosus or steroid-responsive meningitis-arteritis. Occasionally, nonerosive immune-mediated polyarthritis can be secondary to chronic infectious disease, GI disease, or neoplasia.⁶¹ Immune-mediated polyarthritis is also seen in cats and occurs as both a chronic periosteal-proliferative form and a less common erosive form.⁶¹

Lameness, joint swelling, and periarticular pain may wax and wane or be apparently absent in patients with immune-mediated polyarthritis. Therefore arthrocentesis should be performed in the second stage of evaluation of canine patients with FUO. Samples should be obtained from both carpi, both tarsi, and both stifles. The fluid should be examined for color, clarity, and viscosity and submitted for cytology. Bacterial and mycoplasma culture should also be performed if sample size is large enough.

Dogs with FUO and evidence of spinal pain may have concurrent immune-mediated polyarthritis and steroid-responsive meningitis-arteritis.⁷⁶ Therefore arthrocentesis is also recommended in all dogs in which this form of meningitis is suspected.

96.2.2.13 Blood Culture

Blood cultures are indicated in all patients with unexplained fever and are particularly indicated in the presence of a cardiac murmur; back, bone, or joint pain; or neutropenia. Peracute bacteremia associated with sepsis is usually caused by gram-negative organisms such as *Escherichia coli*. Subacute or chronic bacteremia is usually associated with a persisting focus of infection such as infective endocarditis or diskospondylitis.¹¹ More than one half of all canine infective endocarditis cases are caused by infection with coagulase-positive staphylococci and streptococci. Organisms implicated in diskospondylitis include *Staphylococcus intermedius*, *Streptococcus canis*, *Brucella canis*, and *E. coli*. In some cases, these organisms may be seeded from other locations such as the skin or urogenital tract.

Few prospective studies have been done of blood culture techniques in veterinary patients, although this subject has been extensively reviewed in the human study literature.⁵⁶ In human medicine, the likelihood of obtaining a positive culture result is directly correlated with the volume of blood drawn, regardless of whether the blood is obtained as a single blood culture set or divided into several sets over a 24-hour period. In one study, the yield from a 30-ml blood sample was found to be 62% more than that from a 10-ml sample. However, the sensitivity of blood cultures is also improved by obtaining more than one set. For example, in a study of bacteremic people, 91.5% of bacteremic episodes were detected by the first blood culture set, and 99.3% were detected by the first two sets. Increasing the number of blood culture sets will also increase the specificity of the test because contaminants are unlikely to be present in all sets.

In dogs and cats, blood culture techniques should focus on the collection of adequately large volumes of blood, with less emphasis on the timing or periodicity of the collections. The total volume of blood that can safely be obtained will depend on patient size. If size allows, more than one blood culture set should be obtained to increase the sensitivity and specificity of the test. Samples for blood culture should be obtained

1034

1035

Infectious Diseases of the Dog and Cat, 3rd Edition

by venipuncture, not from intravascular catheters, and the operator should prepare the site using aseptic techniques and should wear sterile gloves for the venipuncture. The blood sample should be immediately and aseptically inoculated into both aerobic and anaerobic blood culture bottles. Bottles of different sizes are available and should be selected to give the optimum ratio of blood-to-culture medium (see Diagnosis under Cardiovascular Infections, [Chapter 87](#)). Blood culture bottles containing resins may be used for patients receiving antibiotic therapy.⁴⁶

96.2.2.14 Serology

Serologic tests available for the diagnosis of infectious disease include assays for specific antibodies or antigens, as well as molecular tools such as Western blotting and polymerase chain reaction. Consideration of the signalment, clinical signs, geographic location, and possible vector exposure of the patient should direct selection of the most appropriate tests. Vaccination history, timing of the samples, local disease prevalence, sensitivity, specificity, and positive and negative predictive value must be considered when interpreting the results of any serodiagnostic test.

Serologic tests are also available for the diagnosis of certain immune-mediated diseases. For example, the Coombs' test detects antibodies against erythrocytes and is used in the diagnosis of immune-mediated hemolytic anemia. However, patients with this disorder are likely to have concurrent localizing clinical signs and are unlikely to present with F.U.O. Antinuclear antibody (ANA) can be detected in patients with systemic lupus erythematosus. However, diagnosis of this uncommon multisystem disorder requires the demonstration of multiple clinical and immunologic abnormalities and should never be based on elevated ANA alone.^{14,13} In addition, ANA can be elevated in some normal dogs and in association with other medical conditions. Rheumatoid factor has been found to be of poor sensitivity and specificity in the diagnosis of canine rheumatoid arthritis.⁶¹ This disorder is more appropriately diagnosed by a combination of radiographic changes indicating an erosive polyarthritis together with joint fluid analysis and possibly synovial membrane biopsy.

In summary, extensive arrays of wide-ranging serodiagnostic tests are not recommended in the investigation of F.U.O, and the use of *immune panels* is particularly discouraged. Ideally, serologic tests should be used to investigate a diagnosis that is suspected based on other findings.

96.2.2.15 Nuclear Medicine

Nuclear medicine has provided several techniques that can be used to visualize infection or inflammation in human patients.⁶⁵ Scintigraphic imaging can demonstrate many of the steps involved in the inflammatory process and can therefore potentially localize some causes of F.U.O. For example, leukocyte infiltration of tissues can be visualized with indium-111 or technetium 99m-labeled neutrophils. The latter approach has been used experimentally to localize abscesses in dogs²¹ but has not been applied to clinical cases. Other techniques in nuclear medicine include the use of radiolabeled human immunoglobulin, or gallium-67, which binds to transferrin in the blood, to nonspecifically demonstrate areas of increased fluid extravasation associated with enhanced vascular permeability in inflammation. Radiolabeled interleukins have also been used to localize inflammatory cells, and bacterial infection can be detected with labeled antibiotics such as technetium 99m-ciprofloxacin. A recent development in human medicine is the use of positron emission tomography with fluorine-18 fluorodeoxyglucose. This substance accumulates in areas of increased glucose metabolism such as tumors and inflammatory lesions.

Infectious Diseases of the Dog and Cat, 3rd Edition

96.2.2.16 Tissue Biopsy

Specimens can be obtained percutaneously, with or without imaging, or by direct surgical collection. Generally, the organs biopsied are indicated by the suspicions of the clinician; however, in undiagnosed fevers, multiple organ biopsies are often taken via exploratory laparotomy. Samples are placed in fixatives for routine histopathology; however, samples should also be submitted or saved fresh frozen for cultivation of organisms or nucleic acid testing based on the results of the histologic examination. Special stains for fungal or rickettsial agents must be used in some cases in which these agents are suspected based on initial findings.

96.3 THERAPY OF FEVER

96.3.1 Trial Therapy

In many cases, the investigation of the FUO patient will achieve a definitive diagnosis, and treatment of the underlying cause will lead to resolution of the fever and other clinical signs. However, in some cases of true FUO, a diagnosis is not reached, and in other cases, diagnostic testing is discontinued because of client or patient factors. In these cases, therapeutic trials are undertaken in the absence of a definitive diagnosis. Antibiotic, antifungal, or corticosteroid therapy are often used in therapeutic trials.

The goals of a therapeutic trial should be to confirm a presumptive diagnosis indirectly, control or cure the underlying disease, and resolve the patient's clinical signs, without inducing intolerable side effects or exacerbating an undiagnosed disease.

A therapeutic trial should be planned and monitored as rigorously as the diagnostic plan. It is important to begin with a tentative diagnosis, select safe and appropriate therapies, and implement a careful monitoring program, using predetermined criteria for success or failure of the therapeutic trial. Medication should be used at appropriate doses, and the duration of therapy should be sufficient to detect both the presence and absence of a response, particularly because fever can wax and wane independent of therapy.

Good client communication is essential in developing and monitoring a therapeutic trial, and clients should understand the risks of such an approach. Such risks include the continued progression of an undiagnosed disease if an ineffective therapy is used, development of medication side effects or toxicities, and the possibility of exacerbating an underlying infectious disease if immunosuppressive therapy is used. Clients should also understand that some medications, such as antifungals, can be expensive. A therapeutic trial is unlikely to be helpful if the client abandons the plan because of expense, side effects, or lack of immediate response to treatment.

Many causes of FUO are inflammatory or immune mediated; therefore glucocorticoids are commonly used in patients with FUO in the absence of a specific diagnosis. This approach can be dangerous if infectious disease has not been ruled out first. If glucocorticoid therapy is used in this way, the patient should be monitored closely for exacerbation or development of new clinical signs. The indiscriminate use of glucocorticoids may also interfere with future diagnostic testing or future more specific therapies. This practice is a particular concern for patients with neoplasia such as lymphoma. Glucocorticoids can also have nonspecific antiinflammatory effects and may improve the patient's clinical signs without addressing the primary cause of the fever. This characteristic is also true of some antibiotics, such as metronidazole or doxycycline.

1035

1036

Infectious Diseases of the Dog and Cat, 3rd Edition

Empirical antibiotic therapy is commonly used in small animal patients with fever, often with a successful outcome. Ideally, such therapy should be based on culture and susceptibility testing, although this is not always feasible. In trial therapy for FUO patients, antibiotics should be chosen based on a tentative but specific diagnosis, with consideration of spectrum of activity, and an understanding of pharmacokinetics. A significant risk of indiscriminate antibiotic therapy is that it contributes to antibiotic resistance in bacterial populations,³⁵ which may also be true for other antimicrobial agents.

When a systemic mycosis is suspected, often based on typical radiographic or ocular lesions, but cannot be confirmed, trial therapy with antifungal agents may be attempted. Fever may resolve within days, but fungal lesions may respond slowly to therapy; hence trial therapy with antifungals can take several weeks.

96.3.2 Antipyretic Therapy

If elevated body temperature is the result of nonfebrile factors such as heat stroke or prolonged seizure activity, physical methods of cooling should be employed. Examples include the use of fans and cool water baths and administration of cooled fluids via IV or by colonic or gastric irrigation. These methods are seldom needed for the true FUO patient because body temperature rarely exceeds 41.1°C (106°F) in these cases. Also important to remember is that fever is a *regulated* elevation in body temperature; therefore any attempts to physically cool the patient will be working against the body's own thermoregulatory mechanisms. Fever is also a protective adaptive response to the effects of infection and can have beneficial effects. External cooling is the treatment of choice for hyperthermia in which core temperature exceeds the thermoregulatory set-point. Thus when external cooling is used to treat hyperthermia, no opposition of regulatory process takes place in an attempt to increase heat gain, as is the case with fever.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 96-6 Doses of Antipyretic Agents Used in Dogs and Cats

DRUG	SPECIES	DOSE (mg/kg) ^a	ROUTE	INTERVAL (HOURS)	ADVERSE EFFECTS AND PRECAUTIONS
Acetaminophen (Paracetamol)	D	10–20	PO	12–24	Hepatotoxicity if overdosed.
Aspirin	B	D: 10 C: 10	PO	D: 8–24 C: 48–72	Do not use in cats. May cause GI irritation or bleeding; avoid if GI ulcer present. Reduces platelet aggregation. Caution with severe liver or renal disease. Dose carefully in cats due to prolonged half-life.
Carprofen	B	2	PO, IV, SC, IM	12	Mild GI irritation. Avoid if bleeding disorder. Idiosyncratic hepatotoxicity reported in dogs. Limit to 2-day duration in cats as safety unknown.
Ketoprofen	B	1	PO	24	May cause GI irritation or bleeding; avoid if GI ulcer present. Reduces platelet aggregation. Potentially hepatotoxic or nephrotoxic. Injectable available. Limit to 5-day duration in cats.
Meloxicam	B	0.1	PO	24	As above. Not currently approved for veterinary use in the USA.

D, Dog; *C*, cat; *B*, dog and cat; *GI*, gastrointestinal; *USA*, United States of America; *PO*, by mouth; *IV*, intravenously; *IM*, intramuscularly; *SC*, subcutaneously.

^a Dose per administration at specified interval.

Body temperatures above 41.1°C (106°F) can lead to CNS damage, disseminated intravascular coagulation, metabolic derangements, and even death. Fevers of 39.5°C to 40.8°C (103°F to 105.5°F) are more typically seen in FUO patients and may be associated with nonspecific signs such as anorexia, lethargy, arthralgia, and dehydration. Dehydration is caused by reduced water intake and increased sensible and insensible losses in the fever patient. IV fluid therapy can correct these conditions in the debilitated patient. In some conditions, attempts to lower the body temperature by cooling and antipyretic drugs might be considered. In patients with

Infectious Diseases of the Dog and Cat, 3rd Edition

concomitant reduced cardiac output, systemic vascular hypertension, or extreme obesity may benefit. If quality of life is significantly affected by the fever, or if body temperatures are in excess of 41.1°C (106°F), antipyretic medications should be considered in patients with FUO. [Table 96-6](#) lists the dosages and potential adverse effects of acetaminophen and several nonsteroidal antiinflammatory drugs that may be effective in reducing fever. These medications inhibit cyclooxygenase and therefore act centrally to reduce the hypothalamic set-point.

1036

Many antipyretic drugs can potentially cause GI irritation, ulceration, or bleeding, and they should not be used concurrently with glucocorticoids. Hepatotoxicities and exacerbation of bleeding tendencies are also possible side effects. The risk of nephrotoxicity is increased if these medications are used in patients with preexisting renal disease, hypotension, hypovolemia, or concurrent administration of nephrotoxic medications. Nonsteroidal antiinflammatory drugs should be used cautiously in elderly or debilitated patients. However, if used carefully, these medications can relieve discomfort while allowing continued diagnostic testing of the patient with FUO.

97 CHAPTER 97 Prevention and Management of Infectious Diseases in Multiple-Cat Environments

Janet Foley

Multiple-cat environments contain at least five cats and include multiple-cat homes, breeding catteries, pet stores, research catteries, shelters, foster or rescue homes, veterinary hospitals, groomers and boarding facilities, and feral cat colonies. Cats in multiple-cat environments are usually infected with different pathogenic microorganisms because infectious disease (ID) prevalence often is correlated with animal density and population size and because caretakers of multiple-cat households often have limited resources for disease control. Many of the important cattery infections are chronic, difficult to treat, or both, thus efficient management and disease prevention are paramount for success in multiple-cat husbandry.

Some degree of exposure to infectious agents is inevitable, given the ubiquitous nature of viruses such as feline herpesvirus (FHV) and feline calicivirus (FCV) and the environmental persistence of others such as feline panleukopenia virus (FPV). IDs may be transmitted directly by immediate or close contact between reservoir and susceptible hosts, indirect transmission including through inanimate vehicles (fomites), air or droplets, or various mechanical or biologic vectors. Whether infection becomes important in a cattery depends on host, environment, and pathogen attributes. Pathogen attributes include virulence, dose, and route of pathogen inoculation. Virulence is not under the control of the cattery manager, but dose and route of infection may be. Environment and host contributors to IDs also are important targets for minimizing IDs. This chapter reviews management strategies in catteries, major cattery infectious syndromes, and special cases of multiple-cat environments.

97.1 GENERAL MANAGEMENT STRATEGIES

Management of IDs in catteries should emphasize preventive medicine (Fig. 97-1). Colony immunity—the resistance of a group of animals to invasion and spread of an infectious agent—should be maximized, as should the *colonization resistance* (CR) of each individual. CR is the innate and acquired capability of an animal to resist ID and includes behaviors (such as avoiding filth), physical barriers (mucus, epithelium, fur), physical and chemical attributes of the host (low gastric pH, intestinal peristalsis, urine flow, mucociliary escalator), classical immunity, and normal flora. Animals with impaired CR (e.g., cats with feline immunodeficiency virus [FIV], geriatric or immunosuppressed cats, cats receiving antibiotics) not only are more susceptible to disease but also reduce colony immunity.

Ideally, a preventive management program should be implemented by a team consisting of at least a veterinarian and cattery manager who are familiar with the physical structure of the cattery, cattery staff and operations, and other details. Effectively managing a cattery to decrease risk of infection includes (1) minimizing population and individual risk factors for ID and (2) *movement control*, which is the regulation of access to other cats and fomites that could transmit infection.

97.1.1 Isolation and Quarantine

Cats that appear healthy but could be incubating IDs should be in quarantine for at least 10 days and preferably 3 weeks. During quarantine, the cats should receive well-cat care treatments (e.g., vaccinations, antiparasite treatments) and be observed daily by someone qualified to perform physical examinations and detect clinical signs of ID. When the quarantine period is over, it is presumed that the cat is clinically healthy.

1038

Infectious Diseases of the Dog and Cat, 3rd Edition

At that time, it should be allowed to interact with or be caged near other well cats in a way that minimizes stress and facilitates cleaning and cattery management.

Fig 97-1 Good husbandry is vital to an effective preventive medicine program.

Cats showing signs of ID must be isolated—but not in the quarantine area because it would result in infection of the quarantined cats. In a veterinary clinic or shelter, isolation needs and areas are obvious. In a cattery or home, a cat could be isolated in a bathroom; however, it is very difficult for owners to avoid carrying infections on their clothing, shoes, and skin from a sick cat to other cats. A cat with dermatophytosis, an upper respiratory infection (URI), diarrhea, or other contagious illness should not be isolated in the same house as healthy cats; they should be moved to a separate building or a veterinary clinic that will accept them. To ensure that IDs are not tracked throughout a cattery, a specific order of care should be followed: (1) feed and clean well cattery cats, (2) feed and clean quarantine cats, and finally, (3) feed and clean isolation cats. In a large facility, isolation cats should be handled by someone who is not also handling the well cats. Only if absolutely necessary should a caregiver attend to well cats after attending to cats in isolation, and then *only* if the caregiver has changed clothes and shoes and washed all exposed skin. If the facility is a shelter, a clinic, or another facility that does not keep cats longer than an average of 3 weeks, then cats remain in effective quarantine or isolation at all times.

In some situations, such as high-volume shelters, quarantining animals is impossible. In such cases, the next best option may be cohort admission. One method of cohort admission is to fill cages consecutively according

Infectious Diseases of the Dog and Cat, 3rd Edition

to the date each animal enters a shelter and ensure that cats have no contact with contaminated elements in the environment (*all-in-all out*). In shelters or clinics with too many sick animals, the isolation area must be expanded. Isolation expansion is contrary to the common practice of allowing sick animals to come in with well animals ready for adoption. Mildly ill animals may still be adoptable; potential owners should be allowed to view mildly ill animals in an isolation area.

97.1.2 Risk Factors for Disease

Risk factors for disease should be systematically evaluated and corrected if possible. Risk factors include environmental factors and population characteristics. The two most important cattery risk factors are (1) overall cat numbers and (2) density, or the number of cats per unit space. Other intrinsic environmental risk factors include caging strategies, stresses (e.g., dogs, noise, unstable social structures), rate of new cat introduction, sanitation, air flow and quality, well-cat programs, insect and vermin control, and season and climate. Population risk factors include population age composition, inbreeding status, breeds housed in the cattery, and presence of concurrent diseases.

1038

1039

97.1.2.1 Cat Numbers and Density

Cat numbers and density should be kept as low as possible, with an emphasis on minimizing the proportion of kittens and immunocompromised cats. Caging in stable cat groups should allow for some social interactions but not fighting. Cages should provide plenty of opportunities for cats to hide, vertical space, natural light and air, and windows through which cats can look. The details of group housing cats are too numerous to discuss thoroughly in this chapter but have been reviewed in other excellent sources.²⁴

Cages for individual cats should be more than sterile boxes because the increased susceptibility to disease caused by stress outweighs the reduction achievable by ease of cleaning. Environmental enrichment (hiding places, vertical spaces, and things to look at and play with) is very important (Fig. 97-2). Cages should not extend all the way to the ground (with bottom cages being at least a foot off the ground), and sick cats should never be housed above well cats; sick cats should be in isolation. *All* components of the cattery should be either disposable or completely disinfectable, precluding items such as carpet-covered scratching posts, carpeted floors, and porous wood structures. Any potentially nondisposable items should be kept in closed rooms and decontaminated or disposed of when the group of cats has finished with them.

97.1.2.2 Sanitation

Sanitation is important but often improperly handled. The main sources of ID are not cages—they are cats and contaminated, uncleanable environment components (such as carpet). Cleanliness is essential in a cattery. If a cattery has dirty litter boxes, litter scattered around, or a smell of ammonia in the air, it is not clean. When a cage, bowl, tray, or litter box is introduced to a cat, it should be new or should have been cleaned with 1:10 diluted bleach with at least 10 minutes of contact time. For routine cleaning, cages and bowls should be kept clean and litter changed every day. Everything in the cattery should be scrubbed and sanitized weekly, which frees the cattery managers from bleaching all bowls and litter boxes daily and leaves them more time to improve the cats' behavioral welfare, manage isolation and quarantine, and enjoy the cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 97-2 Hammocks provide cats with a peaceful environment.

97.1.2.3 Air Flow and Quality

Air flow and quality are significant factors, but their importance is overrated. The advantages of increasing air turnover from 10 to 15 changes per minute are not enormous, but the increase in expense is. In general, the greater the population density, the greater the need for increased number of air changes per hour. In homes, by far the most efficient way to achieve quality air is to open windows or have indoor-outdoor catteries. Most cats do not need air conditioning as long as they have fresh water, protection from rain, and shade. In cold weather, cats need heat.

97.1.2.4 Population Risk Factors

Population risk factors for ID include population age composition, inbreeding status, breeds housed in the cattery, and presence of concurrent diseases. Many of the risk factors that increase the likelihood of endemic or epidemic disease in catteries are also factors increasing risks to individual cats. Individual cats are more prone to infectious disease if they are very young, especially if they are colostrum deprived or very old, if they are stressed or on inadequate nutrition, or if they are already incubating an infection. In cats, inbreeding per se is not a risk factor, but being a member of a more susceptible pedigree may be.

97.1.3 Well-Cat Programs and Vaccinations

Well-cat programs and insect control minimize individual risk factors for ID, maximize colony immunity, and provide a systematic opportunity for cats to be evaluated and either treated or removed from the population if they are not well. Routine screening of cats should be performed *at least* annually by a veterinarian, preferably at the cattery, and should include a complete physical examination of all cats and vaccination boosters for the respiratory viruses and any other disease that may be a problem in the cattery.

The veterinarian and cattery manager should inspect the animals and premises for arthropods. Fleas transmit tapeworms and diseases such as bartonellosis, and all arthropods promote allergic reactions and dermatopathy.

Infectious Diseases of the Dog and Cat, 3rd Edition

Cats can be infested with lice, ear mites, and mange mites. Catteries should have zero tolerance for arthropods. If any arthropods are seen during a routine inspection, the entire premises should be cleaned and treated with an approved pesticide, and every cat should receive treatment for ectoparasites. Monthly antiarthropod treatment should be provided if needed to ensure that no cats are infested.

Vaccinations have four primary disadvantages: (1) some vaccines cause mild disease or transient immunosuppression; (2) parenteral, adjuvanted vaccines can trigger vaccine-associated sarcoma; (3) vaccines induce antibodies that could interfere with testing for the disease; and (4) use of vaccines may lead to a false sense of security that cats are adequately protected and other preventive management practices can be neglected. Although disadvantages exist, colony immunity is increased with the appropriate use of vaccines. Vaccine programs may be different for each different cattery. During primary vaccination, killed virus (KV) vaccines must be given at least 2 times (at least 2 to 4 weeks apart) before effective immunity is produced and thus are inappropriate in catteries with high turnover rates. KV vaccines may be advantageous in facilities where vaccine-associated diseases are unacceptable (e.g., in research catteries) and where it is important that no vaccine-induced antibodies are produced. Traditional modified live virus (MLV) vaccines use high-passage virus to give animals a mild infection. The protective effects develop more quickly than they do with KV vaccine, but respiratory vaccines may cause a mild URI. High-antigen mass (HAM) vaccines have lower passage, less attenuated virus strains than traditional MLV vaccines. These vaccines have are supposed to be able to overcome maternal antibody interference with vaccine efficacy. Because HAM vaccines are given mucosally, it is hoped that a local mucosal antibody (IgA) may be produced that could block the attachment of the virus to receptors, thus aborting an infection if the animal were exposed. Advantages of HAM vaccines include protection from vaccine-associated sarcomas, earlier protection than MLV vaccines, and possible protection for young kittens despite the presence of maternal antibodies. The major disadvantages are mild, temporary vaccine-induced immunosuppression and morbidity.

1039

1040

97.1.4 Morbidity and Mortality

It is important to diagnose causes of mortality and morbidity in a cattery to better plan and implement medicine programs. Necropsies should be performed after deaths, especially in breeding and research catteries. When infectious causes are suspected, laboratories should be advised of tentative diagnoses before the necropsy, if possible. It is impractical to submit samples from every sick cat for diagnosis, but spot-checking is very helpful, particularly during an apparent outbreak.

97.2 IMPORTANT INFECTIOUS SYNDROMES IN CATTERIES

97.2.1 Respiratory Disease

97.2.1.1 Etiology

Respiratory tract disease (upper, and less commonly lower, respiratory tract infection) is the most prevalent and easily recognizable infectious problem in catteries, and it is also the most difficult problem to manage.¹² The five most important pathogens in feline URIs, in increasing order of importance, are *Bordetella bronchiseptica*, *Chlamydomydia felis*, *Mycoplasma* spp., FCV, and FHV (see [Chapter 16](#)).

B. bronchiseptica, a nonenteric gram-negative bacterium, contributes to mild respiratory tract infections, often in association with respiratory viruses.^{54,3} If the bacterium is protected and kept moist, it can survive in the environment for weeks. Cats may have mild primary bordetellosis with conjunctivitis and mild

Infectious Diseases of the Dog and Cat, 3rd Edition

oculonasal discharge or have *Bordetella* pneumonia. FCV is an RNA virus with a high rate of mutation and is antigenically and genetically diverse.^{50,27} The infection is transmitted by aerosol, and the virus is introduced into cats through oral and nasal routes. Respiratory shedding of virus occurs for at least 10 to 14 days and commonly occur for months in shelters and kittens. FCV infection can cause conjunctivitis and rhinitis with serous ocular discharge, vesicular stomatitis and faucitis (aphthous stomatitis), pneumonia, transient fever and limping, and immune-complex polyarthritis and gingivitis. A very pathogenic series of FCV infections were reported in which cats developed facial and limb edema, apparently caused by vasculitis secondary to FCV, comparable to the hemorrhagic fever syndrome observed in rabbit hemorrhagic calicivirus infections.⁴⁶ FHV is an enveloped DNA virus that only infects felids.³⁷ Kittens often acquire the infection at a very young age, because parturition efficiently induces recrudescence of the virus. Later in life, transmission of the FHV requires intimate contact between cats. After infection, the virus persists in the trigeminal nerve with periodic or chronic activation that manifests in classical URI clinical signs, especially during stressful periods or immunosuppressive events. Disease signs may include conjunctivitis, anterior uveitis, serous ocular discharge with secondary bacterial infection and mucopurulent discharge, or keratitis with or without dendritic ulceration. Ulcerative and necrotizing nasal dermatitis resembling shingles has been described in some cats with FHV infection.²¹ Occasionally, URI signs in cats are caused by infection with *C. felis*, an obligate intracellular bacterium. The reservoir for the feline pathogen is feline conjunctival and genital mucosa (and possibly gastrointestinal [GI]). Chlamydial disease in cats often is acquired shortly after weaning. The typical sign is conjunctivitis, which is often unilateral. *Mycoplasma* spp. are degenerate, obligative parasitic bacteria with no cell wall, reduced genomes, and minimal ultrastructure. The reservoir for mycoplasmas is respiratory and genital mucosa, and transmission is via the aerosol route. Feline diseases attributed to mycoplasmas include URIs, conjunctivitis, and arthritis. Many people remain unconvinced that mycoplasmas are primary URI pathogens in cats, given that they commonly are recovered from clinically healthy cats.

97.2.1.2

Clinical Findings

Some or all cats with URIs show signs of conjunctivitis, anterior uveitis, ocular or nasal discharge, gingivitis, faucitis, stomatitis, glossitis, fever, and lymphadenomegaly. Vesicular stomatitis and faucitis are suggestive of FCV infection. Lameness and joint pain suggest infection with *Mycoplasma* organisms or FCV. A greenish colored or tenacious ocular or nasal discharge indicates bacterial contamination in the site but does not help identify the underlying pathogen. A cough suggests bronchitis (allergic or infectious) or pneumonia. Although far less common, a cat with a cough may have *cattery cough* (i.e., *B. bronchiseptica* tracheitis). Keratitis and corneal ulceration suggest FHV infection. Chronic sinusitis, often with turbinate destruction, may be from infection with either FHV or FCV followed by secondary bacterial infection. Fever develops most commonly with FHV or FCV infections. Cats with serous or purulent ocular discharge, nasal discharge, or both without the other more specific diagnostic signs could be infected with more than one of the URI pathogens.

97.2.1.3

Diagnosis

Rapid laboratory confirmation of the etiologic agent is unlikely. Possible tests include cytology of conjunctival cells, bacterial, viral, and mycoplasmal culture, and the polymerase chain reaction (PCR). URIs are managed in a cattery by minimizing their impact. Infected and exposed cats may have recurring disease, and few catteries (except specific pathogen-free [SPF] research catteries) are free of URIs. Chronically symptomatic cats can be identified during quarantine when the stress associated with the move often induces recrudescence of chronic or latent disease and should be excluded from the cattery.

Infectious Diseases of the Dog and Cat, 3rd Edition

Unfortunately, some of the MLV vaccines (often given before or during quarantine) induce mild to moderate URIs that are clinically indistinguishable from disease caused by field-strain pathogens. Commercial vaccines are available for feline bordetellosis, FCV, FHV, and *C. felis*. Pregnant queens should be vaccinated only with KV vaccines. Some catteries use partial doses of intranasal (HAM) vaccines to protect kittens as young as 1 to 2 weeks old. This practice can be dangerous because HAM vaccines induce mild, transient immunosuppression. Cats in well-managed breeding catteries should have excellent maternal-induced immunity, particularly if colostrum intake is ensured in all neonates. Innate resistance of every cat should be maximized.

As mentioned previously, the fraction of the cattery that consists of susceptible cats (immunosuppressed, geriatric, or young cats) should be minimized. Environmental decontamination for URIs should consist of frequent cleaning rather than sterilization because the primary reservoirs for URIs are other cats. Most URI pathogens are susceptible to many commonly used cattery disinfectants.

97.2.1.4

Therapy

Individual cats with URIs should receive nursing care and fluids if needed and be encouraged to eat. Antibiotics should be reserved for cats that have green, purulent discharge; may be septic; or are strongly suspected of being infected with *Chlamydophila*, *Mycoplasma*, or *B. bronchiseptica* organisms. For purulent discharge, a good, broad-spectrum drug with activity against pathogenic staphylococci is appropriate, such as cephalexin or amoxicillin-clavulanate. For possible sepsis, drugs with excellent broad and enteric spectra should be included, such as amoxicillin- or ticarcillin-clavulanate, enrofloxacin, or a penicillin with an aminoglycoside. The drug of choice for *B. bronchiseptica*, *Mycoplasma* spp., and *C. felis* is doxycycline, although acceptable substitutes may include enrofloxacin and azithromycin for mycoplasmas and *C. felis* and trimethoprim-sulfamethoxazole for *B. bronchiseptica*. *B. bronchiseptica* isolates often are resistant to multiple drugs.⁹ Cats with suspected *C. felis* or *Mycoplasma* spp. infection may be candidates for topical ophthalmic antibiotics and usually improve clinically within a few days. It is *not* appropriate to treat all affected cats with antibiotics because most are infected with viruses, and antibiotic use adversely affects normal flora, increases susceptibility to additional infections, and promotes antibiotic resistance.

No specific drugs are used to treat FCV, but several drugs may mitigate infection with FHV, including idoxuridine (Herplex® Allergen, Inc., Irvine, Calif.), trifluridine (Viroptic®, King Pharmaceuticals, Bristol, Tenn.), and vidarabine (Vira-A®, Parke Davis, Morris Plains, N.J.), all given topically 5 to 7 times a day (see [Chapter 2](#)). Acyclovir is an excellent systemically active drug used to treat human herpesvirus infection but is ineffective against FHV. Lysine occasionally is used to treat human and feline herpesvirus infections, with the justification that it antagonizes use of arginine in herpesvirus protein synthesis if dietary arginine is restricted. However, restriction of arginine is not safe for cats; nevertheless, some clinicians report that lysine treatment improves the clinical status of some cats with FHV infection. α -Interferon has direct antiviral properties and has been used with some success in FHV infection but is only available as a recombinant human protein, to which cats quickly become resistant (see [Chapter 16](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

97.2.2 Gastrointestinal Disease

97.2.2.1 Etiology

Stress, diet change, and a few primary pathogens can instigate diarrhea and vomiting, but many opportunistic organisms also accompany primary pathogens or other bowel disruptions. The complicated etiology makes management difficult. The major primary GI pathogens in catteries are FPV, *Salmonella enterica* serotypes, *Campylobacter* spp., *Giardia lamblia*, *Cryptosporidium parvum*, and *Tritrichomonas fetus*.

97.2.2.2 Clinical Findings

FPV (a parvovirus) is a small DNA virus that produces life-threatening diarrhea, vomiting, and immunosuppression (see [Chapter 10](#)). FPV has prolonged environmental persistence, is resistant to most chemical disinfectants, and has a tropism for rapidly dividing cells such as epithelial cells of the GI tract, white blood cell precursors in bone marrow, and cerebellar Purkinje's cells in neonatal or very young kittens. The incubation period of FPV can be between 3 days and 2 weeks but is usually 5 to 7 days. Animals younger than 6 months are most likely to develop severe disease, whereas adult animals may have mild disease that is indistinguishable from diarrhea of any other cause. Infection with FPV manifests as vomiting and diarrhea that lead to dehydration. Infection is usually accompanied by immunocompromise from loss of white blood cells as the infection targets the bone marrow precursors, which can predispose the animal to septicemia, shock, and death. In the neurologic form of feline panleukopenia, damage to the Purkinje's cells results in poor gross motor control from the cerebellum, although other peripheral nerves and the cerebrum remain intact.

S. enterica ser *typhimurium* is a zoonotic enteric bacterium with a broad host range including humans, birds, rodent, cows, pigs, horses, dogs, and cats. Cats with salmonellosis may be nonsymptomatic, diarrheic, or systemically ill. Hematologic values in cats are sometimes suggestive of panleukopenia with neutropenia that has a severe left shift. *Salmonella* endotoxin creates a massive disruption of the host inflammatory mechanisms, resulting in release of acute-phase proteins from liver, fever, vasodilation, increased vascular permeability, thrombosis, reduced organ perfusion with blood, reduced blood pressure, disseminated intravascular coagulation, shock, and death (see [Chapter 39](#)). *Campylobacter* organisms are zoonotic gram-negative, motile, curved, rod-shape bacteria. Many organisms are common in juvenile or stressed animals and results in a range of clinical signs from no symptoms in carriers to severe diarrhea. *Campylobacter upsaliensis* has been associated with bloody diarrhea outbreaks in day care centers for children and in groups of dogs and cats.^{97a,105a,190a} Often, diarrhea associated with campylobacteriosis is self-limiting, but debilitated, dehydrated, or very young animals may die of the infection without extensive nursing care (see [Chapter 39](#)).

G. lamblia is a flagellate protozoan, which in addition to the apicomplexans *Cryptosporidium felis* and *Cryptosporidium parvum*, is a primary pathogen (see [Chapters 78](#) and [82](#)).²⁵ *C. parvum* has a wide host range including wild mammals, cattle, dogs, and cats. Diarrhea is most severe in young and immunosuppressed animals. *T. fetus* also is a flagellate, is better known as a parasite in cattle, and superficially resembles *G. lamblia* in fresh feces. Cases have been reported in cats with severe, watery diarrhea.¹² The infection is spread directly from cat to cat.

Infectious Diseases of the Dog and Cat, 3rd Edition

Numerous GI opportunists may exacerbate clinical diarrhea, including the enteric *Helicobacter* spp. (*colifelis*, *canis*, *hepaticus*, *bilis*, *pullorum*, *fennelliae*, and *cinaedi*); *Clostridium difficile* (a zoonotic anaerobe associated with severe disease [see [Chapter 39](#)]); and *Isospora* spp. Human pseudomembranous colitis is a nosocomial infection with underlying disease, antibiotic usage, or both, and *C. difficile* in cats probably is as well. *Isospora* spp. in small numbers are exceptionally common in kittens. The life cycle is complex and includes sexual and asexual stages. GI cells become damaged when the *Isospora* progeny emerge. The number of asexual reproductive cycles appears to be programmed; only two or three occur in any one host individual, and infection is self-limiting. The disease associated with large numbers of *Isospora* is profuse, watery diarrhea, often with concurrent bacterial infection (see [Chapter 81](#)).

97.2.2.3

Diagnosis

Testing for GI pathogens can be difficult, because some animals with primary pathogens lack clinical signs, and the presence of opportunists is difficult to interpret. Exhaustive testing is expensive, is difficult, and often fails to identify a specific cause. Severe, life-threatening disease is suggestive of FPV infection in which clinical evaluation might reveal dehydration and bowel fluid and gas distension; if the animal is septic or in shock, signs may include pale mucous membranes, delayed capillary refill time, and increased heart and respiratory rates. Laboratory tests to evaluate diarrhea start with the complete blood cell count (CBC). Most viruses cause mild to moderate reduction in white cell counts, whereas FPV infection causes severely depauperate or almost no white blood cells, reflecting the viral infection in the bone marrow.

1041

1042

Some of the commercially available fecal enzyme-linked immunosorbent assays (ELISAs) designed for the detection of parvovirus antigen in canine feces can be used for cats. Because the tests are antigen ELISAs, they are positive only when virus is in the sample. Some false-positives result occasionally because of vaccinations, thus cats should not be diagnosed with parvovirus enteritis unless they have appropriate clinical signs or a very low CBC. Bacteria involved in vomiting and diarrhea can be evaluated by a Gram stain of feces followed by aerobic, microaerophilic, and anaerobic culture. Aerobes including *Salmonella* spp., *Escherichia coli*, and *Yersinia enterocolitica* may be identified using standard microbiologic techniques. *Campylobacter* and *Helicobacter* organisms generally must be cultured in reduced oxygen, because they have only a small amount of superoxide dismutase and cannot tolerate more than about 10% oxygen; room air has about 20% oxygen. Routine microaerophilic culture on selective agar often is conducted at elevated temperatures (e.g., 42° C) and may miss less thermotolerant strains. However, the majority of pathogenic *Campylobacter* spp. are detected and additional infections identified if fecal Gram stains are performed, especially if carbol fuchsin is used as a counter stain. To identify a clostridial infection, an anaerobic culture can be performed on selective media, and immunologic assays can be used to detect *C. difficile* toxin A. *Helicobacter* spp. may be much more difficult or impossible to culture.

Fastidious helicobacters and campylobacters may be evaluated using biopsy and molecular techniques. PCR is a relatively new test that identifies nucleic acids specific to a microorganism (commonly used for parvoviruses and feline enteric coronavirus [FECV]) and can be used to test any tissue in which virus is suspected, including feces, gut, bone marrow, respiratory secretions, and the cerebellum and brain.

Thorough parasite evaluation includes direct microscopic examination of fresh feces, flotation, and ELISA or fluorescent antibody (FA) testing. *Giardia*, *Trichostrongylus*, and coccidia organisms can be seen in fresh feces in saline. Fecal flotation is a standard procedure for identifying parasites but often reveals parasites that are not contributing to the diarrhea. Failure to find *Isospora* oocysts on flotation or direct smear does not rule them out as contributing to the diarrhea, because the test has low sensitivity in early infection. *Cryptosporidium* and *Giardia* spp. in feces may be more easily detected with ELISA or FA, but FA testing

Infectious Diseases of the Dog and Cat, 3rd Edition

requires a fluorescent microscope, and the ELISA generally is available as a send-out test to a commercial laboratory (see [Chapter 78](#) and [Appendices 5 chapter7](#) and [6](#)). However, these tests markedly improve sensitivity for detection of *Cryptosporidium* organisms.

Cattery management of GI disease should include surveillance and outbreak investigations to clarify the status of infection in the colony and prevention of new cases through support of CR and blocking disease transmission. Surveillance should include regular quantification of GI disease present, including number of cases for which specific pathogens are identified. Animals can best resist GI infections when they are otherwise healthy and well nourished, not stressed, have intact normal bacterial flora, and have been appropriately vaccinated. Problems arise in high-density catteries with high turnover of animals, highly susceptible animals, and changes in diet. It is important to ensure that kittens receive colostrum. Even if vaccinations are given to all incoming animals, they have no effect on most of the GI pathogens. Kittens may not be protected because of maternal antibody interference and immunologic immaturity, and no cats are be protected immediately after being vaccinated. The available vaccines for GI pathogens include FPV and *Giardia*. FPV vaccine is available as KV, MLV-traditional, and MLV-HAM.

It is better to perform less-frequent but thorough disinfections than daily cursory disinfections, although spot cleaning should be performed every day. Because many GI pathogens are difficult to kill, the environment should be as dry as possible, exposed to ultraviolet light, and decontaminated with bleach. To prevent the casual spread of GI pathogens, bleach foot baths should be set up at or built into entrances to catteries or shelters. If possible, a 14-day quarantine is helpful. If the facility has an inadequate amount of space and holding time for a functioning quarantine, the next best option is cohort admission.

97.2.2.4 Therapy

In cases in which specific diagnostic tests are not run or results are all negative, empiric treatment of diarrhea may be advised, including antibiotics, motility modulators, a bland diet, or antiinflammatory agents. Each has drawbacks. Antibiotics may adversely affect normal flora. Drugs to reduce gut motility and diarrhea increase retention time of all luminal contents, including pathogens that can exacerbate the disease. Bismuth subsalicylate should be used carefully in cats because they have very low tolerance for salicylic acid. Even a bland diet can be counterproductive if the animals will not eat it.

Treatment for parvovirus includes nursing care, management of hydration and electrolyte status, prevention and management of secondary bacterial infection and septicemia caused by loss of white blood cells, and facilitation of the recovery of the bone marrow. Other GI infections generally have a better prognosis than parvovirus if identified and treated appropriately. Treatment of many parasitic infections is straightforward. Metronidazole and fenbendazole are the drugs of choice for *Giardia* organisms (see [Table 78-3](#)). However, treatment failure is common, particularly in Abyssinians, Bengals, and some other purebred cats. If treatment fails, the feces should be reevaluated to determine whether the protozoa are *Tritrichomonas* spp. that have been misdiagnosed as *Giardia*, and additional diagnostics should be performed to identify other underlying diseases that might be present. *Cryptosporidium* organisms are considered self-limiting; if treatment is necessary, paromomycin and azithromycin might be considered, although both have low to moderate efficacy. Treatment of *Tritrichomonas* organisms is quite difficult. Metronidazole and paromomycin have been used; however, neither is very effective, and paromomycin is toxic in cats. Coccidiostatic drugs such as sulfadimethoxine can reduce the number of asexual progeny being produced by the organism so that the host's epithelium can repair itself. Often animals with severe coccidiosis respond better to treatment when they also receive metronidazole, clindamycin, or ampicillin.

Infectious Diseases of the Dog and Cat, 3rd Edition

Primary bacterial pathogens should be treated with antibiotics appropriate to the bacterium (see [Tables 39-2, 39-6, and 39-10](#)). For *Campylobacter* spp., good choices include erythromycin, tetracycline, enrofloxacin, and tylosin. Triple therapy is helpful for severe or refractory cases, including bismuth subcitrate or subsalicylate (caution in cats), ampicillin, and metronidazole. The author has found it helpful to substitute enrofloxacin for ampicillin in some animals. Older literature indicates that patients receiving antibiotics for *Salmonella* spp. may become carriers. With modern antibiotics, the greater concern is the evolution of resistant strains, although most infections can be eradicated with chloramphenicol, enrofloxacin, tetracycline, or trimethoprim-sulfonamide drugs, provided the bacteria are susceptible.

1042

Adjunctive therapy should include fluids as needed and possibly lipopolysaccharide hyperimmune serum. If opportunistic bacteria are detected, an additional evaluation for underlying diseases should be performed and the diseases treated if possible. Many animals have self-limiting opportunistic infections; antibiotics only serve to scour the gut of normal flora and increase the likelihood of additional problems. If an animal is diagnosed with a *C. difficile* infection, it is particularly important to address the underlying disease and decontaminate the environment. The two best drug choices are metronidazole and vancomycin, because many isolates are resistant to metronidazole. Public health veterinarians may be concerned justifiably about the use of vancomycin in shelter animals.

1043

97.2.3 Dermatophyte Infections

Dermatophytes are molds in the Ascomycota; 95% of all cat cases of dermatophytosis are caused by *Microsporium canis*.⁴⁰ The conidia gain access to keratinized epithelium, often through a defect in the stratum corneum, then germinate, and mycelia enter cornified strata. As arthroconidia develop in tissue, clinical signs develop because of fungal products such as elastase, collagenase, and keratinase and as a result of allergic responses to the fungi. The incubation period for ringworm is between 4 days and 4 weeks. Infection finally may be resolved by cell-mediated immunity in weeks or months, although some carriers remain chronically infected. Severe or chronic disease prevalence is higher in geriatric cats and those younger than 1 year, as well as Persian cats, cats that have FIV and feline leukemia virus (FeLV) infections, are pregnant or lactating, are malnourished, are taking antiinflammatory drugs, or that have cancer or are stressed. Ringworm is zoonotic.

Accurate diagnosis of ringworm is critical because ringworm contamination can rapidly get out of control. Unfortunately, many shelters euthanize affected cats because they cannot contain ringworm. Classically, the condition is characterized by a circular, inflamed lesion with stratum corneum hypertrophy from which hair is lost and crusting develops. Severe ringworm may be confused superficially with mange, whereas mild cases may be subtle, with small areas of hair loss or a few crusts. The most common locations include the face, ears, feet, and tail. Examination with a Wood's lamp reveals *bright* green fluorescence in about 50% of affected animals. Microscopic examination for ringworm is performed on hairs plucked from the periphery of suspect lesions. Hair is cleared of keratin by suspending it in 10% to 20% potassium hydroxide (KOH). The slide is then gently heated for 15 to 20 seconds or allowed to stand for 30 minutes at room temperature before being examined. Infected hairs appear swollen and frayed, with loss of normal structure. Arthroconidia and hyphae occasionally can be seen.

Fungal culture is the most reliable method of assessing the presence of ringworm. Samples are collected by plucking hair from the edge of the lesion or running a new toothbrush through the coat. The hairs or toothbrush tines are placed onto an appropriate agar such as dermatophyte test medium (DTM) or rapid sporulation medium (RSM) that contain antibiotics and antifungal drugs to discourage growth of contaminants, although some nondermatophytes do grow. DTM contains phenol red, which turns red in the presence of alkaline metabolites produced primarily by dermatophytes and a few saprophytes. Bromothymol

Infectious Diseases of the Dog and Cat, 3rd Edition

blue in RSM turns blue-green in the presence of dermatophytes. Plates incubated in air at room temperature for days to a few weeks, should be observed for visible fungal mycelia and color change daily. When candidate dermatophytes are observed, hyphae should be examined under the microscope for the characteristic conidia (most easily seen on RSM) to confirm the diagnosis. This step, which commonly is skipped, is essential. The morphology and presence of macroconidia and microconidia are essential for confirming and identifying dermatophytes; their characteristics are described in the package insert with the culture plates or in various microbiology texts.

In addition to controlling infection in the environment, colony management of ringworm should incorporate the assumption that infected animals periodically enter the facility, and minimizing movement and contact are important. Ringworm-positive and possibly affected animals should be isolated, especially from cats with URIs. Staff members should wear gloves, smocks or coveralls, and boots or shoe covers while working with affected cats. After contact with ringworm-positive cats, staff members should not have contact with well cats until they have showered and changed clothes. Affected animals should not be allowed into the main facility until several weeks after their apparent clinical recovery and culture results have been negative for 2 weeks. Ringworm is very viable in the environment. Grooming instruments and fomites such as toys should be disposable or able to be decontaminated. Dermatophytes are susceptible only to prolonged contact (preferably overnight) with strong bleach. Washable items can be cleaned in a dishwasher if it has a water temperature at least 43.3° C (110° F).

Many cats spontaneously recover in about 3 months. Topical treatment reduces contamination of the environment and arguably does not reduce the clinical severity or accelerate recovery.⁴¹ Clipping, which should be performed *gently* with a #10 blade, removes infected hairs from the animal and therefore environment. A lime-sulfur dip (4%) used twice weekly is relatively effective and safe if patted on rather than rubbed into the coat. Creams, ointments, and azole-containing shampoos have disappointing results.

The drawbacks to systemic therapy are the high cost, toxic side effects, long course of treatment required, and lack of efficacy in reducing clinical severity or speeding recovery. Griseofulvin is fungistatic, less expensive than itraconazole, and more likely to cause vomiting, diarrhea, and bone marrow suppression. Itraconazole does not efficiently resolve ringworm in cats, and its adverse effects include hepatic disease and vasculitis. Daily oral lufenuron therapy has been reported as an effective treatment for ringworm, although some trials have not documented improved recovery. Vaccinating affected cats with a killed *M. canis* vaccine is intended to speed recovery. (See [Chapter 58](#) for additional information about this disease.)

97.2.4 Retroviral Infections

The retroviruses—FeLV and FIV—are insidious, feline-specific infections that can predominate densely housed populations of cats unless preventive management strategies are implemented.⁴⁴ FeLV is transmitted through direct contact with urine, saliva, milk, and blood of infected cats or through in utero exposure. Neither FeLV nor FIV can persist in the environment. After exposure, many cats eliminate the infection and become immune. If the virus is not eliminated, infection may persist for months to a few years until the cat develops neoplasia, dysregulated blood cell production, immunosuppression, or one of many rare and bizarre FeLV-associated syndromes such as cutaneous horns, immune complex nephritis or arthritis, or both. Because signs of FeLV infection can be vague (e.g., weight loss, vomiting, lack of energy) and because of the long latent period during which cats can be infectious but not symptomatic, it is critically important to screen cats before entry into a multiple-cat environment and to maintain an FeLV-free colony. Most FeLV infections are identified by ELISA, which detects the p27 antigen that is present in viremic cats. After exposure to FeLV, a cat has positive test results in blood within days to a week and if able, eradicates the virus within about 2

1043

1044

Infectious Diseases of the Dog and Cat, 3rd Edition

weeks. To ensure without a doubt that the virus has been eliminated, healthy cats should be retested in 4 to 6 weeks. If a cat has a positive result at that point, they should be considered chronically infected.

If effective screening tests are performed, it is unlikely that cats with FeLV will be introduced, but good husbandry practices should be in place to prevent viral transmission in the event that an FeLV-infected cat is missed. FeLV-positive cats should be isolated or kept only with other infected cats. Some safe commercial vaccines against FeLV infection can be given yearly. Expert opinions differ about the vaccine's effectiveness. Certainly, most vaccinated cats do not develop FeLV infection, but neither do most otherwise well adult cats.

FeLV is a fatal infection; at best, cats do well clinically for months to a few years. The only goals for treatment are to keep virus levels as low as possible, reduce the impact of FeLV-associated disorders, and maximize quality of life. Treatment usually fails within a few months. If managers opt to treat FeLV-positive cats, they should be well educated about preventive management to protect healthy cats do not acquire the infection and about quality of life of infected cats so that euthanasia can be performed at an appropriate time. (For additional information about FeLV infection, see [Chapter 13](#).)

FIV is a lentivirus that is closely related to the human immunodeficiency virus (HIV; see [Chapter 14](#)). The main routes of FIV transmission are via biting and breeding. Cats can live together in one home without transmitting the disease, although biting tends to be most common during initial introductions. After infection, the cat develops a high level of viremia followed by host immune-induced significant reductions in circulating virus load. Over time (5 or more years), progressive immunocompromise develops—manifest as *feline acquired immunodeficiency syndrome (AIDS) related complex*—with secondary oral disease, severe URIs, hemotropic mycoplasma infection, neoplastic disease, and other conditions, followed by true AIDS.

The screening test for FIV is an antibody ELISA. PCR for FIV is not sensitive enough for diagnostic use, although real-time PCR shows promise. Because ELISA gives some false-positive results, infection can be confirmed with a Western blot. Maternal antibodies may interfere with FIV testing in kittens, but false-positive test results rarely occur at 4 months of age and are very unlikely by 6 months.

The decision about how to manage FIV in a cattery is difficult because although infected cats have an excellent quality of life for years, they have a contagious, fatal infection. If a manager can prevent transmission, affected cats can be kept in a multiple-cat environment if they are well nourished, protected from stress and other infectious diseases, and are treated for secondary conditions. Antiretroviral drugs have been researched extensively, but no cure for FIV infection exists. Because even moderately immunosuppressed cats are more susceptible to infection, FIV-positive cats may contribute disproportionately to the load of infectious organisms in a multiple-cat environment, increasing risks for other cats. Cats with FIV should be housed only with other cats with FIV and should not be housed with FeLV-positive cats. A vaccine for FIV exists, and new technologies are actively being researched that will probably result in additional vaccines within a few years. Unfortunately, widespread use of vaccine will make screening difficult because vaccinated cats will have positive ELISA results.

97.2.5 Feline Enteric Coronavirus and Feline Infectious Peritonitis

FECV is a ubiquitous, clinically silent feline coronavirus (FCoV) infection found in virtually all cats in endemic multiple-cat environments.⁷ The virus localizes in GI villous tip epithelium and produces mild pathologic lesions with minimal if any detectable clinical signs (see [Chapter 12](#)). The virus is spread directly among cats through exposure to infected feces. The significance of FECV in cats is that mutant forms of FECV known as *feline infectious peritonitis virus (FIPV)* arise frequently in cats and may acquire the ability

Infectious Diseases of the Dog and Cat, 3rd Edition

to enter and replicate within feline macrophages.⁴⁸ When accompanied by a particular feline immune response, this can result in feline infectious peritonitis (FIP; see [Chapter 11](#)). FIP is the cat's immune-mediated response to the infection; immune complexes are formed, and immunologic reactions lead to the characteristic pathologic and clinical abnormalities. In noneffusive FIP, granulomatous masses form on kidneys, on mesenteric lymph nodes, on liver, in the brain and eyes, or all of these and may lead to organ failure. Cats with effusive FIP develop a high-protein, yellow-colored effusion fluid in their chest or abdomen, causing dyspnea or abdominal distention.

The diagnosis of FIP is based on a composite of history, signalment, clinical observations, physical examination, and laboratory findings. FIP is most common in 1- to 3-year-old cats from multiple-cat households and shelters. Cats typically have symptoms of a cyclic nature, antibiotic-unresponsive fever, lethargy, and failure to grow.⁸ CBC abnormalities include elevated total protein (mainly globulin) and mild neutrophilia and lymphopenia. Because FECV and FIP virus (FIPV) antibodies *completely* cross-react, the diagnosis of FIP by antibody tests in a healthy cat cannot be made. These antibody detection tests should be appropriately termed *FCoV antibody tests* rather than FIPV antibody tests. Because of its extremely high sensitivity and the lack of discernable differences in the viral genomes, PCR that detects viral RNA *cannot* differentiate between FIPV and FECV, although a positive PCR in tissues from some anatomic locations such as the brain (which is not invaded by FECV) strongly suggests FIP. Newer experimental mRNA-detection methods show some promise in making this distinction (see [Chapter 11](#)). The only way to confirm a diagnosis of FIP is to identify the FIPV in biopsies or at necropsy—if necessary, by using an FCoV-specific immunohistochemical stain. Finding large quantities of FCoV by immunofluorescence in tissues outside the enteric lumen is typical of FIP.

Virtually every cat with FIP dies. Given the infection's immune-mediated pathogenesis, immunosuppressive drugs may slow disease progression but do not result in a cure. Cats should receive broad-spectrum antibiotics and nursing care for as long as they are comfortable. Once the disease becomes debilitating and weight and appetite decline, the cat should be euthanized. Very little can be done to effectively prevent FIP in multiple-cat environments. Cats acquire FIP directly from other cats via fecal-oral spread of FECV and resultant mutation of the FECV within the individual cat's gut. If cats are exposed to FECV, the risk that FIP may develop *always* exists; FECV can only be eradicated in very small groups of cats (less than four *per building*). In multiple-cat groups, 40% to 60% of the cats shed virus in their feces at any given time, and virtually all cats have seropositive FCoV test results. The available FIP vaccine is not very effective in protecting cats from FIP or FECV, but it appears safe. It must be given before FeCV exposure to have any efficacy. Prevention of FIP should focus on keeping cats as clinically healthy as possible and efficiently diagnosing existing infections.

1044

97.3 SPECIAL SITUATIONS

1045

97.3.1 Veterinary Hospitals

Veterinary hospitals are unique multiple-cat environments characterized by high turnover, high proportions of ill cats, and often, multiple species. The missions of a veterinary hospital with respect to cats usually include well-cat preventive care, ill-cat care, possible boarding, and possible management of in-house cats (e.g., residents, blood donors). Preventive management in a hospital should rely on movement control and routine disinfection. All surfaces exposed to cats (e.g., floors, cages, examination tables) should be washed daily with soap and water and disinfected with bleach after each cat contact. The movement of obviously infectious cats should be highly restricted and if hospitalized, such cats should be housed in isolation wards and managed by

Infectious Diseases of the Dog and Cat, 3rd Edition

staff members who do not interact with well cats until they have changed their clothes and, preferably, showered. Most veterinary hospitals have little need for a routine, incoming-cat quarantine procedure.

97.3.2 Boarding and Grooming Catteries

The mission of boarding and grooming facilities generally includes well-animal management. The first step in movement control is to ensure that sick or infectious cats are not admitted and are routed to a veterinary hospital. This step requires a vigilant, well-trained staff. If cats are boarded for prolonged periods, they should be quarantined initially. For all cats that are entering or leaving the facility, movement control should preclude contact of cats with each other and fomites. Cages and all equipment must be cleaned and disinfected between each cat contact. Kitten boarding and grooming should be minimized, and all incoming cats should have current vaccinations.

97.3.3 Shelters

Various shelter types with various missions exist, ranging from animal control facilities that accept all cats and have high turnover to *no-kill* and other animal shelters with random-source intake but low turnover and some long-term residents. In some animal *sanctuaries*, admission is severely restricted, and cats may stay for life. Most shelters have a high prevalence of infectious disease because of concurrent debilitating factors (e.g., stress, poor nutrition, inadequate well-cat care), numerous circulating infections, crowding, inadequate sanitation, and inadequate vaccinations. Optimal practice of shelter medicine is a very complicated subject; appropriate use of quarantine, movement control, and isolation are extremely important. Cats should receive vaccinations for the common diseases on entry. Medical and well-cat preventive care should be performed in consultation with an in-house veterinarian. It is unfortunate that the majority of sick cats in shelters acquire their infections from the shelter, a fact that should prompt shelter managers and veterinarians to make preventive colony management a top priority.

97.3.4 Retail Outlets

Retail pet stores share some characteristics of shelters in that they may have high turnover, constant visitation from the public, noise, and stress. The control of infectious diseases in pet stores is exacerbated by the high prevalence of kittens in the population. However, retail stores have considerable control over the incoming population—if they choose to exercise it. Kittens that are shipped from distant sources shortly after weaning are *very* stressed and susceptible to disease. Stores should only accept fully vaccinated kittens older than 3 months of age from highly reputable sources. Shipping must be humane and as stress-free as possible. All incoming cats should be screened at intake by a medically knowledgeable staff person (preferably a veterinarian or veterinary technician) and placed either in quarantine or isolation. Any money saved by skipping this step results in a far greater expense later when the cats become ill and the clients become dissatisfied. Cats in isolation should be under the care of a veterinarian. Cats in quarantine may be available for purchase but should not be mixed with cats that have completed quarantine or with possibly infected fomites, including the public. Obviously, humane and stress-free environments with minimal exposure to noise, excellent sanitation and nutrition, and gentle handling also minimize infectious disease.

97.3.5 Research and Specific Pathogen-Free Catteries

In many ways, infectious disease control in SPF catteries is easier than in other multiple-cat environments. If incoming cats are quarantined individually or in small groups they can be tested and denied entry unless they

Infectious Diseases of the Dog and Cat, 3rd Edition

are nonsymptomatic and free of antibodies (or antigen) for FeLV, FIV, FECV, FHV, FCV, and FPV. Commercially available SPF cats often are infected with FECV and multiple GI pathogens, including *G. lamblia*, *C. parvum* and *C. felis*, and *Campylobacter* spp., producing infections that often are asymptomatic and difficult to eradicate. Obtaining completely disease-free cats may require cesarean delivery of kittens and housing in small, contained, sterile facilities. These miscellaneous opportunistic infections may be most intolerable in research programs with immunosuppressed animals, but it is disconcerting how many endemic, ineradicable infections are common in even well-managed, multiple-cat environments. It is also amazing how well most cats tolerate them.

98 CHAPTER 98 Prevention and Management of Infection in Kennels

Dennis F. Lawler

Dog kennel populations can be described as stable or transient and can be defined further by their purpose. Relatively stable adult canine populations are found in kennels that support purebred interests (breeding or performance), in those that produce puppies for commercial pet channels, in research kennels that maintain long-term residents, and in multiple-pet households. Transient populations are usually associated with veterinary hospitals, grooming and boarding facilities, community shelters, retail outlets, suppliers that acquire and condition dogs for resale, and research kennels that do not maintain long-term residents. Shelters that do not euthanize have characteristics of both stable and transient kennels. Additionally, characteristics of both stable and transient populations can be noted in breeding and performance kennels if bidirectional transport of dogs constitutes a substantial and ongoing portion of routine activities.

98.1 ALL KENNEL POPULATIONS

98.1.1 General Characteristics

Regardless of their intended purpose, all kennel populations share general features, including close proximity of residents, some means of confinement, a system for sanitation and husbandry, a level of health care, and environmental effects ([Fig. 98-1](#)). Yet, each facility possesses unique features that influence occurrence of infectious diseases. For example, in most geographic areas, nearly all dogs housed in kennels are exposed to the same environmentally stable agents, such as canine parvovirus (CPV; see [Chapter 8](#)). However, kennels that produce many litters of puppies are likely to experience greater incidence of clinical CPV infection because of environmental contamination and sequential passage to susceptible younger litters.

Clinical diseases caused by more labile agents are influenced by interactions between environmental stressors and the natural biology of the agents. Seasonal tracheobronchitis in crowded boarding kennels is one important example of the latter (see [Chapter 6](#)). Another important example relates to bacterial infections of the female reproductive system in breeding kennels. A slight increase in mastitis or metritis might be expected—and should be anticipated—in association with seasonally increased humidity. When such events become frequent, other management errors are likely contributory. Most common among these errors are inadequate clipping of hair from mammary glands before lactation, infrequent or inadequate removal of feces (particularly from pens housing litters), inadequate flushing of pens during cleaning (and poor general sanitation practices), poorly trained caretakers, and failure to examine lactating bitches with sufficient frequency.

One underlying characteristic of all kennel populations is frequently problematic and can be the most difficult to address: the nature of human decision making. Increased population susceptibility to infections is the usual outcome of the more common management errors that are made by kennel operators. These errors include (1) overcrowding of facilities, (2) inattention to basic principles that relate to movement of dogs within and among populations, (3) improper environmental management, and (4) poor breeding stock selection in production environments.

Regardless of the type of facility, most kennel operators are aware that some means of vaccination and parasite control are necessary. However, appreciating the level of planning and the expenditure that accompanies effective prevention may be difficult. Too often, greater effort and financial loss will ultimately

Infectious Diseases of the Dog and Cat, 3rd Edition

associate with problem solving, absent of established prevention based on education and forethought. Most frequently, then, it is in the application of routine preventive practices, and also in the mechanisms of problem solving, that the assistance of experienced professionals becomes critical. In all environments, planned preventive management is far more efficient and cost effective compared with purely therapeutic or reactive management. In this respect, training staff members thoroughly in environmental hygiene and personal protection is particularly important because of the zoonotic aspect of many infections agents.

98.1.2 Transmission

Transmission of infectious agents can be direct through immediate or close contact between reservoir hosts and susceptible subjects. Microorganisms can also spread by inanimate vehicle (fomite), by air or droplet, or by various mechanical or biologic vectors.⁶ Host factors that influence expression of infection as clinical disease include age, inbreeding coefficient, nutritional status, and general health. Organism factors include virulence and dose of the infecting strain and route of inoculation. Variable but unique environmental factors (season, crowding, ventilation, sanitation) influence the interaction among source, organism, and host and often strongly influence the outcome.^{16,17} Recognizing the nature of these interactions in individual kennels is an extremely important part of developing effective preventive management strategies that are tailored to each facility.

98.1.3 Disease Management

Depending on logistic and economic circumstances, the goal may be to prevent one or more diseases (i.e., disease does not occur) or to maintain acceptable suppression (i.e., disease occurs with control of morbidity and mortality). The key factor is interrupting transmission of microorganisms, and the essential element is knowing the biology or life cycles of target infectious agents. An important point to realize is that target organisms may change with the seasons and may change over time for various reasons. The latter is particularly critical in facilities that have unstable populations. In all cases, management procedures that need to be considered include vaccination and parasite control, ongoing surveillance, disinfection practices, training of staff in procedures to minimize transmission, traffic patterns within the facility, changes in the population, and genetic supervision of breeding kennels. Long-term successful management is possible only if major target organisms have been identified and all aspects of the preventive process have been addressed.

1046

1047

The sanitary state of the kennel influences occurrence of infectious disease directly by providing or preventing access to concentrations of microorganisms and indirectly by modulating stress. Disinfection alone is not a substitute for good overall management. In many cases, kennel operators simply wish to know which disinfectant should be purchased (see [Chapter 94](#)). However, the nonspecific effectiveness of chemical disinfection depends substantially on the intended environment and manner of use.^{1,10,11,15} The primary goal of environmental management is to maintain surroundings that harbor the lowest possible number of infectious agents and that reduce stress as much as possible.

Disinfection and effective parasite control are essentially impossible in kennels with dirt flooring, especially in warm, humid climates or during wet seasons. Increased environmental microorganism load can compromise reproductive or work performance, and additional parasite burden can be devastating for puppies. Facilities that use grass surfaces ultimately face the same problems unless these areas can be rotated regularly; the household is the lone possible (but not universal) exception.^{1,11}

Infectious Diseases of the Dog and Cat, 3rd Edition

Gravel runs provide drainage and are not prohibitively expensive, and sanitation can be managed reasonably well for small numbers of dogs if preventive health care is adequate. For larger facilities, gravel maintenance and disease control require more effort. Digging by dogs is followed by accumulation of standing water, providing a reservoir for infectious agents such as enteropathogenic bacteria and possibly flagellate parasites. Chemical disinfection is more difficult because of the large surface area provided by several inches of gravel and because large amounts of organic material accumulate readily, reducing the effectiveness of many disinfectants. Weed control and removal of wasted feed must be aggressive to control external parasites and rodents. Regular worming schedules should be implemented and monitored frequently with fecal examinations. Scrupulous daily removal of feces is imperative. Complete replacement of gravel materials at intervals may solve these problems but adds greatly to investments of time, money, and labor.^{1,11}

Concrete pens are more expensive to construct, but sanitation and disease control can be managed more effectively. A surface that is slightly roughened (to minimize injuries) and gradually sloped for drainage can be disinfected regularly and kept clean daily without difficulty. Cracks and other damage need to be repaired as they occur. Environmental management programs designed to maximize effectiveness of disinfecting agents in individual kennels still must be based on knowledge of primary target disease agents, but broadly applicable general principles of sanitation greatly facilitate this process (Table 98-1).^{1,11}

Pens of any design should be dry and sheltered from prevailing winds during inclement weather, and puppies should not be allowed to become wet or chilled. Rapid changes in temperature and humidity can facilitate development of infectious diarrhea and respiratory disease, especially when the environment is crowded or when young dogs are present. Increased stress and easier transmission of infectious organisms are the most likely explanations for disease outbreaks.

Cages should be cleaned and disinfected daily and between occupants. Periodic steam cleaning is helpful when available.⁶ In the absence of steam cleaning or power spraying capability, frequent and copious flushing of pens with water is an important adjunct to a sanitation program. Animals should not be placed in wet cages or pens because of the risk of injury or direct exposure to disinfectant. For the same reason, caretakers need to be trained thoroughly in proper application of disinfectant chemicals, in the necessity for aggressive sanitation, and in personal safety. Animal handling should ordinarily be done on an age-priority basis, such as youngest first and progressing through older groups.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 98-1 General Principles of Environmental Management in Kennels

1. Regular cleaning and disinfecting schedule should be established.
2. Surfaces should be cleared of wastes and other organic material before disinfectants are applied. Organic materials compromise the effectiveness of many disinfectants.
3. Disinfectants and other cleaning products such as soaps should be combined only by, or on direction of, the manufacturer. Inappropriate combinations can cause loss of effectiveness. Manufacturer's directions for product use should be followed exactly. Dogs should be removed from pens that are being disinfected and reintroduced when pens are dry.
4. Many products are more effective in hot water and less effective in hard water or when combined inappropriately with other agents. Municipal water supplies are usually safe for drinking, but wells, ponds, and other nonstandard water sources should be monitored for bacterial and protozoal (i.e., *Giardia*) contamination, as well as for mineral content.
5. Bedding should be clean and dry. Access by insects, rodents, and birds should be prevented. Bedding should be changed as often as needed to maintain sanitation. Some litters of puppies may require multiple changes daily.
6. Feed should be stored in containers that prohibit access by insects, birds, and rodents (i.e., metal cans with tight-fitting lids). Great caution must be used with home-formulated feeds, especially in large kennels, from nutritional and disease perspectives.
7. Fecal waste should be disposed of daily, and waste containers should be disinfected frequently. Fecal wastes should not be disposed of within animal areas.
8. Equipment such as heating and cooling systems and vacuums should be cleaned and serviced regularly by qualified persons to avoid creating habitats for microorganisms.
9. Stored equipment, debris, weeds, and other items not critical to kennel function should not be allowed to accumulate.

98.1.4 Nutrition

Population nutrition is a challenge because effective feeding management in group environments requires consideration of the type of kennel, individual housing, seasonal influences, ambient temperature, amount of work or exercise, and environmental stressors such as crowding, exposure to sudden weather changes, and burden of infectious agents. Energy requirements are increased by lower ambient temperatures, work, exercise, gestation, lactation, and environmental stressors and tend to be decreased by inactivity and higher ambient temperatures. Each dog is part of the population, but each dog is an individual in terms of health, temperament, and nutritional requirements. Nutritional needs of individuals can vary widely in the same facility, among breeds, within the breed, and even among siblings. Therefore dogs in populations need to be fed as individuals and according to their apparent (and often changing) needs, which requires a consistent level of oversight.

1047

1048

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 98-1 Functional kennels should provide a comfortable environment for dogs and provide for ease in sanitation and husbandry.

Nutritional fads and extremes should always be avoided. Anecdotal reports of effects of unusual diets or supplements should be regarded suspiciously until results of controlled studies can be produced. Nutritional supplementation adds considerably to overhead costs and is seldom necessary or particularly effective if basic feeding practices are sound. In studies of growing puppies that were supplemented with vitamin-mineral combinations or excessive protein, no beneficial effects on immunologic measures were found.¹⁴ Good-quality, nutritionally complete and balanced commercial products should be chosen for applicable life stages, and manufacturers' claims should be supported by feeding studies and not simply by analytical results based on National Research Council guidelines.

A study of long-term caloric restriction in dogs demonstrated that reduced intake (25% less food) over the lifetime of 24 Labrador retrievers, as compared with 24 control-fed pair mates, resulted in a significantly longer (15%) median life span. Along with this outcome were associated a significant number of favorable morphometric changes that included lower body weight, body fat mass, and body condition scores, as well as longer maintenance of lean body mass into late life. Physiologically, variables that measure insulin-glucose metabolism were influenced favorably, along with time of expression of numerous diseases of later life, such as osteoarthritis.^{10,8,9} No increase in the incidence of infections was noted in the food-restricted group of dogs, although the research environment was managed aggressively with respect to sanitation and preventive health care.

The importance of this research, in addition to the obvious question of maintaining lean body mass and avoiding any degree of obesity, is that it further underscores the need to be conscious of the individuality of dogs in group environments. Some problems of late life, such as effects of osteoarthritis, are actually initiated relatively early. For example, in the food-restriction study, several of the control-fed dogs had evidence of osteoarthritis by early adulthood. These individuals tended to have more severe clinical signs of osteoarthritis during middle and late life. Among food-restricted dogs, osteoarthritis of multiple joints occurred less often,

Infectious Diseases of the Dog and Cat, 3rd Edition

was generally less severe, and was associated with much later occurrence of clinical signs.⁹ The risk of infections in these compromised individuals is likely to become proportionately greater as other management and sanitation practices become progressively less adequate or essentially neglected.

98.2 STABLE KENNEL ENVIRONMENTS

98.2.1 Breeding Kennels

98.2.1.1 Isolation

Stable facilities usually have low adult population turnover and therefore offer opportunity for point-of-entry control of infectious diseases. Entering dogs in larger breeding kennels should be isolated for approximately 4 weeks for observation, worming, vaccination, and selected surveillance laboratory procedures. (See [Appendix 5](#) and respective chapters for testing for specific microorganisms and preferred diagnostic and screening procedures.) Brucellosis testing should always be done before departure from the source kennel and repeated one or more times at 30-day intervals in the destination kennel (see [Chapter 40](#)). Isolation should occur outside of usual traffic patterns. Isolated dogs should be cared for after other residents or by different personnel. When this practice is not possible, hand washing, clothing change, and separate footwear may be indicated if the risk of introducing new infectious agents is high.¹

In smaller kennels where time, space, and funding do not permit isolation, careful evaluation of the infectious disease status of the source kennel should precede entry to the destination kennel. Vaccinations, parasite checks, and other surveillance procedures should be completed 2 to 4 weeks before entry, and veterinary examination also should be completed before entry.

98.2.1.2 Inbreeding

Inbreeding is frequently practiced to concentrate traits that are perceived as being superior. However, excessive emphasis on aesthetic desirability (such as coat color or conformation or on any individual trait) can be hazardous. Excessive inbreeding can be associated with immunocompromise and increased susceptibility to infection (see [Chapter 95](#)),³ which may explain in part why certain breeds seem to have disproportionate susceptibility to diseases such as CPV infection. In fact, one important signal that excessive inbreeding may be occurring in a production facility is a general increase in the frequency of infections and especially increased severity of infections that ordinarily occur as relatively minor problems. Declining reproductive efficiency may also be observed consequent to excessive inbreeding, resulting in smaller litters and greater neonatal mortality.¹³ Another indicator of excessive inbreeding is increased incidence of behavioral disorders among breeding kennel residents or offspring. That abnormalities in all of these areas will occur simultaneously is not obligatory, but eventually all appear if excessive inbreeding or poor choices of breeding stock are practiced over time.

98.2.1.3 Age

Advanced age represents a theoretical risk factor for infections because of naturally declining immune function.⁵ However, practical experience in kennels that are managed well has shown that occurrence of, and death from, infectious diseases does not increase with advancing age if other management factors are controlled well. Longitudinal evaluation of immune functions were conducted as a part of lifetime

Infectious Diseases of the Dog and Cat, 3rd Edition

evaluation of the effects of restricted food intake.⁴ These studies demonstrated age-related decline of absolute numbers of total lymphocytes, T cells, CD-4 lymphocytes, and CD-8 lymphocytes in males and females.⁴ This experimental population of 48 dogs was part of a much larger colony, and despite decline in some measured immune functions, neither control-fed nor calorie-restricted dogs appeared clinically to be differentially susceptible to infections.⁴ Therefore maintaining older dogs in stable, well-managed populations seems to pose no significant infectious risk to individuals or to the kennel, provided that other aspects of genetic, environmental, and nutritional management are done properly.

Poorly managed breeding kennels may experience increased neonatal mortality from bacterial infections. In these facilities, however, increased neonatal mortality resulting from hypoxia also may be observed through careful necropsy practices because outcomes of poor management practices usually occur in multiples. The highest risk for infection in most kennels occurs after weaning as a consequence of the relationship of maternal antibody decline to exposure to infectious organisms by animal or environmental contact.⁷ Deficient vaccination and parasite control, environmental mismanagement, and poor breeding selection policies become evident, but recognizing these contributing factors is more difficult in kennels that retain few puppies past the immediate postweaning period.

Information about problems that occur at destination kennels may be necessary when planning corrective strategies in some source kennels, but multiple-source or poorly managed destination kennels can present interpretive dilemmas. In the latter instances, evaluation of multiple facilities may be necessary.

98.2.1.4

Health Maintenance

Vaccination and parasite control need to be individualized by kennel because the biologic and environmental factors that interact to influence occurrence of infectious diseases can result in varying patterns of morbidity and mortality.

Identifying and targeting offending infectious microorganisms do not differ procedurally from individual clinical presentations, but population-based problems almost always occur in magnitude commensurate with population size, density, and stress. Investments in determining the type and extent of specific infectious disease prevalence are worthwhile. Clinical signs and response to empiric therapy alone should not be used as criteria for designing or modifying management programs. Most kennel populations harbor several infectious agents that induce clinical disease variably and often in cyclic fashion. Transmission can be interrupted effectively when all offending agents are identified and when their seasonal and environment-based influences are understood.

98.2.1.5

Mortality

Veterinarians are sometimes reluctant to recommend postmortem examination, and clients may be reluctant to agree. However, in breeding kennels, causes of mortality must be identified. Most puppy mortalities occur as stillbirths (30%) or during the 0- to 3-day neonatal period (50%).¹² Variations in this expected pattern should prompt investigation. Neonates react in limited scope to dissimilar insults, whether infectious, physiologic, environmental, or genetic (anatomic or metabolic) in origin. When infectious causes are suspected, consulting laboratories should be advised of tentative diagnoses before necropsy, if possible. Tentative diagnoses can be established through review of clinical signs in pertinent literature and should be supported by further review at the time of gross necropsy so as to ensure that proper samples are taken. Appropriate procedures must then be followed for taking correct diagnostic samples, given that these

Infectious Diseases of the Dog and Cat, 3rd Edition

can vary among infectious agents. Successful diagnosis depends absolutely on proper sample preservation, shipping, and processing.¹ (See [Chapters 1, 33, 56, 70](#), and [Appendix 5](#) for pertinent information.)

Increased morbidity and mortality in specific age groups within populations should increase suspicion for genetic or infectious causes. However, clinical findings should be considered in light of overall kennel health and management status because transmission of infectious agents has an environmental component. For example, increased incidence of viral enteritis among puppies may reflect overproduction and crowding with successive litters such that the environment facilitates transmission from older to younger puppies. Alternatively, the number of litters that are present simultaneously may be managed well, but inattention to proper sanitation or traffic patterns may facilitate transmission. Patterns of morbidity and mortality, established over time, can be used along with specific diagnoses to develop preventive strategies. However, these efforts will be successful only if all possible contributing factors are considered and addressed.

98.2.2 Research and Performance Kennels

In research and performance kennels that maintain long-term residents with minimal reproductive activity, isolation on entry, parasite control, vaccination, and surveillance should be practiced aggressively, as is the case for breeding kennels. The intensity of the control program is usually less than it is in production kennels with high puppy populations, although the size and density of the adult population do influence stress and ease of transmission of infectious agents.

In research kennels, valid interpretation of experimental data depends absolutely on having a complete health database. Careful attention should be given to the type of research that is in progress and the potential for undiagnosed infections to compromise experimental data. For example, nutritional or gastrointestinal research should be accompanied by aggressive monitoring for enteric viral, bacterial, and parasitic agents. Cardiovascular research necessitates continuing evaluation for bacterial diseases, especially those that have systemic potential. The quality and outcome of studies involving immunity, such as vaccine research, depend on documenting that only the experimental agent is introduced (i.e., potentially interfering infectious agents are surveyed and not found), on knowing the status of control subjects with respect to the experimental agent, and on knowing the immunocompetence of dogs in control and test groups. The last point relates at least partially to degree of inbreeding, and therefore knowledge about source kennels can be extremely important to data interpretation.

Specific-pathogen-free dogs can be purchased for research kennels; however, in many circumstances, these dogs originate from more transient types of kennels. When new diseases are recognized in destination kennels, investigation of the status of source kennels can facilitate early diagnosis, which in turn supports rapid implementation of control measures to minimize further transmission. At times, alternate-source kennels may need to be sought, but accurate records are essential to support exclusion of problem sources on factual grounds only.

Giardiasis and nocardiosis are relatively common problems in performance kennels. Both conditions are consequences of the purpose of the kennel. Population concentration and movement of dogs among kennels tend to facilitate transmission of *Giardia*, and drinking from field water sources presents ready sources of infection and reinfection. Environmental sanitation is helpful in reducing clinical disease associated with *Giardia* cysts in the kennel. Use of quaternary ammonium disinfectants and flushing the kennel with a power sprayer should help reduce the cyst burden in the environment. Infection of sporting dogs with *Nocardia*, an opportunist organism, likely occurs during field training, hunting, or competition. Vigilance for clinical signs is important in sporting kennels (see [Chapters 49](#) and [78](#)).

1049

1050

Infectious Diseases of the Dog and Cat, 3rd Edition

98.2.3 Households

Extensive evaluations are less the custom for entry of new pets into multiple-pet households. Vaccination and parasite control should be current before entry, and physical examination should be conducted for external parasites. Sanitation should be strict with respect to fecal wastes, but the home environment usually limits use of disinfectant chemicals. When two or more dogs in the same household have similar clinical signs, an important point to remember is that proximity often means common exposure to infectious agents. However, individual characteristics, such as behavior, age, or immune status, also may influence clinical expression. Clinical illness in one dog in a multiple-dog or a multiple-pet household does not rule out group exposure.

Practicing clinicians should remember also that a neighborhood or a community represents a population as well, albeit less dense compared with a kennel environment. Nonetheless, clinicians in community practice often recognize temporally associated, similar clinical signs among pets that are owned by different households in a geographic area. These occurrences often tend to be treated symptomatically, especially if the clinical signs are not severe. Although this approach might represent practical clinical medicine, it does result in missed opportunity for specific diagnosis. Progress in community practice would be facilitated by increased attempts at specific diagnosis, and this information would be helpful in recognizing seasonal or other circumstantial influences on clinical expression of disease caused by some organisms. With specific diagnosis, more directed attempts at prevention become possible, and recognition of potential zoonoses is facilitated.

98.3 TRANSIENT ENVIRONMENTS

Management of infectious diseases in transient environments is much more difficult. Maintenance is short term, and sources usually are random. Residents are often stressed by illness, inappetence, or anxiety. This combination of population and environmental factors allows multiple simultaneous introduction of infectious agents to a transient and susceptible population. In all transient facilities, sanitation should therefore be extremely strict. In addition, admissions to these environments should be limited to individuals that are currently vaccinated, except in those populations that are composed largely of unowned pets. In the latter instance, strict sanitation, temporary isolation where possible, and vaccination on entry are important management factors. In transient environments, sanitation procedures, traffic patterns, waste disposal, hygiene procedures that limit dissemination of microorganisms and parasites, and recognition of clinical signs of illness should be part of personnel training. Procedures should be written and reviewed frequently for updating. Veterinary consultation is a necessary and very important part of disease management in transient populations.

98.3.1 Veterinary Hospitals

Disinfectants are important because of the high frequency of presentation of animals with infectious diseases and the risk of transmitting to other hospitalized patients or establishing nosocomial infection patterns.⁶ Disinfectants should be chosen for broad-spectrum activity unless specific agents are being targeted (see [Chapter 94](#)).^{1,11,15} Hospital personnel should be taught to clean and disinfect table surfaces and equipment between patients, to wash hands after each hospitalized or boarded patient is handled, to wear protective gloves when handling patients that are known or suspected to be infectious, and to recognize clinical signs of major internal and external infections. The outdoor area of the hospital should be cleaned and disinfected regularly to prevent exposure of patients by environmental contamination.

Infectious Diseases of the Dog and Cat, 3rd Edition

Patients with potentially contagious diseases should be isolated as well as possible, with rapid removal of wastes from animal areas. Careful attention to fomite transmission of environmentally stable and unstable agents is needed because transmission distances are usually very short. Special care should be taken to protect individuals that might be immunodeficient.³

Thorough vaccination programs should be pursued with all clients individually and through community education by local veterinary associations. Current vaccinations should be required for elective surgery and boarding patients and updated before admission. Every entry, whether inpatient or outpatient, should be checked carefully for external parasites and for signs of dermatophytosis (see [Chapter 58](#)).

98.3.2 Grooming and Boarding Kennels

Population turnover is high and constant; residence is usually very brief. Separation anxiety, close proximity or crowding, and poor ventilation often facilitate transmission of infectious agents by direct, aerosol, and fomite routes. Some opportunity for control is afforded by the fact that dogs and cats in these kennel populations are nearly always owned pets. Appropriate vaccinations can be required before entry, and entry also should be accompanied by brief screening for external parasites or dermatophytosis and by examination of the haircoat to detect signs of diarrhea or excess respiratory or ocular secretion. Veterinarians should play active roles in helping to establish policies for vaccination requirements, preentry parasite control, screening for signs of general health, and training of personnel.

Grooming and other equipment that is used in common among dogs should be kept meticulously clean and disinfected after each use. Disposable feeding bowls can work well for controlling spread of infections in some facilities, but expense and potential for some residents to shred and swallow disposable equipment needs to be considered. Operators of grooming and boarding facilities should be trained to recognize external parasites such as fleas, ticks, and lice and to note clinical signs suggesting sarcoptic mange and dermatophytosis. In addition, all personnel involved should understand how these diseases, as well as major viral and bacterial diseases, are transmitted.

98.3.3 Shelters

Most shelters house random-source populations with high turnover and high incidence of infectious diseases. Point-of-entry control is essentially impossible, except for individuals that have obvious clinical signs on entry. Crowding occurs frequently and represents a circumstance that is sometimes unavoidable. However, crowding does greatly increase risk for repeated introduction and rapid transmission of infectious diseases.

All clinically healthy dogs should be vaccinated and wormed. Intranasal vaccines for respiratory diseases should be provided. Unhealthy animals should be segregated for triage. Those that have severe clinical signs of infection, and especially those with high potential for transmission and low potential for survival, should be euthanized unless they can be isolated effectively for treatment.² Animal control officers should be trained to recognize general clinical signs that suggest infection so that accidental introduction of infectious agents is minimized. In large shelters, daily veterinary attention is essential. In smaller shelters, all supervisors should understand disease-control policies, and veterinary consultation should be available at all times.

1050

1051

Infectious Diseases of the Dog and Cat, 3rd Edition

98.3.4 Retail Outlets

Residents of retail outlets are usually young puppies that are shipped from distant sources shortly after weaning. Residence is short term, and stress associated with weaning, shipping, anxiety, and anorexia is significant. Some level of direct or indirect contact with other species frequently occurs.

Point-of-entry control is possible but must be based on accurate individual diagnosis (either in-house or after sale) and records that clearly establish source and means of transportation. Control is established by working with suppliers and their veterinarians to implement improved breeding programs. Preshipping management changes may also be needed, as well as improved means of transportation, adjusted allowable population density at the destination kennel, revised management procedures at the source and the destination outlet, and use of different suppliers, if necessary. Each work shift should have at least one employee trained to recognize clinical signs of viral, bacterial, parasitic, and dermatophyte infections. Species segregation should be strict.

98.3.5 Research Kennels

Research kennels that maintain short-term residents must understand the conditioning or health programs that suppliers use and must have aggressive and thorough in-house veterinary service. If residence duration is sufficiently short, time for development of clinical signs of infectious diseases may be insufficient. Negative effects on research protocols and their results may therefore be unrecognized. In general, the principles that apply to influence of infectious diseases on research projects in long-term facilities also apply to transient research populations.

98.3.6 Suppliers

Suppliers usually work with adult dogs from random sources and have varying conditioning programs. At a minimum, these measures should include careful examination, vaccination, parasite control, and behavioral evaluation. Facilities are usually too small and residence terms too short to permit effective isolation of all new entries. Operators should be trained therefore to recognize general signs of internal and external infectious diseases. The ability to conduct routine screening of feces for intestinal parasites is also helpful and can usually be done at minimal expense.

99 CHAPTER 99 Immunocompromised People and Shared Human and Animal Infections: Zoonoses, Sapronoses, and Anthroponoses

Craig E. Greene

Julie K. Levy

99.1 IMMUNODEFICIENCIES IN HUMANS

Immunodeficiencies in people have various physiologic and pathologic causes (Table 99-1). Genetically induced deficiencies cause an increased susceptibility to numerous pathogens, which vary according to the type and penetrance of the defect.¹¹⁹ Age is one determinant; for example, fetuses, neonates, and young children have underdeveloped immune systems. Similarly, frail older adults, especially those in nursing homes or hospitals, have apparent increased risks of developing infections. In addition to having physical disabilities and altered resistance, they may also be cognitively impaired.¹⁹⁹ Invasive fungal infections are an increasing problem in older adults.⁹⁹ A closed institutional environment favors more intense exposure to microorganisms because of limited ventilation and frequent close contact with other individuals. When pets are brought to these facilities, they are often a source of infections for residents of these facilities.

Concurrent factors such as other illnesses, pregnancy, burns, or indwelling tubes, catheters, or implants increase the risk of infection by breaching natural barriers to infectious agents. Immunodeficiency is also a result of cancer chemotherapy and leukopenic disorders and may be the result of congenital or hereditary defects in the immune system. The most rapidly advancing cause of immunodeficiency in people is the acquired immunodeficiency syndrome (AIDS) resulting from infection with the human immunodeficiency virus (HIV).

Approximately 1,039,000 to 1,185,000 people in the United States are infected with HIV, and approximately 25% do not know they are infected.^{63a} Up to 50% own companion animals,^{47,166} as is typical for the population at large.¹⁹⁴ Approximately 132 million pet dogs and cats live in the United States.¹ The estimated prevalence of companion animals in all United States households is 60%, 38.2% of which are dogs, 30.5% cats, 5.7% birds, and 2.8% horses. Although more households have dogs, the total number of cats is greater than that of dogs. The psychological benefits that these companion animals provide are great, and the risk for acquiring infections from animals is low. Nevertheless, certain precautions that are taken while handling and caring for pets reduces any inherent risks. The information in this chapter emphasizes documented AIDS-related zoonoses, although people with immunodeficiencies from any cause should use similar guidelines when handling their pets. Furthermore, because zoonoses can develop in immunocompetent people, many of the principles and practices can be used by anyone with pets.

Table 99-1 Characteristics Associated with Immunocompromised People

Susceptible Individuals by Age

Fetuses, infants, preschoolers, older adults

Health Issues

Hospitalizations, concurrent illnesses, organ transplantation, diabetes mellitus, chronic renal failure, pregnancy, burns, leukopenia, congenital immunodeficiencies, hepatic cirrhosis, malnutrition, splenectomy

Therapeutic Agents

Cancer chemotherapy, immunosuppressive therapy, antirejection therapy

Medical Instrumentation and Procedures

Catheters, indwelling tubes, synthetic implants, splenectomy

HIV Infection

AIDS complex

HIV, Human immunodeficiency virus; *AIDS*, acquired immunodeficiency syndrome.

99.2 ZOONOTIC RISK

In the strict sense, *zoonoses* are defined as infectious diseases naturally transmitted from living animals to humans.⁸⁹ Based on their animal reservoir hosts, they can be *synanthropic* with an urban or a domestic animal cycle or *exoanthropic* with a feral or wild animal cycle. Immunocompromised people who own pets are at greater risk of contracting directly transmitted zoonotic infections than those without pets (Table 99-2). Inhalation or ingestion of infectious body secretions and excretions are the common means by which many zoonotic infections may be transmitted directly. However, transmission can occur percutaneously through contamination of preexisting skin wounds or by bites or scratches. Spread can also occur after contact of mucosae with vehicles or fomites such as contaminated utensils or food or water. Vector transmission via arthropod-borne transmission also occurs in some infections of dogs and cats, and people can become infected when these vectors feed on them. In some cases, dogs and cats can bring vectors that are already infected with an organism closer to people. Once infected, spread of true zoonoses among humans is uncommon. Some zoonotic infections can be highly severe or fatal because people are inadvertent hosts.

Sapronoses are infections of people and animals that are maintained in nature by replication of the organism in soil, water, or vegetation or in the decay of dead animals or animal excreta. With these zoonoses, people and animals acquire infections simultaneously and independently of each other. Sapronoses were previously but inaccurately called “sapro-zoonoses,” but they are not truly acquired by people from living animals (see Table 99-2).

Anthroponoses are infections in which the source, replication, and primary means of transmission occur in humans. Some of these infections can affect animals such as dogs and cats (see Table 99-2).

The importance of zoonotic diseases has become more apparent because of the AIDS epidemic in humans. In fact, the appearance of unusual zoonotic infections in people was one reason that AIDS was first recognized. The increasing incidence of zoonotic infections in immunosuppressed people makes it imperative that veterinarians

Infectious Diseases of the Dog and Cat, 3rd Edition

know the most updated information about these diseases. Compared with veterinarians, most physicians are not as well trained in zoonoses and their advice, when given, is often to give up their pets.^{4,66} Veterinarians may be in a better position to advise immunocompromised people about the relative risk of pet ownership and provide them with accurate information on precautionary measures. No significant difference was found in the type of opportunistic infections in people with AIDS, regardless of whether they owned a pet.⁴⁷ Although veterinarians are among the best educated concerning animal infections, few have taken an active role in educating their immunodeficient pet owners.^{4,166} People with AIDS who have questions about their pets most frequently consult physicians, nurses, and community health personnel, many of whom give conflicting advice, whereas very few consult their veterinarians.^{4,47,65} Many people with AIDS have misconceptions about zoonoses and have received misleading or no information concerning the transmission risks.⁴⁷ Surveys have shown that more than 60% to 90% of people infected with HIV have been advised by human health professionals to give up their pets, whereas only 5% have followed this advice.^{25,166} The latest guidelines from the United States Public Health Service and the Infectious Disease Society of America indicate that rather than give up their pets, immunocompromised people can take simple precautions to prevent infection.^{7,11,95,113}

At first glance, the risk of acquiring animal infections may seem to dominate the medical literature and media reports, but only a relatively small fraction of infections in people can actually be attributed to pet contact. People with immunosuppression are at increased risk for acquiring all types of infections, including zoonoses. People are more likely to acquire infections from other people than from animals. Furthermore, some of the highly publicized zoonoses in AIDS patients such as toxoplasmosis are caused by reactivation of a previously acquired infection and are not related to pet exposure. The Internet is a tremendous resource for information on zoonotic diseases. [Table 99-3](#) lists important Web sites for health care workers associated with immunocompromised individuals.

99.3 OCCUPATIONAL AND ENVIRONMENTAL RISKS

Veterinarians and animal health workers may be at greater risk for acquiring zoonoses. People who work in allied professions involving animal products for food or fiber are also at risk, as are those on farms or who visit zoological gardens where animal contact is allowed. In the zoological gardens, almost all exposures involved domestic herbivores and infections with fecalborne pathogens such as *Campylobacter*, *Giardia*, *Salmonella*, and *Cryptosporidium* spp.²¹ In a study of veterinarians in South Africa, those in farm practice were 3 times more likely to have contracted a zoonotic disease than those working in other veterinary fields.⁷⁸ Urban zoonoses can be caused by members of the genera *Bartonella*, *Coxiella*, *Ehrlichia*, and *Rickettsia* ([Table 99-4](#)). These diseases have synanthropic cycles in which vertebrate hosts and their associated arthropod vectors can survive in metropolitan regions. Increasing population densities, encroachment on sylvan cycles of infection, increased homelessness, greater numbers of immunosuppressed people, and poor hygiene in economically disadvantaged inner city environments are all responsible for this development.⁴⁶ In one study in northern Florida, the prevalence of zoonotic infections such as toxoplasmosis or bartonellosis among feral and pet cats was equivocal,¹⁰⁹ making feral cats appear to pose no greater risk to people than owned pet cats. In another report, feral and pet cats from one county in rural North Carolina had similar prevalence rates of infection with *Cryptosporidium* spp., *Giardia* spp., and *Toxocara cati*. However, a statistically higher seroprevalence of *Bartonella henselae* and *Toxoplasma gondii* antibodies was found in feral cats,¹³⁶ presumably because of greater exposure to outdoor vectors of these diseases. These studies seem to refute the common conception that feral cats have poor health and are poor choices as pets, especially for immunocompromised people. A more important criterion appears to be whether the potential pet frequents outdoor environments.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 99-2 Means of Zoonotic Infection Transmission^a

Zoonoses from Dogs and Cats

Bite or saliva: Rabies (see Chapter 22), pasteurellosis (see Chapter 53), capnocytophagiosis (see Chapter 53), helicobacteriosis (see Chapter 39), mycoplasmal infection (see Chapter 31), tularemia (see Chapter 48), bordetellosis (see Chapters 6, 88, and 100)

Scratch or close physical contact: Dermatophytosis (see Chapter 58), bartonellosis (see Chapter 54), tularemia (see Chapter 48), sporotrichosis (see Chapter 63), *Malassezia pachydermatis* infection (see Chapter 58), *Chlamydomydia felis* infection (see Chapter 30)

Aerogenic: Plague in cat (see Chapter 47), tularemia (see Chapter 48), bordetellosis (see Chapters 6 and 88), coxiellosis (see Chapter 29), rhodococcosis (see Chapter 35)

Feces: Toxoplasmosis (see Chapter 80), cryptosporidiosis (see Chapter 82), campylobacteriosis (see Chapter 39), enteric yersiniosis (see Chapter 39), helicobacteriosis (see Chapter 39), salmonellosis (see Chapter 39), giardiasis (see Chapter 78), ancylostomiasis, toxocariasis

Urine or genital secretions: Canine brucellosis (see Chapter 40), leptospirosis (see Chapter 44), coxiellosis (see Chapter 29)

Shared Vector-Acquired Zoonoses

Ehrlichiosis (see Chapter 28), Rocky Mountain spotted fever and *Rickettsia felis* infection (see Chapter 29), tularemia (see Chapter 48), plague (see Chapter 47), borreliosis (see Chapter 45), bartonellosis (see Chapter 54), dipylidiasis

Zoonoses from Other Animals

Rhodococcus equi infection (horse), *Mycobacterium marinum* infection (fish), psittacosis (birds), salmonellosis (reptiles and amphibians), *Mycobacterium bovis* (cattle), cowpox (cattle)

Sapronoses (Environmentally Acquired Infections)

Pneumocystosis (see Chapter 68), microsporidiosis (see Chapter 75), *Mycobacterium avium*-complex infection (see Chapter 50), infection with rapid-growing mycobacteria (see Chapter 50), cryptococcosis (see Chapter 61), coccidioidomycosis (see Chapter 62), histoplasmosis (see Chapter 60), blastomycosis (see Chapter 59), aspergillosis (see Chapter 64), anthrax (see Chapter 35), listeriosis (see Chapter 35)

Anthroponoses (Infections Transmitted from Humans to Dogs and Cats)

General: Group A streptococcal infections (see Chapter 35), *Mycobacterium tuberculosis* infection (see Chapter 50), methicillin-resistant staphylococcal infections (see Chapter 36), *Streptococcus pneumoniae* infection (see Chapter 35), *Entamoeba histolytica* infection (see Chapter 78)

Unique to people: Cytomegalovirus disease, herpes simplex virus disease, varicella-zoster virus infection, human papillomavirus infection, hepatitis B infection, influenza virus infection

Overgrowth or invasion by indigenous microflora: candidiasis, bacteria associated with sepsis%

^a Predominantly dog and cat, unless otherwise indicated.

99.4 BENEFITS OF PET OWNERSHIP

Pets offer important physiologic and psychological benefits for people, especially for those who are ill (Table 99-5). Important friendships exist between people and their pets. Although illness and disability often alienate

1053

1055

Infectious Diseases of the Dog and Cat, 3rd Edition

homebound people with AIDS from their family, friends, and acquaintances, pets provide continued companionship and help their owners overcome the deleterious effects of loneliness.^{38,161a}

Pets also provide pleasure, protection, and a sense of worth.³⁸ It may be more detrimental to the well-being of isolated immunocompromised people to lose their pet companions than to risk acquiring a zoonotic infection.

99.5 SUPPORT GROUPS

Immunodeficient people may develop emotional and physical limitations that prevent them from adequately caring for their pets. Extended, unanticipated hospitalizations and physical or financial limitations are often present. In addition, needs for preventive and disease-related veterinary care and feeding are expected. Veterinarians can advise their clients about the relative risks of and precautions to contain zoonoses and direct them to support groups to help them with home pet care. Veterinarians can also assist by channeling donations of money and offering their time and professional expertise to these local groups. Veterinarians can discretely demonstrate their willingness to participate in a zoonoses prevention program by having signs or brochures in their waiting room. They must recognize that the increased cost of surveillance and treatment to prevent zoonoses increases the financial obligation for the client. In addition to home pet care, support groups can provide speakers, slide shows, newsletters, and brochures concerning pet care, zoonoses, and personal hygiene. They can provide assistance with screening suitable pets, financing pet health care, and educating pet assistants for routine care and emergencies. Numerous organizations are available to help with these needs. Pets Are Wonderful (PAWS), which originated in San Francisco, and Pet Owners With AIDS/ARC Resource Services, which is based in New York City, are nonprofit volunteer organizations dedicated to providing information and at-home support for immunocompromised people who want to keep their pets. PAWS publishes *Safe Pet*

Infectious Diseases of the Dog and Cat, 3rd Edition

Guidelines, a brochure from their San Francisco office that gives immunocompromised pet owners background information on keeping their pets and themselves healthy. A list of a national network of support organizations and brochures is provided in [Table 99-3](#).^{76,159}

99.6 PET ADVISEMENT

Although veterinarians generally are better prepared to answer questions about animal diseases and human risks than physicians, few patients view them as the primary providers of this information. Paradoxically, physicians seem to be uncomfortable discussing zoonotic with their clients and view the veterinarian as playing a more important role in this service. Surprisingly, veterinarians and physicians rarely communicate with each other about this topic; physicians' perceptions of relative risk did not match data on known disease transmission.^{73,127}

99.7 DISEASES

More than 250 organisms are known to cause zoonotic infections, and approximately 30 to 40 involve companion animals. Of these, a selected few have been reported with greater frequency in people with immunodeficiency and AIDS (see [Table 99-2](#)).⁵ The appearance of a few of these infections (cryptosporidiosis, *Mycobacterium avium*-complex infection, cryptococcosis, salmonellosis, toxoplasmosis) has been used to define the onset of AIDS in people with HIV infection. Some of the AIDS-related zoonoses are acquired directly from companion animals, and others are probably acquired from environmental exposure rather than from pets. The zoonoses described in the next section only include those that have been associated with exposure of immunodeficient people to companion animals. Most of the zoonoses, with the exception of infections caused by *B. henselae* or zoophilic dermatophytes, are more commonly acquired from the environment or other vectors or hosts than from dogs or cats. Nevertheless, pet ownership does pose a risk to immunocompromised people and should always be considered.

99.7.1 Spread by Bites and Through Saliva

Bites are among the most common source of zoonoses, and immunocompromised people have the greatest risk of developing a systemic infection as a result of bite wound injuries (see [Chapter 53](#)). Numerous organisms such as *Capnocytophaga* and *Pasteurella*, which represent oropharyngeal flora, are frequently found in bite infections. In addition, many other aerobic and anaerobic bacteria have been isolated. Whenever people are bitten, especially those who are immunocompromised, they should be advised to immediately seek medical attention for their injuries.

99.7.1.1 Rabies

Virtually any mammal can transmit rabies; however, in many parts of the world, pets are not commonly involved in transmission, likely because of previous postexposure prophylaxis (people) and vaccination (dogs and cats). In areas where vaccination of domestic dogs is mandatory, wild animals are the major reservoir species for human exposure. In these areas, such as the United States, the annual incidence of rabies in cats has exceeded that of dogs, and cats are the most common domestic animal to have rabies.^{92a,103} Despite this fact, most recent human cases have been associated with exposure to bats. In parts of the world where uniform vaccination of dogs has not been implemented, the risk of people acquiring rabies from feral domestic dogs is high. Despite the fact that cats do not frequently transmit rabies to people, they should be vaccinated because the financial, psychological, and health implications of

Infectious Diseases of the Dog and Cat, 3rd Edition

exposure are disruptive. The incidence and prevalence of infection in a given area depend on geographic factors. Not all exposed people need postexposure prophylaxis; this has to be determined on an individual basis (see [Chapter 22](#)).

99.7.1.2

Capnocytophagiosis

Capnocytophaga (formerly DF-2) is a risk to immunosuppressed people who develop more severe systemic complications. *Capnocytophaga* and *Pasteurella* spp. are the most documented bacterial species involved in systemic complications from bite wounds (see [Chapter 53](#)). Splenectomy, chronic obstructive pulmonary disease, alcoholism, old age, or other immunosuppressive diseases are associated with an increased risk of fatal sepsis from these bacteria. Signs are acute severe cellulitis and bacteremia, which may develop within 24 to 48 hours of the bite. Cats and dogs should not be allowed to lick open cuts or wounds.

99.7.1.3

Pasteurellosis

Although cats statistically are associated with fewer bites than dogs, the severity of *Pasteurella* infection is greater than infection by other organisms cultured from their saliva. This is likely because of the virulence of *Pasteurella multocida*, which is carried in the oropharyngeal and nasal regions in a high percentage of cats. (For additional information on aerobic and anaerobic organisms associated with cat bites, see [Chapter 53](#).) Although *Pasteurella* is virulent in its own right, the immunocompetence of the bitten individual is also an important factor in the final outcome.

99.7.1.4

Infection with Mycoplasma and Other Bite-Inoculated Organisms

Various organisms including anaerobic bacteria can be inoculated into bite wounds from dogs or cats. (See [Chapter 53](#) for an extensive discussion of the public health risks.) Bites or scratches should always be washed immediately with soap and water. All people, especially those who are immunocompromised, should be advised to consult with a physician immediately.

99.7.1.5

Helicobacteriosis

Helicobacter infections occur in people and their pets; however, many host-adapted species are involved. *Helicobacter pylori*, a primary human gastric commensal and pathogen, has been isolated in a laboratory cat colony in association with human exposure; however, it is considered unusual and natural infections are unlikely. Epidemiologic studies do not show an association between cat ownership and *H. pylori* infection in people.¹⁸⁷ The presence of *Helicobacter heilmanni*, an animal pathogen, was found in a human with gastric erosions and in his two cats.⁵⁴ Genetic analysis showed that the human and feline strains were closely related and that more than one strain can concurrently infect a person. One isolate from cats and humans was identical, suggesting zoonotic or anthroponotic spread.

1056

Oral-oral transmission is the primary means of gastric helicobacter spread between animals and people, so contact with the oral cavity or saliva of pets should be avoided. Humans are most likely to acquire this infection from other people because they are the reservoirs for *H. pylori* and other human strains. Precautions to prevent infection should be taken, such as not sharing feeding utensils with people or pets. (For additional information on the zoonotic risks, see [Chapter 39](#).)

1057

Infectious Diseases of the Dog and Cat, 3rd Edition

99.7.1.6 Blastomycosis

Blastomycosis is a systemic mycosis caused by a dimorphic fungus and develops in dogs and people that live in endemic areas. Although it is usually acquired from inhalation of spores from mycelia in the soil, localized infections can develop as a result of inadvertent transdermal inoculation of yeasts while handling body tissues or exudates of animals. Localized infections have developed in animal health workers after accidental needle punctures and lacerations at necropsy and in others after being bitten by a dog^{72,148} (see [Chapter 59](#)).

99.7.2 Spread by Scratch or Close Physical Skin or Mucosal Contact

99.7.2.1 Bartonellosis

Bartonellosis is caused by a group of small gram-negative bacteria that infect people and animals. A few of the species involve infections in cats and dogs. The immune system of the host is as important as the organism in determining the outcome of infection. *B. henselae* causes various illnesses, including cat-scratch disease or regional pyogranulomatous lymphadenitis, neuroretinitis, Parinaud's oculoglandular syndrome, and aseptic meningitis (see [Chapter 54](#)). In contrast, immunodeficient people can also develop bacteremia, aseptic meningitis, peliosis hepatis, and bacillary angiomatosis. *B. henselae* and *Bartonella clarridgeiae* can be isolated from clinically healthy cats, and exposure to cats is associated with many of these diseases in people. Cat ownership was associated with an increased risk of *B. henselae* seropositivity and with cognitive decline in individuals infected with HIV.^{159a} The organism has also been isolated from clinical healthy and diseased dogs.^{44,79,123} *B. henselae* infection has been identified as a cause of fever of unknown origin in children.⁹² Other *Bartonella* spp. have been isolated from people, dogs, and cats, but a direct zoonotic association has been made only for *B. henselae* and *B. clarridgeiae*. *B. henselae* has adapted to live in feline erythrocytes and has probably coexisted with cats for millenia. *B. henselae* has been isolated from the blood of African lions¹⁴⁶ and using the polymerase chain reaction (PCR), it was demonstrated to be detectable in the dental pulp of stray cats that had been buried for 1 year^{1b} and in 800-year-old feline museum specimens.^{183a}

Fleas have been associated with transmission of infection between cats and humans. Eliminating and controlling fleas is essential for reducing the spread of infection among cats. Because the means of transmitting infection from cats to people is uncertain but possibly involves flea excreta, cat bites or scratches should not be rubbed with uncleaned hands and should be washed immediately. Hands should always be washed immediately after handling known or suspected flea-infested cats. Dog or cat bites might be directly contagious because oral secretions may contain blood in animals with gingival hemorrhage. No absolute recommendation can be made for serologic or blood-culture screening of all cats because treatment efficacy is questionable and the potential exists for inducing antimicrobial resistance. Testing of cats to determine whether they are infected is not generally advised unless they are clinically symptomatic. Because of the high rate of infection in cats, the asymptomatic nature of infection, and the chance of inducing antimicrobial resistance, routine treatment of identified infected cats should be questioned. Because immunity can develop in cats to specific strains, resulting in clearing of infection with time, kittens (younger than 6 months old) are more susceptible to infection, and they have a much higher rate of exposure within a given environment (see [Chapter 54](#)). Declawing is not recommended; however, nails can be clipped to reduce the chance of their lacerating the skin. Behavior that invokes biting or scratching

Infectious Diseases of the Dog and Cat, 3rd Edition

should be avoided. To prevent bartonellosis or other infections, cats should never be allowed to lick exposed cuts or wounds. Immunocompromised people are also at risk for becoming infected with other *Bartonella* spp. through vectors that feed on other domestic animals or wildlife species.

Immunocompetent hosts infected with *Bartonella* are not usually treated unless they have one of the bacteremic forms of the disease or are temporarily immunosuppressed. The most effective antimicrobials have included doxycycline, azithromycin, erythromycin, or rifampin.

99.7.2.2

Chlamydophila felis

Chlamydophila felis has been identified as a cause of conjunctivitis in cats and has been incriminated in infections in humans. Fewer than 10 cases have been reported of zoonotic transmission to people with a range of upper and lower respiratory tract infections. Unfortunately most of these claims were made before the availability of genetic identification and the reclassification of the genus *Chlamydia*, separation of the species *Chlamydia psittaci*, and the recognition of *C. felis*.³¹ In almost all instances, the reports were ambiguous with only circumstantial evidence, and the claims were not supported by simultaneous isolation and genetic comparison of the organism from the people and the incriminated cats. In one instance⁸⁴ a definitive genetic comparison was made in which chronic conjunctivitis in an immunocompromised human was attributed to *C. felis*. In another report¹⁰⁷ of 15 people with chronic follicular conjunctivitis, PCR and genetic analysis were used to identify human *Chlamydia pneumoniae* and avian *C. psittaci*, which predominated, and two of the cases involved a mammalian strain. Both of the people with the mammalian strain had kittens with conjunctivitis; however, no isolation or comparison of organisms was performed from the cats. Based on the scarcity of reports and the frequency of isolation of this *C. felis* from cats with upper respiratory illness, the zoonotic transmission must be uncommon, especially in immunocompetent people. This is also true in comparison to the higher rate of zoonotic transmission of *C. psittaci* infection from birds.

99.7.2.3

Sporotrichosis

Sporotrichosis is a disease caused by the saprophytic dimorphic fungus *Sporothrix schenckii* and is found worldwide in soils rich in organic matter. Dogs and cats can be affected with cutaneous, lymphatic, or disseminated forms (see [Chapter 63](#)). Humans can be affected by puncture wounds; however, they can be infected by cats through close contact and presumably through small wounds caused by claws or teeth contaminated with the organism.

99.7.2.4

Malassezia pachydermatis Infection

Malassezia pachydermatis, a commensal yeast of animals including dogs and cats, has been identified as a cause of nosocomial infection of infants in intensive care units in hospitals.^{41,192} Health care workers transmitted the infection and likely became infected by their pet dogs at home. Isolates from the infants and those of the workers' dogs had matching genotypes. Improving handwashing stopped the spread of this infection (see [Chapter 58](#)).

1057

Dogs with and without inflammatory skin disease and their respective owners were sampled in pairs for culture and PCR to detect *M. pachydermatis*.¹²⁶ Fungal culture was found to be insensitive, but perhaps it was more clinically relevant than PCR because it detected higher prevalence of organisms on people with clinically diseased pets. PCR methods did not detect a difference in the rate of carriage between the two

1058

Infectious Diseases of the Dog and Cat, 3rd Edition

groups of people. Perhaps higher concentrations of organisms on diseased skin facilitate the less sensitive culture method. It is presumed that both groups of people became contaminated from contact with dogs with or without dermatitis. This study reinforced the theory that *M. pachydermatis* is a commensal on canine skin. Health care workers in intensive care units or those who care for immunocompromised people must have thorough handwashing techniques.

99.7.2.5 Dermatophytosis

Infection in pet animals is caused by two zoophilic fungi—*Microsporum canis* and *Trichophyton mentagrophytes*—and cats and dogs, respectively, are their inapparent carriers. Cats infected with feline immunodeficiency virus (FIV) harbor more diverse fungal genera, such as *Malassezia*, than uninfected cats.¹⁶¹ People develop classic lesions with circular alopecia, scaling, crusting, and ulceration. Topical therapy of lesions in people is often rewarding, but topical and systemic therapy of pets and environmental decontamination and cleanliness are often needed to prevent recurrence (see [Chapter 58](#)).

99.7.2.6 Cowpox Infection

People with immunodeficiencies are especially susceptible to cowpox infections transmitted from cats (see [Chapter 19](#)).

99.7.2.7 Retroviral Infections

Veterinarians are exposed to feline retroviruses such as feline leukemia virus (FeLV), FIV, and feline foamy virus (FeFV) during the course of their work (see [Chapters 13, 14, and 17](#)). Blood samples from 204 veterinarians, laboratory scientists, and other people with occupational exposure to cats, were tested for antibodies to FIV, FeLV, and FeFV and for FeLV provirus by PCR.³⁶ The subjects reported a mean of 17.3 years of exposures to cats and high-risk exposures such as cat bites and scratches and injuries with sharp instruments. Neither serologic nor molecular evidence of exposure in these individuals was found. Nevertheless, people, especially those who are immunocompromised, should be cautious when handling secretions of these animals because immunocompromised cats are often coinfecting with opportunistic pathogens that may have zoonotic risks.

99.7.3 Aerogenic Spread

99.7.3.1 Bordetellosis

Infections caused by *Bordetella bronchiseptica* have been reported in immunocompromised people.^{57,196} This commensal bacterium of animals has pathogenic potential, and bordetellosis has been reported in people with close animal contact, including contact with dogs or cats^{57,77} (see [Chapters 6, 16, and 88](#)). The infection usually involves the respiratory tract; however, it may become disseminated. Although bordetellosis is uncommon, even in immunocompromised individuals, it has been recommended that immunocompromised people, their pets, or both should avoid contact with animals in dog kennels, catteries, or animal shows, where the infection is more prevalent. Swine and rabbits are another major source of infection, so contact should be avoided. If necessary, vaccination of an immunocompromised person's pets may be considered to help control the spread of an outbreak of infection; however, the vaccination procedure should be carefully monitored because immunosuppressed people may also become

Infectious Diseases of the Dog and Cat, 3rd Edition

infected with the organism used in the modified live intranasal vaccine. Young children and infants have been infected in this way (see [Chapter 100](#)).^{134,150} Therefore such individuals should not restrain their pets during the vaccination; ideally, they should not be in the room when the vaccine is being administered.

99.7.3.2 Coxiellosis

Serologic evidence of *Coxiella burnetii* infection is much higher in veterinarians who remove bovine placentas without wearing gloves than in those who do.¹³⁴ Because coxiellosis has developed in people who have been exposed to parturient cats (see [Chapter 29](#)), protective gloves and garments, including masks and protective eyewear, should be worn when performing procedures involving the genital tissues or secretions of parturient or aborting animals.

99.7.3.3 Plague

Yersinia pestis is a bacterium of rodents that is transmitted by their fleas. Many reports have been made of infected cats that have infected people, presumably through direct contact. Cats can also play a role in human infections because they can harbor infected fleas and bring them into close contact with people. Cats develop plague, presumably through contact with infected fleas or rodents. People become infected from cats either aerogenously, which causes a pneumonic form of illness, or by percutaneous inoculation, which causes regional lymphadenomegaly (see [Chapter 47](#)). Although cats are more susceptible, dogs pose a risk to humans by transporting infected fleas or the carcasses of their flea-infested prey into the home.¹²⁴

99.7.3.4 Tularemia

Francisella tularensis is an endemic organism found in many parts of the world (see [Chapter 48](#)). People can become infected in various ways and because of the virulence of the organism, even immunocompetent hosts are susceptible. Cats are the most common domestic animal vector for human infection. The cats become infected by insect bites or ingesting infected prey. People can become infected from tick bites or from cats through bites, scratches, or aerosols. Preventing cats from hunting and controlling insect vectors are the primary means of reducing infection risk.

99.7.3.5 Rhodococcus Infections

Rhodococcus equi, a soil saprophyte, has been isolated from patients with AIDS who have respiratory infections and have been exposed to the bacteria through horses or farm animals or environmental exposure to the soil. The organism is found in greatest numbers in soil contaminated by herbivore manure. Clinical signs are usually related to pneumonia with pulmonary abscess formation. Dogs owned by a nurse who worked in a respiratory unit in a hospital were determined to be the source of a *Rhodococcus bronchialis* infection in a hospitalized patient.¹⁵² The organism was found in the patient's wounds and on the hands, scalp, and mucous membranes of the nurse, as well as on the skin of her two dogs. (See [Chapter 35](#) for additional information on *Rhodococcus* infections.)

99.7.3.6 E. coli Infections

Severe peracute hemorrhagic pneumonia was documented in dogs in a research facility.⁸³ Two of the isolates were serotype 06 and two were 04. Isolates from all four dogs were positive for the virulence

Infectious Diseases of the Dog and Cat, 3rd Edition

factors α -hemolysin and cytotoxic necrotizing factor 1 and for the adhesin factor class-III papG allele.	
Although no zoonotic transfer was documented, this class of extraintestinal pathogenic <i>E. coli</i> is becoming more frequently implicated as a cause of extraintestinal infection in animals and people and may represent a zoonotic risk to humans who work with research dogs.	1058 1059

99.7.4 Fecal-Oral Spread

Enteric organisms of zoonotic risk can be detected in the feces of clinically healthy dogs and cats.^{83a,86,165} In most cases, the organisms do not cause additional problems unless the animal develops diarrhea. In this case, the increased frequency of bowel movements and fluidity of the stool promotes spreading and environmental contamination. A concern is that protozoa such as *Toxoplasma*, *Giardia*, and *Cryptosporidium* spp. can become established in freshwater and saltwater environments and in the animals that inhabit them.⁶³ Data suggest that *Toxoplasma gondii* oocysts can sporulate in sea water and can remain infectious for several weeks. Areas of freshwater runoff into the ocean have the highest risk of causing contamination. Survival of the organisms in the water can result in widespread dissemination and establishment of infection in invertebrates and vertebrates.

99.7.4.1 Toxoplasmosis

Toxoplasmosis has been an extremely publicized zoonotic disease, partly because it is acquired from pets, partly because of the training in animal diseases received by physicians. Approximately 30% of childbearing women in the United States have antibodies to *T. gondii* and are protected against congenital transmission. If one of the remaining 70% of the women should become pregnant and infected during pregnancy, the probability that the fetus will be infected is 20% to 50%. The most severe complications in the fetus occur between the second and sixth months of gestation.

Toxoplasmosis occurs in 10% of patients with AIDS and is thought to be responsible for at least 30% of central nervous system (CNS) complications.⁶⁵ Most cases of CNS toxoplasmosis are a result of reactivation of quiescent infections rather than of recent exposure. *Toxoplasma* antibody seroconversion is unusual in adults with HIV and appears unrelated to cat exposure.¹⁸⁵ Although it can be acquired by ingestion of oocysts shed by infected cats, infection in people living in industrialized countries is usually caused by ingestion of undercooked meats, especially goat, mutton, or pork. Actually, the overall risk of becoming infected by cats in the household is comparatively low, although young children can contract infection from soil exposure in rural environments.¹⁸⁵ Isolated outbreaks of disease have also been reported after handling or inhaling soil or dust contaminated by cat feces or contaminated water supplies.¹³ Typically, cats shed oocysts for no longer than 2 weeks after their first exposure to the organism and generally do not shed them again. This is true even when they are receiving high exogenous doses of glucocorticoids or have immunosuppressive diseases such as FIV AIDS. Therefore cats that have positive serologic test results for antibodies to *T. gondii* either as IgG or IgM will likely not shed again because the first shedding period is generally finite. However this serologic testing should be done early in the course of pregnancy if it is to be predictably useful. However, pregnant women rarely become infected from their own cats, so serologic testing is not more helpful than taking general precautions against exposure. However, children who acquire a cat before 15 years of age and who are from rural backgrounds have a likelihood of being seropositive for *T. gondii*, and higher titers are associated with owning greater numbers of cats.¹⁴³ This finding suggests that the children were exposed to the organism through the soil around their households. Oocysts must sporulate to be infectious, a process that takes 1 to 5 days. Because the feces

Infectious Diseases of the Dog and Cat, 3rd Edition

do not remain on the fur and oocysts do not appear to sporulate on the fur, handling of cats is an unlikely source of infection (see [Chapter 80](#)). One report has been made of an epidemic of toxoplasmosis in humans that was traced to soil contamination by cat feces.¹⁷⁴ In an indoor riding arena, cats defecated and contaminated the soil. Dust generated by exercising horses generated airborne particles, which were presumably inhaled by the riders, resulting in clinical disease.

Because of their environmental resistance, oocysts can enter the freshwater and marine water supplies and cause disease in people or animals that ingest contaminated water or invertebrates harboring these organisms. Outbreaks have been associated with contamination of municipal water supplies by oocysts from feral or wild felids,^{22,28,34} and evidence exists of widespread infection among marine mammals.⁵⁵

Immunosuppressed people should wear gloves and wash their hands after contact with soil or raw meat. Cat litter boxes should be changed daily, preferably by an immunocompetent person who is not pregnant. Hands should be thoroughly washed after changing the litter box or gardening or after other contact with the soil. All raw fruits and vegetables should be washed well before being eaten. Cats should be kept inside and fed only commercial diets or well-cooked table food. Patients do not have to be advised to part with their cats or have them separately tested for toxoplasmosis, either serologically or by fecal examination. Cats can be treated with effective drugs to reduce or clear oocyst shedding. Cats that have serologic positive test results (especially a measurable IgG titer) are likely protected from oocyst shedding because it is transient and generally occurs after the very first exposure.

Pet owners and physicians should be reminded that consumption of undercooked meat is the predominant way humans become infected with toxoplasmosis. Wearing gloves and using precautions during cooking are important to ensure that raw meat does not contact cutting boards or foods that are to be eaten raw, such as salads. Surface water can also be contaminated by oocysts; filtering or boiling water is the only effective way to eliminate the risk. All people with HIV or who are pregnant should be tested for IgG as early as possible so that they can be educated about any potential complications or risks and predict whether they are already infected. (See [Chapter 80](#) for additional information on preventing this infection.)

99.7.4.2

Cryptosporidiosis

Cryptosporidiosis is an intestinal infection caused by a ubiquitous, relatively non-host-specific coccidian parasite of vertebrates and can be acquired from young domestic herbivores (i.e., calves, lambs, kids, piglets) or less commonly from pets (see [Chapter 82](#)). *Cryptosporidium parvum*, the least host-specific species, has been identified in many mammals including humans, dogs, and cats. Other species, such as *Cryptosporidium canis* and *Cryptosporidium felis*, are predominant strains in dogs and cats, respectively; however, they also have been found to infect humans with HIV that develop diarrhea, and thus must be considered to be zoonotic.^{37,62,144} In one study of people with HIV with and without cryptosporidiosis, pets were not a major risk factor for infection.⁶⁷ *C. felis* was identified as an unusual species of *Cryptosporidium* isolated from people with HIV in Portugal; however, in only one instance was the infection associated with kittens in the home.¹¹⁴ Kittens, especially those with diarrhea or concurrent immunosuppressive infections with FeLV or FIV, or puppies are more likely to have clinical illness characterized by diarrhea and shedding of organisms. Organisms can be found in the feces of animals with or without diarrhea.^{86,121,158,165} Healthy mature animals are often clinically unaffected. Human-human transmission occurs without animal reservoirs, and outbreaks have been noted in daycare centers and family groups. The usual source of outbreaks from environmental exposure is raw sewage or contaminated water sources.¹⁰⁵⁹ Water runoff from land with grazing animals, animal-holding facilities, or sewage treatment facilities can¹⁰⁶⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

contaminate surface water supplies. Oocysts are highly resistant and can remain infectious under cool, moist conditions for many months as long as they do not freeze. They can survive in freshwater and saltwater and in water that has been chemically treated in swimming pools. Chlorination of water does not kill these parasites, and filtration systems for municipal water must be extremely efficient to eliminate these organisms.²⁴ Boiling water for 1 minute will kill them. *Cryptosporidium* oocysts can be found in 90% of untreated municipal water supplies and in 30% of treated systems that draw their water from lakes and rivers. As a result, most people do not become infected with this organism because of exposure to their pets; approximately 15% of patients with AIDS develop this complication.³²

Newborn and young pets may transmit this infection; stray animals or any pets with diarrhea should not be adopted. Infected dogs and cats with diarrhea have transmitted infection to people.⁷⁵ Puppies or kittens younger than 6 months should have their stools examined by a veterinarian for *Cryptosporidium* oocysts. Stools can be examined with acid-fast staining or immunoassay methods (either by enzyme-linked immunosorbent assay or fluorescent microscopy), which greatly increase the likelihood of finding organisms compared with conventional microscopic methods. Unfortunately, without using molecular techniques, it is impossible to distinguish the public health risks of particular strains because not all of the strains found in animals infect people. For this reason, it would be better to be overly cautious when the organisms are found. In addition, immunosuppressed people should avoid exposure to calves and lambs and should not drink untreated water directly from lakes or rivers.

Immunocompetent people show signs of abdominal pain and self-limiting diarrhea for 5 to 10 days. Immunodeficient individuals have severe, watery, debilitating, chronic diarrhea that is refractory to therapy. Oocysts in feces are small (2 to 4 μ m) and are difficult to see without concentration procedures and special staining.

Treatment is more difficult than that for other intestinal protozoa, so avoiding infection is the best plan. Immunosuppressed individuals should avoid direct contact with infected adults and should not handle diaper-age children without wearing gloves. Good hygiene while caring for infants or young children, especially those who are in daycare or nursery facilities, is essential. Immunosuppressed individuals should not share a room or bathroom with people known to be infected. Drinking contaminated tap or surface water (e.g., from lakes or rivers, the ocean, certain chlorinated pools, or ornamental water fountains) or contacting contaminated surface water during recreation or by eating contaminated raw foods may also result in cryptosporidiosis. Some municipal water supplies are contaminated, so water may need to be boiled for at least 1 minute, or submicron water filters may be needed. The safety of commercial beverages, including bottled waters, may vary; however, those that are pasteurized are generally safe. Immunosuppressed people should not eat raw oysters.

99.7.4.3

Giardiasis

The cause of giardiasis, *Giardia duodenalis* (synonyms *intestinalis* and *lamblia*), is a ubiquitous protozoal enteropathogen found in the intestinal tracts of vertebrate animals and people. Molecular techniques have been used to reveal that *G. duodenalis* has different phenotypic and genotypic strains; transmission between different host species occurs in some human outbreaks with less adapted genotypes, whereas in others, human adapted strains are responsible for clinical illness in people.¹⁷⁵ Human infections involve strains from Assemblages A and B, with each having their own groups of preferred animal hosts. Dogs and cats can become infected with Assemblage A, whereas only dogs are infected with Assemblage B. Species-specific assemblages also exist for dogs (Assemblages C and D) and cats (Assemblage F). No documented cases of giardiasis acquired from cats have been reported, but the same Assemblage B has been

Infectious Diseases of the Dog and Cat, 3rd Edition

found to infect dogs and people. Infected dogs and cats should be a presumed health risk. No guarantee can be made that infected animals can be effectively cured, and no evidence suggests that once cured they are completely protected from reinfection. (For additional information on the genetic assemblages, treatment, and prevention of *Giardia*, see [Chapter 78](#).) Waterborne outbreaks of giardiasis occur frequently and are a major health concern. Results from genetic analyses of strains involved in waterborne outbreaks suggest that water sources become contaminated with *Giardia* from wildlife or livestock. Outbreaks can occur when several people ingest contaminated water, and the infection can subsequently spread among individuals.¹⁷⁵ Zoonotic incidents involving dogs and cats are not usually waterborne and are more likely to result from direct fecal contamination.¹⁷⁵ Although *Giardia* organisms are probably the most prevalent enteric parasite of dogs and cats, infection is often subclinical and cyst excretion is intermittent.^{117,178} Young (younger than 6 months old) animals and those with diarrhea should be avoided as pets. Pets being considered for adoption can be screened for *Giardia* infection, and treatment can begin if needed. With or without use of protective gloves, hands should be washed after handling fecal material from infants, children, or animals in daily life. Boiling or filtering drinking water for people and pets eliminate the risk of infection from a contaminated water supply.

Outbreaks involving human-human transmission often involve people in group environments where hygiene may be poor such as in some daycare centers or communal groups of economically disadvantaged individuals. The primary sign of infection in immunocompetent people is watery, foul-smelling diarrhea with flatus, and abdominal distention or asymptomatic shedding can occur. Immunocompromised hosts, which can include infants, older adults, or people with AIDS, have a greater risk of infection and may develop chronic diarrhea with malabsorption. Diagnosing the infection in people may be difficult because the chance of finding the parasite from as many as three stool examinations is no greater than 50%.¹⁶⁰ Therefore treatment is often empiric (see [Chapter 78](#)).

99.7.4.4

Salmonellosis

Salmonellosis develops in approximately 5% of patients with AIDS. Foodborne exposures from contaminated meat account for many infections, but a few pet-related exposures have involved turtles. Severe recurrent diarrhea and bacteremia are common in patients with AIDS. Compared with the prevalence of infection in cold-blooded animals, dogs and cats are rarely colonized with these organisms. Therefore, immunocompromised people should avoid having reptiles and amphibians as pets. Multiple drug resistant *Salmonella typhimurium* DT104 has been isolated from dogs and cats, and cases in people have been identified in association with cats and dogs.⁸⁵ Young, debilitated, coinfecting, or otherwise immunocompromised dogs and cats are more likely to harbor and shed these organisms. Housing and management of animals can be important in the overall carriage rate of *Salmonella*. In one study 54% of group-housed cats, 8.6% of diseased cats, and 0.36% of clinically healthy pet house cats had *Salmonella* organisms in rectal swab specimens.¹⁸² Acquired antimicrobial resistance genes were found in these isolates. Environmental surveillance in a veterinary teaching hospital has shown that surfaces in hospitals are frequently contaminated.³³ This contamination can be a potential reservoir for infection for hospital personnel or animals and pet owners. Cases of multiple drug resistant *Salmonella* organisms have been associated with infections in small animal practices with inadequate hygiene.^{10,42,108,184,} Immunocompromised people, children, and older adults who become exposed are highly susceptible to infection and clinical illness. (For additional information on the epidemiology and prevention of infection in dogs and cats, see [Chapter 39](#).)

1060

1061

Infectious Diseases of the Dog and Cat, 3rd Edition

99.7.4.5 Campylobacteriosis and Helicobacteriosis

Campylobacteriosis is caused by a microaerophilic group of gram-negative, curved, motile rods that are commensal flora of animals. Although *Campylobacter jejuni*, *Campylobacter coli*, and *Campylobacter upsaliensis* have been most commonly isolated from dogs and cats,⁸² *C. upsaliensis* has been associated with enteritis in people, and it is suspected that dogs may be an important source of human infection.⁶⁹ *C. jejuni* is frequently isolated from dogs and cats (especially younger than 1 year of age) recently acquired from pet stores, kennels, animal shelters, or pounds. Pups and kittens with diarrhea have been most commonly associated with human infections. Uncooked meat, especially poultry, is probably a more common source of infection for people. Fecal-oral, foodborne, and waterborne modes of transmission are the principal avenues for infection. A contaminated water supply, possibly as a result of migrating waterfowl or herbivores, may be a source of infection for outdoor pets. Children younger than 5 years with a newly acquired puppy have the highest prevalence of infection.¹⁵⁶ Signs of infection in people are intense abdominal discomfort, bloody diarrhea, fever, tenesmus, and fecal leukocytosis. Immunosuppressed individuals with AIDS develop recurrent diarrhea, dehydration, and bacteremia.

Recommendations for reducing infection among immunocompromised people include avoiding animals with diarrhea and pets younger than 1 year of age. Veterinarians should culture feces of newly acquired animals for *Campylobacter* organisms. Washing hands after handling pets and especially before eating is the most important precaution. Feeding raw meat to pets should be avoided; only commercial diets or cooked foods (greater than 1801/4 F for poultry and 1651/4 F for red meats) should be used. Keeping pets indoors is the most reliable way to help control pet exposure to contaminated environmental sources. Precautions should be taken to prevent the risk of inducing antimicrobial resistant strains by not treating subclinically infected animals. Subclinically infected pets should not be considered for adoption by immunocompromised people.

A wide variety of related, potentially zoonotic *Helicobacter* species exist in domestic and wild animals. For a further discussion of these organisms, see [Chapter 39](#).

99.7.4.6 *E. coli* Infections

Attaching and effacing *E. coli* strains that belong to a variety of serotypes have been isolated from the feces of dogs, cats, and other animals with and without diarrhea.^{101b,131} The virulence factors found in these strains were similar to those found in human strains, suggesting that they may transmit back and forth between people and dogs.

99.7.5 Urogenital Spread

99.7.5.1 Leptospirosis

Leptospirosis is caused by several serovars that can infect a wide variety of animals and are shed in the urine into the water supply or moist environments. People become infected by contact of mucous membranes with contaminated water or through cuts or abrasions on the skin. In a similar manner, people who inadvertently come into contact with fresh urine from infected animals is a potential source of transmission. However, once treatment with proper antibacterial drugs is instituted, the urine of infected

Infectious Diseases of the Dog and Cat, 3rd Edition

dogs is no longer infectious. Most disinfectants kill the spirochete quickly; as a precaution, disinfectant should be applied on urine in cages or runs before they are cleaned. An outbreak of leptospirosis in dog handlers at Lackland Air Force Base in Texas received attention because of the possibility that the dogs were the source of infection; however, contact with rodents or contaminated ground water was not excluded (www.veterinarypartner.com, accessed 02/25/05). Additional studies are needed to determine whether the dogs and people were infected with the same serovar (see [Chapter 44](#)).

99.7.5.2 Brucellosis

Brucella canis is a venereally transmitted organism that is harbored intracellularly by dogs. People usually become infected through contact with the organism in female genital secretions or from laboratory culture. Infection requires a threshold dose, and the number of organisms usually in urine is lower than that in vaginal discharges. Animals with this disease should always be neutered to help reduce the public health risk should they be kept as pets. The zoonotic risk of a neutered animal is low; however, concerns about keeping an infected animal in the household with an immunocompromised person may be valid. (See [Chapter 40](#) for a discussion of the public health risk with this infection.)

99.7.5.3 Coxiellosis

Q fever is primarily an occupational hazard in people who are in contact with domestic livestock, such as goats or cattle, or workers in animal health or slaughter facilities. Cases sporadically occur in urban areas after people are in contact with infected dogs or cats. Parturient cats have been the most important source of these infections. People become infected from aerosols from placental tissues. Pneumonia is the primary clinical sign in infected humans (see [Chapter 29](#)).

99.7.5.4 *E. coli* Infections

Virulent pathogens causing genitourinary infections in dogs and cats could conceivably be pathogenic for humans who have close contact with these animals. Phylogenetic background and virulence genotype of isolates from dogs with urinary tract infections (UTIs) were compared with extraintestinal isolates from people.⁹³ Although similarities were found between individual canine and human isolates representative of five clonal groups, no clinical significance was found in people harboring these similar strains. Nevertheless, this suggested that dogs might serve as a source for potentially virulent human infections. Similarly, virulence markers have been used to document extensive similarities among *E. coli* isolates in two adult humans and a cat, including a strain that caused UTI in one female household member.¹³⁰ Although humans and pets sometimes carry the same fecal strain, this report documents the ready spread of *E. coli* over time and its ability to cause an extraintestinal infection rather than mere commensal colonization. The ability of animal bacteria to colonize people makes antibacterial therapy choices more critical to avoid resistant strains.

99.7.6 Vectorborne Infections

Numerous insects transmit infections to people. The mammalian reservoirs of these infections are often wildlife species; dogs and cats are not usually the direct source of infections for people. Instead, they act as sentinels for infection or they bring the shared vectors closer to humans. Sufficient tick attachment duration is important in the successful transmission of many of these diseases.⁹⁸ Therefore good ectoparasite control for people and pets can help to reduce the threat of infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

99.7.6.1 West Nile Virus Infection

Antibody reactive to West Nile virus has been found in sera of 26% of 116 dogs and 9% of 138 cats tested in Louisiana during the 2002 outbreak of this disease in the United States caused by this virus.^{101a}

1061

Outdoor-only, family-owned dogs had a 19 times higher prevalence rate compared to that of indoor-only, family-owned dogs. Stray dogs had twice the odds of seropositivity as compared to that of family-owned dogs. Family dogs not receiving heartworm preventative had twice the level of positive results as those dogs receiving heartworm preventative.

1062

99.7.6.2 European Tickborne Encephalitis

European tickborne encephalitis is an arboviral infection in Europe that is transmitted by *Ixodes* ticks (see [Chapter 26](#)) and mirrors the geographic range of borreliosis. People and dogs can become clinically ill with this virus infection.

99.7.6.3 Borreliosis

Tick transmission is a required component of *Borrelia burgdorferi* virulence (see [Chapter 45](#)). Therefore as with most arthropod-borne infections, animals do not directly transmit the disease. However, animals share the same environment as people and act as sentinels for infection. Pets may bring the vector into contact with people; however, unless refeeding occurs, handling of ticks by people is not a major risk.

99.7.6.4 Rocky Mountain Spotted Fever

Unlike some of the other tickborne diseases, engorged ticks that are feeding on pets are highly infectious for people if hemolymph of infected ticks contacts broken skin or mucous membranes. People must be very cautious when removing and disposing of ticks from animals. Unfortunately, because of its diverse clinical manifestations, diagnosis of Rocky Mountain spotted fever in dogs and people can be delayed, possibly leading to death. Simultaneous infections in dogs and their owners are not uncommon.^{58,137} Because dogs can serve as sentinels for disease, a high index of suspicion by veterinarians and good communication with people and their physicians can help prevent infection (see [Chapter 29](#)).

99.7.6.5 *Rickettsia felis* and *Rickettsia typhi* Infections

Numerous rickettsial species have been isolated from cat fleas (*Ctenocephalides* species). Dogs and cats may be subclinically infected; however, rickettsial diseases in people are indistinguishable from typhus (see [Chapter 29](#)).

99.7.6.6 Ehrlichiosis and Anaplasmosis

Ehrlichiosis and anaplasmosis are maintained in wildlife hosts and transmitted by bites of infected ticks. Transmission may require at least 36 hours of tick attachment.⁹⁸ *Ehrlichia chaffeensis*, *Ehrlichia ewingii*, and *Anaplasma phagocytophilum* infect people and animals. Circumstantial evidence suggests that exposure to deer blood during dressing of carcasses may be a direct means by which *A. phagocytophilum* is zoonotically transmitted.^{16,173} Humans and domestic animals such as dogs are incidental hosts and are not

Infectious Diseases of the Dog and Cat, 3rd Edition

reservoirs of infection. Furthermore, infection transmission between domestic animals and people is unlikely (see [Chapter 28](#)).

99.7.7 Anthroponoses

99.7.7.1 Methicillin-Resistant Staphylococcal Infections

Methicillin-resistant strains of *Staphylococcus aureus* (MRSA) are important nosocomial pathogens in human hospitals. *S. aureus* is a human-adapted commensal and opportunist. The organisms are usually harbored by people, and medical health workers can become colonized and inadvertently transmit the infection to human patients. Similarly contamination of the veterinary hospital environment can occur as a result of human contact, and organisms can be transmitted to hospitalized animals.¹⁸⁸ MRSA infections have been identified in dogs.* Methicillin resistance in staphylococci is mediated by the *mecA* gene, which encodes the penicillin-binding protein 2a (PBP2a). In one study of various domestic animals,¹⁸⁰ all but one of the MRSA isolated from animals, as detected by the *mecA* gene, had distinct nucleic acid compositions when compared with human isolates. The MRSA that were found were from dogs, indicating that dogs may carry more MRSA than other species. Unfortunately, the MRSA were also highly resistant to multiple antibacterial drugs. In another instance, a cat kept in a rehabilitation geriatrics ward for pet-facilitated therapy was incriminated in a staphylococcal infection in hospitalized patients. Presumably, the infections result from animal health workers or owners transmitting their resistant strains to a pet. The concern is that these organisms can be transmitted from the animal to other people who might be immunocompromised or who have other medical conditions that would be complicated by these highly resistant organisms. Judicious use of antimicrobials by veterinarians and strict personal hygiene, especially hand protection and washing, can help reduce the chance of the infection spreading among animal health workers in veterinary practices. Because of the high risk and ready spread of these organisms through close contact or fomite transmission, additional precautions may need to be taken by workers in the paraprofessional pet industry, such as those in grooming, boarding, and breeding facilities.

The most common dermal isolate from dogs is *Staphylococcus intermedius*. Most strains of *S. intermedius* have predictable and more narrow antimicrobial susceptibilities than *S. aureus*. Reports of this organism infecting people are uncommon; however, in one instance, *S. intermedius* infected a postsurgical wound site of a person after a dog frequently licked the wound.¹⁰¹ A newly recognized isolate from dogs, *Staphylococcus schleiferi*, has a much broader host range, which includes dogs, and a wider antimicrobial resistance pattern, including that of methicillin.^{87,94} That *S. schleiferi*, unlike *S. intermedius*, has been isolated more frequently from human infections is concerning to medical professionals. Additional documentation of this infection in people is necessary, and it may be both a zoonotic and anthroponotic problem. (For precautions in handling patients with MRSA infections, see www.aorn.org/journal/2001/sepci.htm; accessed 2/25/05.)

* References 40, 70, 87, 177, 181, 189.

99.7.7.2 Group A Streptococcal Infections

When initially reported, dogs were incriminated as persistent reservoirs of group A streptococcal infections in people (see [Chapter 35](#)). However, crude antimicrobial susceptibility testing was done, and genetic subtyping of strains is needed to definitely document the epidemiology of infection. Nevertheless, households with high prevalence rates of this infection also have a higher rate of exposure to the organisms

Infectious Diseases of the Dog and Cat, 3rd Edition

through pets. However, compared with the infection in people, the infection is transient in animals; the possibility of other humans in the household being more efficient reservoirs should be considered. Studies have shown that other household members are likely to be colonized with the bacteria when a child is symptomatic.

99.7.7.3 Human Urinary *E. coli* Spread to Pets

Household pets have been proposed as potential reservoirs of *E. coli* that cause UTIs in humans (see previous section); however, it is uncertain whether human strains spread to pets, which might act as reservoirs or amplification hosts. In one study,¹⁵⁷ *E. coli* from women with UTIs were compared with those isolated from dog fecal specimens and from 76 healthy human volunteers. Antibacterial resistance was more common and extensive among isolates from women with UTIs than in the other groups. The data from this report suggested that dogs might acquire resistant strains from infected people, but dog fecal strains were not likely to be sources for human UTIs.

1062

99.7.7.4 *Mycobacterium tuberculosis* Infection

Tuberculosis in dogs can be caused by *Mycobacterium tuberculosis* acquired from infected people,^{61,80} because people are the natural reservoir for this organism. In one report of a person with tuberculosis, the person's dog often sat in the person's lap and licked the owner's face, which may have been responsible for the transmission.⁶¹ Although intradermal skin testing has been used, definitive antemortem diagnosis of tuberculosis in dogs or cats is difficult without special culture and histopathologic confirmation of the granulomatous lesions. Because of the uncertainty of whether this infection in animals can be transmitted back to people, treatment of pets is not usually recommended (see [Chapter 50](#)).

1063

99.7.7.5 *Streptococcus pneumoniae* Infection

One report has been made of transmission of *Streptococcus pneumoniae* from a human to a cat (see [Chapter 35](#)).

99.7.7.6 Avian Influenza

It is hypothesized that all mammalian influenza virus infections arise from an avian reservoir. Aquatic birds are the reservoirs of all types of influenza A viruses. The viruses replicate in the digestive tract of the birds but cause no clinical illness. The viruses can enter the food supply through fecal contamination of the carcasses, which are then ingested by people or other animals such as pigs or horses, or through contamination of water supplies. Similarly other birds, wild and domestic, can become infected as a result of the migratory patterns of the water fowl. In Asia, where pigs and fowl are raised together, cross-contamination with virus is likely. This mixing of the two strains can result to genetic recombination of the isolates with major antigenic shift and new infecting strains within a given host species (see [Chapter 25](#)). This crossover of viral replication from birds to mammals such as people, dogs, and cats is especially prevalent in the Orient. The live-bird markets and spread of infection to swine housed in close proximity are thought to be the important starting point for these pandemics. The newly adapted strains can spread simultaneously in people and their pets; however, clinical illness in infected dogs or cats has generally been limited or subclinical. In the most recent pandemic in October 2004, which was caused by the H5N1 strain, clinical illness was fulminant in tigers and leopards in Thailand and many either died or were culled

Infectious Diseases of the Dog and Cat, 3rd Edition

because of severe clinical signs and risk of infecting other animals and people^{100,176} The outbreak appeared to be caused by the feeding of raw infected chicken to the exotic cats. Gross necropsy findings included severe pulmonary consolidation and multifocal hemorrhages throughout other organs.¹⁰⁰ Diffuse fibrinous pneumonia and multifocal encephalitis were observed. This strain of virus appears to be highly pathogenic for tigers, leopards, and domestic cats and may spread among them.¹⁰⁴ Additional studies on the potential for cats to transmit this virus to people is needed. In Austria, the seroprevalence of antibodies to influenza virus H1N1 was higher among veterinarians than in the general population.¹³⁴ Immunocompromised people should be especially wary because mortality from influenza is highest in immunocompromised individuals. (For additional information on influenza in dogs or cats, see [Chapter 25](#).)

99.7.7.7 Ebola Virus Infection in Dogs

Ebola virus, a member of the family *Filoviridae*, causes fulminant hemorrhagic fever in human and nonhuman primates. During the 2001 to 2002 outbreak of Ebola virus in Gabon, Africa, dogs were observed feeding on animal carcasses. Serum samples containing Ebola virus-specific IgG were more prevalent (25.2 %) from dogs in the virus-epidemic area than levels from dogs from nonepidemic areas of Gabon (15.2%) or France (2%).^{2a} Within the epidemic-area villages, villagers consumed meat from infected animal carcasses found in the forest and subsequently served as the source of infection for others in the village. The prevalence rate in dogs from these villages with an animal source and subsequent human infection was as high as 31.8%. Neither Ebola virus antigens nor nucleotide sequences or cultivated virus were detected in any of the seropositive or seronegative dog blood samples. Clinical signs were not observed in exposed dogs, suggesting that asymptomatic or mild Ebola virus infection occurs in dogs. Whether they could serve as a source of infection for people is uncertain. However, handling dogs that have been exposed to infected carcasses could pose some risk for people. This may help to explain infection among people who had not been associated with other infected humans. The prevalence of infection in Gabon dogs outside epidemic areas may relate to contact with infected small terrestrial animals, bats, or birds.

99.7.8 Zoonoses from Other Animals

99.7.8.1 Nipah Virus Infection

Outbreaks of encephalitis in people in Malaysia have been linked to a new paramyxovirus that affects pigs and other domestic animals (see [Chapter 18](#)). It has been associated with death in pigs on affected farms, and close contact with pigs was considered the primary source of infection.¹³⁸ However, death of infected dogs and cats was also identified as a risk factor for some of the affected people without direct pig exposure. Transmission from these animals to their human owners could not be excluded. Additional work will be needed to determine the risk of potential transmission through these pets.

99.7.8.2 Psittacosis

Psittacosis is an endemic infection of birds worldwide caused by *Chlamydia psittaci*. It may be transmitted by direct contact with birds or indirectly through their feces or feathers. Infected birds may remain carriers. Animal care workers have a high risk of becoming infected.⁷¹ Affected people develop pneumonia with various systemic manifestations, including arthralgia and myalgia. The risk of infection has been greatly

Infectious Diseases of the Dog and Cat, 3rd Edition

reduced through the introduction of tetracycline in poultry feeds; however, this practice produces antimicrobial-resistant strains and does not reduce the prevalence of infection in pet birds. Dogs and cats may become infected with the strains from birds, as can people (see [Chapter 30](#)). The risk of this infection does not appear to be any greater for immunocompromised people than it is for those who are clinically healthy.

99.7.8.3 Listeriosis

Listeriosis is caused by a saprophytic gram-positive bacillus and occurs most commonly in pregnant women, the old or very young, those taking immunosuppressive drugs, or those with AIDS. The organism can be isolated in the environment from soil, and humans may contract it from contaminated meat or vegetables (see [Chapter 35](#)).

99.7.9 Saprinoses

99.7.9.1 Mycobacteriosis

Although people and pets become infected with *Mycobacterim avium* complex (MAC) organisms, the infections are related to common environmental exposure rather than spread among animals or human hosts (see [Chapter 50](#)). Treatment of MAC infection is possible. Nevertheless, in households with immunocompromised people, a decision to remove an infected pet is understandable. *Mycobacterium marinum* infection is acquired by immunosuppressed people who clean fish aquariums or are exposed to other aquatic environments.

99.7.9.2 Cryptococcosis

Cryptococcosis is a fungal disease that has been identified as a respiratory illness in people with AIDS. 1063
Immunocompetent people are subclinically infected. As with the other systemic mycoses, the organisms are 1064
acquired from contact with contaminated soil. Pigeon and other bird droppings enrich the soil and transport organisms into new areas. Areas with large congregations of birds should be avoided. Although cats and occasionally dogs develop cutaneous infections, aerosols from these lesions do not infect people in the immediate environment (see [Chapter 61](#)).

99.7.9.3 Other Mycoses

Numerous fungal infections such as histoplasmosis (see [Chapter 60](#)), coccidioidomycosis (see [Chapter 62](#)), zygomycosis (see [Chapter 67](#)), and aspergillosis (see [Chapter 64](#)) are acquired by people and animals from the environment. They often affect immunocompromised individuals, and heavy levels of exposure can overwhelm the remaining immune defenses. With the exception of blastomycosis, sporotrichosis, and dermatophytosis, people do not become infected directly by their pets.

99.7.9.4 Microsporidiosis

Microsporidiosis has been reported with increasing frequency as a cause of chronic watery diarrhea in human patients with AIDS. Before the beginning of the AIDS epidemic, very few cases had been reported.⁶⁵ The protozoan parasites are a heterogenous group in the phylum Microspora (see [Chapter 75](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

Although various microsporidia infect animals, none of the infections in humans (primarily *Enterocytozoon bieneusi*) has been definitively traced to household pets or any animal reservoir.⁵³ In one report, a child seroconverted after being exposed to a litter of puppies infected with *Encephalitozoon cuniculi*.¹¹⁸ A wide variety of environmental exposures exist, and numerous species of farm animals, monkeys, rodents, rabbits, and fish have become infected. The premise that pets are involved has not been well substantiated. Because of the ubiquitous nature of microsporidians, no specific precautions other than careful handwashing and food washing can be justified.

99.7.10 Other Zoonoses

Numerous other zoonoses have not been documented with any greater frequency in immunosuppressed individuals than in the general population. The references at the end of this chapter and the Public Health Considerations sections in other chapters in this book should be consulted for a more extensive review of all companion-animal-associated zoonoses.

99.8 RECOMMENDATIONS

According to guidelines established by medical experts,⁷ human health care providers should advise people infected with HIV of the potential risk posed by pet ownership. However, those giving advice should be sensitive to the possible psychological benefits of pet ownership and should not routinely advise people infected with HIV to part with their pets. [Table 99-3](#) lists Internet addresses for the Centers for Disease Control and Prevention's (CDC) Healthy Pets, Healthy People program, which offers guidelines for safe pet ownership by people infected with HIV, patients who have had organ transplants, and young children. In regards to infection, handling pets is no more risky for an immunosuppressed person than is contact with other people or the environment. In fact, zoonotic diseases are more likely to be acquired from another infected human than a clinically healthy, parasite-free adult dog or cat.^{66,167} Simple hygienic measures taken by immunosuppressed owners greatly reduces the risk of exposure to zoonoses ([Table 99-6](#)). For additional information on hand hygiene, see [Chapter 94](#). (See [Table 99-3](#) for the online CDC guidelines for hand hygiene.) Factors that can cause animals to become greater risks include some of the unique organisms they can harbor and the lack of sanitary behavior often practiced by animals. Owners can often institute routines in their own behavior that will make it unlikely that they will contract a disease from their companion animals. Veterinarians can institute certain screening procedures to identify potential zoonoses and initiate treatment or prevention protocols if indicated ([Table 99-7](#)). (For information on reducing the risk of transmitting zoonotic agents in animal health or housing facilities, see [Table 99-8](#), and for additional hygiene recommendations, see [Chapter 94](#).)

99.8.1 Screening

In general, precautions should be taken if an immunosuppressed person decides to acquire a pet for companionship or when a pet is being used to provide companionship for people in hospitals or nursing homes. In a survey of American and Canadian animal-assisted therapy programs, 94% used dogs or cats.¹⁸⁶ Two thirds of these animals visited older adults in nursing homes, one fourth were taken to schools, and another one fourth were taken to hospitals. Although unfounded, the major zoonotic concerns were rabies, ringworm, and external parasites.¹⁸⁶ Less than half of the therapy groups consulted veterinary professionals, and only 10% had written guidelines for zoonoses transmission. Although the benefits of animal-assisted therapy are many, guidelines should be developed to reduce risk of zoonotic disease transmission in health care environments.^{29a,56a,101a}

Infectious Diseases of the Dog and Cat, 3rd Edition

In dogs and cats, infectious diseases, including zoonoses, are more frequently a problem when they are puppies or kittens, and the general guidelines for obtaining a new pet include looking for one older than 1 year old. Exotic or wild animals are not as tractable, may cause injuries, and may harbor unusual parasites or infections. Furthermore, stray animals or animals being housed in areas of high-population densities, such as humane shelters, pet-breeding facilities, pounds, puppy or kitten mills, or crowded pet stores may have a greater chance of harboring pathogens. Acquiring a new adult pet from a single-pet household may be the best option. Any newly acquired pet should be thoroughly examined by a veterinarian before being introduced to a household. It should be clinically healthy and have no evidence of illness (especially diarrhea) or immunosuppression. All animals should be examined by a veterinarian for *Cryptosporidium*, *Salmonella*, and *Campylobacter* organisms (see [Table 99-7](#) and respective chapters).

99.8.2 Handling

Immunosuppressed people should wash their hands frequently during the day and consistently after handling their pets or their pets' excretions. Handwashing is especially important before eating, smoking, performing dental hygiene, and putting in corrective lenses. The pet should be kept indoors and its environment should also be kept clean and free of dirt, uneaten food, and excrement.

99.8.3 Health Care

Newly acquired pets should receive their vaccinations and routine anthelmintic therapy for roundworms and hookworms. Serologic testing for FeLV and FIV is recommended for cats. Although FeLV and FIV pose no chance of infecting people, cats affected with these immunosuppressive viruses are more likely to develop other infectious diseases. Measuring IgG toxoplasmosis titers might help determine prior exposure in cats but is not definitive and is not predictive of risk because most people are not infected by their own cats. Younger kittens are more likely to be seronegative and are may shed oocysts after their first exposure to *T. gondii*. IgG seropositivity indicates prior exposure and minimal risk, because cats rarely reshed oocysts after initially being infected (see [Chapter 80](#)). To reduce the risk of zoonotic transmission of parasites and enhance the health of pets, the Companion Animal Parasite Council recommends year-round treatment with broad-spectrum heartworm anthelmintics with activity against roundworms and hookworms and preventive flea and tick products for the life of the pet (see [Table 99-3](#) for the Internet address). Yearly physical examinations and fecal parasite examinations are indicated to maintain the health of the pet, and vaccinations should be administered as appropriate for the lifestyle of the pet (see [Table 100-9](#)). Illness in any pet should be an important reason to seek immediate veterinary care.

1064

1066

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 99-6 Guidelines for People with Immunodeficiencies: Reducing the Public Health Risk Posed by Their Dogs and Cats

Pets can have zoonoses, or infections that also develop in people. People with an immunodeficiency are more susceptible to developing infections. In some instances, zoonoses can spread to people from pets and in other instances, people contract these infections from the same sources, which include contaminated food, soil, water, or other people. No evidence proves that pets can become infected with or transfer the human immunodeficiency virus from one person to another. People do not need to be advised to part with their pets if they are willing to take simple precautions.

Selection

The energy level of the pet should match that of the owner. Choosing a young (younger than 6 months old) puppy or kitten poses a greater risk of infection because of their increased susceptibility to infections. Pets older than 1 year of age and in good health are best. Likewise, stray, exotic, wild, ill, or debilitated animals are more likely to carry zoonotic infections. Potential sources of pets that have poor hygiene, unsanitary facilities, and crowded conditions should be avoided. A veterinarian can give advice on pet selection, screen the animal for infectious agents, and begin a vaccination and parasite control program. Immediate veterinary attention should be sought if a new pet becomes ill. New pets with diarrhea or parasite infection or infestation should not be considered for adoption. Should the owner or the pet become ill, friends and local support groups can help care for the pet.^a

Feeding

Pets should be fed commercial rations or pelleted feeds. If pets are fed meat, it should be cooked until it is no longer pink (and to greater than 176° F [80° C]). Only pasteurized dairy products should be used. Restrict the pet's access to carrion and prevent the pet from hunting; preventing cats from hunting usually requires them to be kept indoors. Pets can drink tap water but should never drink from the toilet. Pet foods should be protected from contamination by vermin.

Recreation

Although declawing of cats is not advised, owners should avoid activities that would result in bites or scratches from pets. Should bites or scratches occur, they should be flushed and washed with water and antiseptic soaps promptly. Animals should never be allowed to lick open wounds or mucous membranes.

Personal Hygiene

Pets' mouths contain organisms that might infect their owner should they enter the owner's body through open wounds or by biting or scratching. Activities that might induce biting or scratching or result in exposure to their saliva, such as licking the face or wounds, should be avoided. Feeding utensils should not be shared with pets. Gloves should be worn when giving pets oral medications or brushing their teeth. As a general rule, hands should be washed after handling pets. Bite or scratch sites should be washed promptly and medical attention sought immediately for any bite injuries. Contact with pets' excreta (urine, feces, vaginal or seminal discharges) should be minimized. Gloves and a face mask should be worn when cleaning the litter box or diarrhea or urine from the pet, or perhaps others can help. Hands should then be washed, even if gloves were worn. Litter boxes should be emptied daily; liners make this job easier and minimize exposure. The litter box should be kept out of food preparation or eating areas. Scalding water is the best method for disinfecting litter boxes. Household bleach is effective against many viruses and bacteria; however, ammonia should be used to decontaminate litter boxes with *Toxoplasma gondii* (see [Chapter 80](#)). Sandboxes should be covered and gloves worn while gardening. Water from the environment for consumption should be filtered or preferably boiled.

Parasite and Transport Host Control

The veterinarian can assist in controlling diarrhea or external parasites, such as fleas or ticks, which may transmit zoonotic infections to people. Gloves should be worn when removing ticks from the pet. Testing for and treating intestinal parasites is also warranted because they can cause diarrhea and in some cases can infect people. Flies and cockroaches should be controlled because they can transfer infectious agents among hosts.

Infectious Diseases of the Dog and Cat, 3rd Edition

Disease Testing and Vaccination

The stools of dogs and cats can be checked for *Cryptosporidium* oocysts (see [Chapter 82](#)). Feces can also be cultured for *Salmonella* and *Campylobacter* (see [Chapter 39](#)) organisms, especially if the pet has diarrhea. Cats can be tested for and treated for *Bartonella* infection, although the need for this controversial (see [Chapter 54](#)). Serologic testing for *Toxoplasma* may reveal the public health risk of a cat, although it is not generally advised (see [Chapter 80](#)). Cats should receive their primary immunizations and periodic boosters. It is extremely important that they be vaccinated for rabies.%

- a A veterinarian can provide the names of assistance programs that can provide in-home pet care, change litter boxes and walk dogs, provide home flea control, provide care for or give medication to pets if the owners are hospitalized or ill, bathe pets, provide foster care and adoption options, and deliver pet food.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 99-7 Veterinary Guidelines for Handling Dogs and Cats: Controlling Directly Transmitted Zoonoses Most Commonly Affecting Immunocompromised People

DISEASE AND PET	DIAGNOSIS	TREATMENT	PRECAUTIONS
Toxoplasmosis: C (see Chapter 80)	NR: fecal exam—oocysts rarely found; serology—cannot predict oocyst shedding; seropositive generally protected because of previous exposure	NR: clindamycin—reduces oocyst shedding; bathing—feces not often on fur	R: litter box hygiene—daily cleaning by immunocompetent assistant; preventing cat from hunting or eating raw meat
Giardiasis: C, D (see Chapter 78)	R: test pups, kittens, diarrheic pets; zinc sulfate method	R: metronidazole, albendazole, fenbendazole	R: litter box hygiene; handling feces with gloves
Cryptosporidiosis: C, D (see Chapter 82)	R: acid-fast or direct FA staining of feces	R: paromomycin; untreated may shed for 2 weeks	R: litter box hygiene; handling feces with gloves
Campylobacteriosis, helicobacteriosis: C, D (see Chapter 39)	R: fecal culture NR: culture stomach contents or biopsy, histopathology with silver stains	R: I—erythromycin, chloramphenicol R: G—metronidazole, ampicillin, bismuth subsalicylate	R: preventing ingestion of raw meat
Salmonellosis: C, D (see Chapter 39)	R: fecal culture, selective media	NR: fluoroquinolones	R: preventing hunting and carrion or raw meat ingestion; if positive, temporarily removing animal from household
Bartonellosis: C (see Chapter 54)	R: blood culture or PCR if screening a cat or dog, respectively, is under consideration NR: antibody testing	R: fluoroquinolones, doxycycline, rifampin, azithromycin	R: strict flea control, screening or avoiding kittens, avoiding bites or scratches and washing immediately if they occur
Bordetellosis: C, D (see Chapters 6, 16, and 88)	NR: endotracheal wash and culture	R: tetracyclines	R: avoiding exposure to boarding kennels, dog shows, and congregated dogs; vaccinating if exposure likely
NR, Not recommended; R, recommended; FA, fluorescent antibody; C, cat; D, dog; I, intestinal <i>Campylobacter</i> organisms; G, gastric <i>Helicobacter</i> organisms; PCR, polymerase chain reaction.			

99.8.4 Grooming

The animal's hair coat and skin should be kept in good condition by occasional baths if needed and regular brushing and trimming of matted fur. Nails of dogs and cats should be trimmed frequently to reduce the chance of scratch injuries. If cats scratch when handled, declawing should be considered. Fleas should be managed with monthly flea preventatives and intensive environmental treatment in the area that the animals frequent (see [Chapter 94](#)), including indoor floors and carpets, especially where they sleep, their sheltered roaming areas, and those areas frequented by other contact animals. Environmental treatment using flea bombs or sprays should include larvicidal growth inhibitors as well as adulticide compounds. Newer oral or topical products that interfere with flea development and reproduction are warranted. More effective control of fleas in the environment may require a professional exterminator.

Infectious Diseases of the Dog and Cat, 3rd Edition

To control ticks, routine daily checking of pets or checking immediately after leaving tick-infested areas is indicated. Use of amitraz collars and topical fipronyl may be indicated in areas of heavy tick infestation. Any attached ticks should be removed with rubber gloves or tweezers, and hands should be washed after removal. Ticks should not be removed or crushed with bare, exposed hands. For further information on tick removal and prevention, see [Chapters 29](#) and [45](#). Flies, cockroaches, and vermin may also transport infectious organisms. Pets should be restricted from areas where rodents burrow, and measures should be taken to eliminate areas near the home where vermin may nest.

1066

Infectious Diseases of the Dog and Cat, 3rd Edition

1067

Table 99-8 Reduce Risk of Transmitting Zoonotic Agents in Veterinary Hospitals or Animal Housing Facilities

MEANS OF SPREAD	RECOMMENDATIONS
General	Wash hands before and after contact with animals or their secretions or excretions. Wear gloves when any pathogens may be present or when in contact with tissue. Wash hands after removing gloves. (For instructions on hand washing see Table 94-7 .) Avoid contact with inanimate objects in the facility until hands are cleaned. Eating, drinking, or storing food should never be done in areas where animals are kept or handled or where their biologic specimens are stored. In cases of known or suspected infection, special diagnostic procedures such as radiographic imaging or surgery should be postponed until the end of the day so that other animals do not come in contact with affected areas until they are decontaminated and clothing can be changed before the next day. All disinfectants applied to surfaces that are cleaned first to remove organic material should have at least 10 minutes of contact before being rinsed.
Bite or saliva	Wear gloves to examine oral cavities. Immediately rinse any bite wounds under water pressure, and apply disinfectant solution. Seek medical attention immediately.
Scratch or close contact	Disinfect scratches by rinsing them immediately in water, and apply disinfectant solution. Animal's bedding and carriers must go home with them. All cage papers, waste, and litter should be disposed of after each pet is discharged and the run or cage disinfected.
Aerogenic	No animals susceptible to a suspected infection should be housed closer than 1.3 meters to each other and never in adjacent cages. Always wear gloves and barrier clothing when handling such pets. Wash hands and change gown immediately after handling or medicating each affected pet. Disinfect surfaces in rooms where animals have had the opportunity to cough or sneeze.
Feces	Wear gloves and gown when handling patients. Diarrhea is especially infectious. If a highly contagious disease, such as <i>Salmonella</i> infection, is suspected, meet clients outside on their arrival, and coordinate their hospital entrance directly into an examination room or quarantine area that can be cleaned. Should the animal be admitted, it must be placed in an isolation area where appropriate barrier hygiene can be practiced. Using gloves, collect specimens with a syringe if they are liquid and a tongue depressor if they are solid.
Urine or genital	Wear gloves if wiping up urine with hands. Otherwise, use a mop soaked in dilute hypochlorite. Add disinfectant such as hypochlorite solution to urine before hosing or spraying cages or runs.
Transport Host (Vermin)	Use fumigants in rooms or buildings with major problems. Otherwise, use baits, sprays, and insect traps to control flies, cockroaches, and rodents.
Arthropod	Bathe and dip the animal or administer oral or topical insecticides, insect repellents, or growth regulators (see Table 94-20).
Sapronoses	Handling infected pets poses minimal risks, although precautions should be taken for certain diseases and by immunocompromised individuals. Avoid outdoor activities in areas where soil is disturbed. Wear masks and gloves when working outdoors under such conditions.
Anthroponoses	Be aware that human pathogens can spread to dogs and cats. Use hygiene, as outlined in previous sections, for preventing pet-person spread and to prevent spread of human infection to pets when a person is known to be or suspected of being infected.

Infectious Diseases of the Dog and Cat, 3rd Edition

Quarantine or isolation	Handling cases of highly contagious zoonoses, fatal zoonoses, or both requires isolated facilities. Isolation should be in a separate room with its own ventilation and cleaning facilities and in an area of the hospital where an ante room can be used for putting on barrier clothing such as gowns, masks, gloves, and protective footwear. Ideally, the area should have its own doorways into and out of the hospital. Disposable materials and animal waste leaving the area for decontamination should be sprayed with disinfectant and double bagged, with the outer bag also being sprayed with disinfectant. All reusable items that leave the area should be either autoclaved or washed and dried at high temperatures with automatic equipment. Reusable items should be washed, rinsed, and soaked in disinfectants after an animal vacates and before the item leaves the area. The facilities should be cleaned and disinfected routinely. A foot bath may be needed to prevent tracking of microorganisms. The animal should be bathed and then dipped in a dilute hypochlorite solution before leaving the area (see Chapter 94).	1067
99.8.5 Excrement		1068

Although pathogens such as *Salmonella*, *Cryptosporidium*, and *Giardia* are immediately infectious, *Toxoplasma* spp. require sporulation of the oocyst to be infectious. Therefore daily cleaning of feline litter boxes can prevent *Toxoplasma* infection. Immunosuppressed individuals should try to avoid direct contact with pet excretions and wear gloves when handling fecal material. When possible, diarrhea should be handled by others. Diarrheic stools are particularly challenging to remove without becoming exposed to pathogens they may contain. Feline litter boxes should be kept out of eating areas and be cleaned by an immunocompetent adult who is not pregnant. Creation of litter-box dust can be avoided by using bag liners and dust-free litters and by moistening litter before sealing bags. Although the litter box should be emptied outdoors or in well-ventilated areas to prevent inhalation, the litter should not be placed directly into the environment. The coccidian oocysts in a litter box can be disinfected once monthly by filling the box with boiling water or dilute (5% to 10%) household ammonia solutions for 10 minutes (see [Chapter 80](#)).

Dogs should be discouraged from coprophagia, and cat litter boxes should be isolated from other nonfeline pets. Within communities, animals should be restricted from defecating in playgrounds, parks, and walkways, or owners should remove their pets' excrement from public places.

Improved health education of children should be provided. Children should be educated not to practice geophagia or pica and to wash their hands after playing in soil. Those with aquatic or cold-blooded pets should wear rubber gloves for cleaning aquariums or terrariums. Diarrheic pets should not be exposed to the general household and should not contact young children of immunosuppressed members in a household. Animals with diarrhea should be bathed as needed to decontaminate their hair coat. Pet owners should be instructed to wear rubber gloves during cleaning of diarrheic or other stools and to use sodium hypochlorite (bleach) at a dilution of 1 ounce per quart of water for disinfection. Similar precautions can be recommended for handling other body fluids, including blood, urine, and saliva. Hands should be washed after the gloves are removed.

99.8.6 Oral Hygiene

Immunocompromised owners should be advised not to let pets lick them on the mouth and to practice good preventive dental hygiene for themselves and their pets. Routine dental prophylaxis with scaling or brushing is recommended for pets exposed to immunocompromised people. Veterinarians or other household members or assistants should assume these responsibilities. Saliva should be washed from hands or open wounds. Rubber gloves should be worn when oral medication is given to pets, or someone else should assume these responsibilities.

Infectious Diseases of the Dog and Cat, 3rd Edition

Bite wounds are probably the most common health risk faced by immunocompromised individuals. Pets that are aggressive in behavior or play should not be kept by immunocompromised people. People who are inadvertently bitten should immediately wash the wound with soap and water and rinse it with dilute organic iodine solutions or quaternary ammonium compounds as an alternative. A physician should promptly examine any injuries. Pets should not be allowed to lick human wounds. Children should be taught not to startle feeding or sleeping animals. Prophylactic antimicrobial therapy may be considered by physicians who know the patient's immunocompromised status.

99.8.7 Nutrition

The diet of pets is extremely important in limiting fecal-oral pathogens. Only commercial diets that have been cooked or pelleted should be fed. Raw or unprocessed meat or offal or unpasteurized dairy products should not be provided. Pets should be prevented from coprophagy, scavenging, hunting, and feeding on carrion or garbage. They may have to be leashed or confined or be supervised outdoors. Bells can be placed on cats' collars to reduce their success at hunting. Water from the tap should always be available to pets. Commercial bottled water should be provided if the tap water is unhealthy from inadvertent contamination with bacteria or protozoa. Access to outside surface water or toilet bowl water should be restricted.

100 CHAPTER 100 Immunoprophylaxis

Craig E. Greene

Ron D. Schultz

Immunoprophylaxis (vaccination) involves enhancement of a specific immune response in an animal in an attempt to protect it against infectious disease. This response can be actively induced through vaccines containing microorganisms, their components, or their metabolic by-products. Immunity can also be passively transferred by the administration of humoral or cellular factors obtained from a previously sensitized donor. Immunoprophylaxis also implies preexposure potentiation of the immune system, and it should be differentiated from immunotherapy, which is the attempt to increase nonspecifically the immune response in an already infected animal. See [Chapter 2](#) for a discussion of immunotherapy and available treatments. Immunoprophylaxis is successful in the prevention of viral and bacterial diseases because the relatively small number of antigens needed to stimulate an immune response is present in these organisms. Fungal, protozoal, and metazoan pathogens and neoplasms contain more complex antigenic determinants and are often controlled with nonspecific immunotherapy. Nevertheless, vaccines are being developed for some of these infections of dogs and cats.

100.1 MATERNAL IMMUNITY

IgG from breast milk is transported across the intestinal epithelium into the circulation of the neonate. This action occurs in the duodenum and jejunum through membrane receptors on the intestinal epithelium that facilitate transport of IgG into the systemic circulation. This process is maximal at the time of birth (under 24 hours) but also occurs to a limited degree throughout the remainder of the nursing period. Animals that do not obtain these maternal-derived antibodies (MDAs) in large quantities during the early nursing period are at high risk for developing infectious diseases. As long as they circulate, MDAs absorbed into the circulation of the neonate feed back to inhibit endogenous IgG production; however, IgG synthesis will ensue again sometime after weaning. Over time, MDAs in the neonate naturally decay, causing a decline in the available protective antibody level until the animal is vulnerable to disease-causing organisms in the environment.

Although IgG concentration and absorption is important in the first few days of neonatal life, secretory IgA (S-IgA) is found in milk during the entire nursing period and becomes the primary defense against enteric and upper respiratory mucosal infections.⁵⁷⁷ In the dam, antigens of pathogenic organisms to which her mucosae are exposed prime T cells for cell-mediated immune (CMI) responses. These antigens activate B cells that produce the immunoglobulin found in her mammary secretions. IgG and IgM are in high concentrations in the colostrum; however, low levels persist throughout the entire nursing period. S-IgA is present in breast milk throughout lactation. S-IgA is highly effective in inhibiting the adherence of pathogens at the mucosal surface, causing their immediate neutralization.

Antibody production in the neonate can be stimulated only when the circulating MDA levels decrease below a specific threshold. This level is not absolute but is determined by the ratio of MDA to the dose level of pathogenic or vaccine antigen. Usually, pathogenic organisms can *break through* a higher level of this *blocking antibody* than attenuated organisms in live vaccines. Increasing the dose (titer) of vaccine antigen allows for earlier immunization in the face of MDA. The level of MDA transferred to each neonate varies according to the titer of the dam, the number of nursing offspring, and the level of exposure of the dam to vaccine or the virulent agent.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.2 PASSIVE IMMUNIZATION

Artificial (passive) transfer of specific antibodies or other immunoreactive substances from one individual to another has been classically used to treat a variety of infectious diseases in humans and animals. Use of passive immunization itself has been decreasing; however, it is beneficial in diseases in which serum antibody is protective; the host does not have the time or ability to mount an immune response; or antimicrobial chemotherapy is not available or effective. When given prophylactically or therapeutically, antibodies with specific organism-neutralizing activities can transfer specific protection from, or reduction in, numbers of infectious agents. Developing passive immunization protocols for opportunistic and nosocomial infections is even considered in human medicine.⁵⁸² Currently, passive immunization is used in small-animal veterinary practice in a few special instances. Various aspects of passive immunization are summarized in [Table 100-1](#). Immunoglobulins have been used to prevent infections with canine distemper virus (CDV), canine parvovirus (CPV), feline panleukopenia (parvovirus) virus (FPV), canine herpesvirus-1 (CHV-1), and feline herpesvirus-1 (FHV-1) in exposed, susceptible neonates. Specific immunoglobulins are less effective in treating infections once they have become established. In addition, they have little role in the protection against organisms that can persist intracellularly in phagocytes or lymphoid cells.

Passive administration of serum or immunoglobulin has a beneficial role in protecting colostrum-deprived neonates (under 2 days of age) against certain diseases such as parvoviral infections. Active immunization must be avoided because of the risk of inducing disease with modified live vaccines and because of the weaker response to killed vaccines at this age. Antisera given to older kittens (under 8 weeks) that become inadvertently exposed to FPV provide protection much sooner compared with that produced after vaccination. Passive immunization may also temporarily benefit severely immunosuppressed dogs and cats receiving cancer chemotherapy that may become exposed to infectious agents during a course of hospitalization.

Immune sera may be of prophylactic or therapeutic benefit in treating litters of puppies that are clinically affected with neonatal herpesvirus infections (see Therapy, [Chapter 5](#)). Serum, for treating CHV infection, should be prepared from recovered bitches that have previously had affected litters. Hyperimmune serum has been beneficial in treating parvovirus-infected cats and dogs within 4 days of experimental postinoculation (PI), which corresponded to the first day or two of clinical illness.^{258,386} In a placebo-controlled study involving dogs presented to a teaching hospital with parvoviral infection, the efficacy of a preparation of specific canine lyophilized IgG was investigated.³⁴⁴ Dogs receiving lyophilized IgG as adjunctive treatment had significantly decreased hospitalization time, reduced severity of disease, and reduced cost of treatment compared with dogs treated with conventional therapy alone. A commercial, multivalent, homologous hyperimmune immunoglobulin preparation (Stagloban® SHP, Hoechst Veterinär Gmb, Munich, Germany) containing a combination of high concentrations of antibodies against CPV, CDV, and canine adenovirus (CAV)-1 had been available in Germany for this purpose, although its manufacture has been discontinued. A commercial heterologous antisera produced in horses containing highly concentrated immunoglobulins is available in some European countries for treatment of cats (Feliserin® PRC, Impfstoffwerk, Dessau-Tomau, GmbH, Rodleben, Germany). This antisera contains a combination of antibodies against FPV, FHV-1, and feline calicivirus (FCV).

Table 100-1 Comparison of Passive and Active Immunoprophylaxis

VARIABLE	PASSIVE	ACTIVE
Advantages	Immediate protection Works for agents that are poor immunogens	Stronger protection Longer protection Anamnestic response
Disadvantages	Allergic reactions Hypersensitivity reactions Delays ability to vaccinate Short-lived protection Transfer of disease more likely	Delayed response
Indications	Exposed susceptible neonates Colostrum-deprived neonates Exposed immunosuppressed animals	Unexposed susceptible neonates Routine immunization Booster vaccinations

Increased levels of endotoxin and tumor necrosis factor have been observed in dogs with naturally occurring parvoviral enteritis.⁴²⁹ Heterologous antiserum produced in horses for *Salmonella typhimurium* endotoxin is commercially available (Septiserum®, Immvac®, Columbia, Mo.), and it has shown benefit in treating endotoxemia in dogs associated with experimental parvoviral infection (see [Chapters 8](#) and [38](#) and Drug Formulary, [Appendix 8](#)).¹²² Passive immunization with heterologous (equine or human) antitoxin is used in the initial treatment of dogs and cats with tetanus (see [Chapter 43](#)). Monoclonal antibodies (MABs) have been provided as specific passive immunoprophylaxis for infectious agents, but because they are usually produced in rodents, tolerance is low to systemically administered foreign immunoglobulins.

The efficacy of passive immunization depends on many factors, including the antibody titer to the specific agent involved and volume administered, the relative importance of serum antibody in controlling the particular infection involved, and the timing of administration of antibody compared with exposure. Because of the large amounts of foreign protein that are administered, allergic reactions are more likely with passive immunization. Transfer of infectious agents is more likely with administration of serum when noncommercially prepared products are used. Unfortunately, the administration of immunoglobulins also delays the ability to stimulate active immunity in the host by vaccination. Large amounts of exogenously administered antibody may negate endogenous antibody production by tying up vaccine antigens or by direct feedback mechanisms that are not clearly understood. The duration of protection received from passively administered antisera is short lived (often 2 to 3 weeks). The amount received is finite and, as with all exogenous proteins, undergoes accelerated elimination from the body, especially if it originates from a different species.

Although not readily available commercially in many countries, canine and feline immune sera can be prepared in veterinary practices by sterile harvesting serum or plasma. Immune serum (or plasma) is derived from clinically healthy, pathogen-free individuals or from groups of animals that have recovered from the disease in question, whereas hyperimmune serum comes from animals that have been well vaccinated against specified infectious agents. Veterinarians who prepare their own serum must carefully screen donors for insidious blood-borne infectious diseases such as bartonellosis, hemotropic mycoplasmosis, feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) infections, canine brucellosis, leishmaniasis, babesiosis, or ehrlichiosis. If noncommercial sera harvested from donor cats are used, the time of protection is unknown and depends on the amount of antibodies administered. In cats, because of naturally occurring blood-group antibodies, ideally, the blood type of both donor and recipient should match, or if cross-matching is not performed, only type A cats should be used as donors.

Infectious Diseases of the Dog and Cat, 3rd Edition

The minimum amount of immune sera required to confer protection is unknown and will depend on the respective antibody concentration. Doses of adult dog serum given to colostrum-deprived pups have ranged from 22 to 40 ml/kg; however, the serum IgG concentrations at this dose have been lower than that afforded by naturally acquired colostrum.^{52,453} Therefore higher range doses might be needed for pups unless they will be given an earlier initial vaccination series. The dose shown effective for cats, which was equal to that provided by nursing colostrum, is 5 ml of adult cat donor serum given subcutaneously (SC) or intraperitoneally (IP) at birth. This application is repeated again at 12 and 24 hours of age.³³¹ This dose is equivalent to 150 ml/kg based on the body weight of neonatal kittens. Careful attention must be paid to sterility during collection process, storage, and administration. Jugular venipuncture is preferred, and the area over the jugular vein should be shaved and prepared aseptically. Blood, at least double the amount of required serum, should be collected into sterile clotting tubes without additives. Serum can be stored frozen in single dose aliquots because IgG is a highly stable molecule; it can be stored up to a year if frozen (–20° C) promptly after collection.³³¹

Usually, serum is given SC; IP routes are possible and sometimes more accessible for puppies and kittens. Oral administration of serum, either alone or in a milk substitute, is probably the most effective means of treating colostrum-deprived neonates in their first (under 24) hours of life. Immunoglobulins might be absorbed to a lesser degree for up to 72 hours. Any mucosal protection afforded by orally administered serum is only temporary because unstable serum IgG, IgM, and IgA are destroyed by proteolytic enzymes once the neonate develops improved digestive function and bacterial colonization. In contrast, because of its stability, natural S-IgA in the dam's milk offers continued protection against mucosal pathogens during the entire period that the animal is nursing. Other routes for serum administration in neonates are intramuscular (IM), SC, intramedullary, and IP. These products have also been used intranasally (IN) to treat neonates with infectious upper respiratory disease. Immune sera is not usually administered intravenously (IV) to small puppies or kittens because of the tendency to produce immunologic or coagulatory reactions in the recipient and because of the difficulty in cannulating a vein. If given IV, plasma anticoagulated with citrate is more desirable compared with serum.

100.3 MATERNAL IMMUNITY AND VACCINATION

Newborn pups and kittens have the inherent capacity to respond immunologically to numerous antigens at birth, but this response is slower and inferior compared with that of older animals. Under normal circumstances, protection against infection during these early weeks of life is afforded by passive transfer of immunoglobulins and small amounts of cellular material from the dam. The amount (2% to 18% of the total) of antibody transferred in utero from an immune dam protects colostrum-deprived puppies or kittens but makes them refractory to immunization for a period (Table 100-2). Subsequently, the immunoglobulin absorbed systemically from colostrum may give the neonate a titer that may almost equal that of the dam in some instances (Table 100-3). Over time, the MDA declines with each disease having a characteristic half-life for elimination (Table 100-4).²⁵⁶ Antibody class is also important with respect to titer loss. Serum maternally derived IgA, IgM, and IgG in neonates are usually lost in the order given.

1071

Infectious Diseases of the Dog and Cat, 3rd Edition

1072

Table 100-4 Half-Life of Maternally Derived Immunoglobulins in Neonatal Dogs and Cats

DISEASE ^a	HALF-LIFE (DAYS)	USUAL DURATION OF PROTECTION AGAINST DISEASE (WEEKS) ^b
Canine distemper ¹⁹³	8.4	9–12
Canine parvovirus ^{456,457}	9.7	10–14
Infectious canine hepatitis ⁷⁵	8.4	9–12
Feline panleukopenia ⁵¹⁰	9.5	8–14
Feline leukemia ²⁶¹	15.0	6–8

Feline coronavirus infection ⁴⁴³	7.0	4–6

a Numbers in this column refer to reference numbers cited at the end of this chapter or on the CD.

b The duration of maternal antibody protection against disease usually corresponds to the interval over which vaccines are ineffective.

c Feline herpesvirus-1 infection.

Fig 100-1 Elimination of maternal antibody in the neonate in relation to vaccination. At a critical period, the antibody titer may block a modified live virus vaccine but fail to protect against infection with virulent virus. Higher antigen mass or less-attenuated vaccines break through this maternal antibody barrier sooner than lower antigen mass or more attenuated products.

Infectious Diseases of the Dog and Cat, 3rd Edition

The absolute titer of MDA in the serum of a neonate depends on the quantity of immunoglobulin received during nursing and the absolute titer of the dam. The amount is also inversely proportional to the size of the litter. Titers may be increased by vaccination of the dam just before conception. In one instance, vaccination during pregnancy has also been shown to have benefit for protecting neonates (see later discussion, Feline Vaccination Recommendations, Feline Viral Respiratory Disease); however, caution should be exercised by avoiding the use of attenuated-live products. Titer values are so variable among individual animals that quantitative predictions cannot be made short of direct measurement of serum immunoglobulins of the dam or puppy. Commercially available enzyme-linked immunosorbent assay (ELISA) kits are available for semiquantitative measurement of antibodies to CPV with or without CDV (Immunocomb®, Biogal®, Kibbutz Gal'ed, Israel; TiterCHEK™

CDV/CPV, Synbiotics, San Diego, Calif.; see [Appendix 6](#)).⁵⁸⁵ Repeated measurements (nomogram determinations) in neonates are usually impractical and expensive. Veterinarians usually use multiple vaccines, given at 2- to 4-week intervals, in an attempt to break through maternal immunity before exposure to virulent organisms ([Figs. 100-1](#) and [100-2](#)). Frequently given vaccines may also accelerate the depletion of the MDA present in the neonate's circulation. Attempts to overcome the interfering effects of MDA on vaccination have included antigenically related vaccines, such as measles for CDV; alternate routes, such as IN administration for canine or feline respiratory viruses or *Bordetella*; and different vaccine strains or types that are able to overcome maternal immunity at a younger age as with higher titer, lower passage CPV vaccine.

1072

1073

Fig 100-2 Comparison of response to sequential (2-week interval) vaccination in neonates with (*top*) and without (*bottom*) maternal antibody protection. The presence of maternal antibody delays the neonate's ability to produce successful active immunization.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.4 ACTIVE IMMUNIZATION

Vaccination, the production of an active immune response, involves stimulating the host with antigenic extracts or whole cultures of microorganisms. Clinical vaccination in small animals has been limited to diseases caused by viruses, bacteria, and some protozoa.

100.4.1 Types of Vaccines

Classic vaccines have generally been derived from whole organisms and are either live attenuated (modified live) or noninfectious or inactivated (killed). The advantages and disadvantages of these conventional whole-agent products are summarized in [Table 100-5](#). To increase potency and remove nonessential, potentially allergenic proteins, newer vaccines are being developed. Live agents are being modified by genetic deletion or recombination or use of naked nucleic acids. Newer noninfectious vaccines are using subunit fractions of purified agents or synthetic peptides produced by genetic recombination or antiidiotypes (see later discussion). [Table 100-6](#) compares these newer vaccines.

100.4.2 Live

Live whole agents in vaccines must be modified (attenuated) so that they retain immunogenicity and the ability to replicate in the intended host without producing illness. Attenuated vaccines stimulate CMI and long-lived humoral immune responses compared with noninfectious (inactivated or purified antigen) vaccines. T-cell stimulation is superior with attenuated products. Because they replicate in the host, initial antigenic content is of low importance; however, any factor that neutralizes or inactivates the vaccine will make it ineffective. Attenuation of agents is usually achieved by adapting them to unusual hosts, by subjecting them to prolonged storage, or by serial passage in tissue culture. Vaccines also have been developed by inoculating only partially attenuated strains of organisms at sites other than those of their tissue tropism. Use of an alternate vaccination site has been used to produce parenteral vaccines against respiratory pathogens, such as for feline viral respiratory disease. The agents undergo limited replication at the alternative sites, but, unfortunately, they may produce a greater systemic response rather than local antibody response. Furthermore, inadvertent contact of these agents with respiratory tissues may cause disease (see later discussion, Postvaccinal Complications).

Quality control is an essential factor in the production of biologics to ensure that cell lines used in attenuating vaccine agents do not contain latent pathogens, especially in veterinary vaccine production, because this usually involves primary and secondary cell cultures (see Adventitious Agents under Postvaccinal Complications, later). Primary cell cultures are those derived from tissues harvested directly from an animal. Secondary cultures originate from further cultivation of primary cell lines. Both of these lines are at risk of containing pathogens. Established (continuous) cell lines employed for diagnostic virology, which have been adapted for stable growth in vitro, are usually too anaplastic for vaccine production. Unlike human vaccines, the primary or secondary cell lines for animals are usually produced from cells of the species for which the vaccine is intended. This practice increases the risk of contamination with potentially pathogenic, latent, or passenger organisms.

Live vaccines are usually lyophilized (freeze dried), which increases their stability and storage life span. Temperature is another important factor determining storage life span; vaccines should always be stored refrigerated at 4° C (39.2° F). Commercially prepared live vaccines usually contain excess antigen because some deterioration is expected.

Infectious Diseases of the Dog and Cat, 3rd Edition

Genetically altered recombinant vaccines involve removing genetic sequences that code for virulence factors while maintaining reproductive function. A gene-deleted FHV-1 vaccine has been developed experimentally.³⁰⁵ This method allows for selective attenuation of a variety of infectious agents when existing modified live-agent vaccines are ineffective. Insertion of a genetic marker may also be desired when determining vaccinated versus naturally diseased animals is important. When antibody titers are being used to distinguish between natural and vaccine exposure, such as with FIV infection, a unique vaccine marker would be beneficial.

Live agent recombinant vector vaccines use vector agents that are nonpathogenic to the intended host. These expression vectors are organisms in which genetic code has been inserted to produce key immunogenic proteins on a sustained basis after inoculation of the host. Vector systems can also be genetically altered to elicit killer T-cell or cytotoxic T-lymphocyte activity. Protein epitopes can be targeted by vaccines that are important for the agent's attachment, replication, development, or spread within the host. Multiple genes may be inserted, including those for cytokines such as interleukin (IL)-2, which may enhance the immune response to the simultaneously generated immunogenic proteins.

Expression vectors have included poxviruses, simian virus 40, bovine papillomavirus, adenovirus, and herpesvirus.^{31,609} Bacterial vectors such as *Salmonella typhimurium* and *Mycobacterium bovis* bacille Calmette-Guérin (BCG) and plants can also be used. All potentially pathogenic vectors must be attenuated for the host. Poxviruses such as vaccinia work well because of their large genome and wide host range. One potential problem with recombinant vector vaccines is that the host may mount an immune response to the vector. A recombinant vaccinia virus expressing FeLV gp70 envelope protein was not successful in producing antiviral antibodies in cats.¹⁹¹ Instead, inoculated cats developed neutralizing antibody against the vaccinia virus. Experimental recombinant vaccinia virus products have been capable of inducing immune responses in dogs to human influenza virus, rabies virus, herpesvirus, and hepatitis virus.²⁵

1074

Table 100-5 Comparison of Two Main Types of Conventional Whole-Agent Vaccines

	MODIFIED LIVE (ATTENUATED) VACCINE	NONINFECTIOUS WHOLE AGENT (INACTIVATED) VACCINE
Advantages	Rapid protection Prolonged protection Lower antigen mass needed Administer by natural routes Stimulates secretory antibody Better able to stimulate CMI Can administer locally (IN, PO) Better stimulator of interferon Overcome MDA interference One administration can protect Reduced allergenicity	No reversion to virulence Increased immunity with added adjuvants Stability in storage Safe in immunosuppressed animals
Disadvantages	Risk of adventitious agents Can produce vaccine-induced illness in immunosuppressed hosts Susceptible to inactivation Require more rigorous testing for potency and reversion to virulence Require multiplication in host Might revert to virulence No preservatives for storage	Primarily stimulates humoral immunity Minimum of 2 doses needed for maximum protection Increased risk of allergic complications Shorter duration of immunity than modified live vaccines Higher antigen mass needed Restricted to parenteral use Adjuvants frequently required More hypersensitivity reactions (local and systemic)
Indications	Outbreaks Pregnant Production of mucosal immunity Routine vaccination	Pregnant animals Debilitated/immunosuppressed animals Colostrum-deprived neonates (passive immunization preferred)
Diseases for which used	Canine: Parvoviral enteritis Hepatitis Bordetellosis (IN) Parainfluenza Distemper Measles Feline: Panleukopenia Calicivirus infection Rhinotracheitis Infectious peritonitis (IN) Bordetellosis (IN) <i>Chlamydomphila</i> infection	Canine: Lyme borreliosis Coronaviral enteritis Parvoviral enteritis Hepatitis Bordetellosis (parenteral) Leptospirosis Herpesvirus-1 infection Babesiosis Giardiasis Rabies Feline: Panleukopenia Calicivirus infection Rhinotracheitis FeLV infection Rabies FIV infection Giardiasis <i>Chlamydomphila</i> infection
CMI, Cell-mediated immunity; IN, intranasal; PO, by mouth; MDA, maternally derived antibody; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus		

1074

Table 100-6 Comparison of Newer Types of Vaccines

TYPE ^a	PRODUCTION METHOD	ADVANTAGES/DISADVANTAGES	EXAMPLES
Attenuated (Modified Live)			
Genetic deletion ³⁰⁵	Selected genome removed to reduce virulence	A: Controlled attenuation D: Only certain organisms can be modified this way; costly to produce	Experimental: FHV-1 ^b infection
Recombinant vector ^{115,481,559,561}	Genomic portion encoding for immunogen of pathogenic organism inserted into an avirulent "vector" organism	A: Stimulate immunity without disease-producing potential; may co-express immunomodulators or multiple agents simultaneously D: May produce persistent immunopathologic response; may spread environmentally; may produce genetic instability of vector or host; costly to produce; vector can be cytolytic	Experimental: oral and parenteral rabies; FIP, panleukopenia, feline leukemia, canine distemper, CPV infection ^b ; Commercial: canine distemper Recombitek® CDV (Merial) ^b ; Feline leukemia PureVax® and Eurifel® (Merial) ^b ; Feline rabies PureVax® (Merial)
Nucleic acid (DNA, RNA) ^{263,473}	Naked genes encoding for antigen are inserted into a plasmid carrier	A: Triggers cell-mediated immunity; yields protein antigens in natural form; easy to manufacture D: Potential antinucleic responses; introduces foreign genes into host	Experimental: canine distemper Experimental: CPV infection
Noninfectious			
Purified subunit ³¹¹	Organism propagated in vitro with purification of selected components; otherwise chemical synthesis of specific immunogenic	A: Purified proteins; less allergenic; no postvaccinal illness D: Works primarily for humoral immune proteins; protection; costly to produce	Experimental: CPV-V ₂ protein Commercial: bordetellosis (cell wall extract), Bronchicine® (Pfizer) ^b ; feline leukemia, Leukocell® 2-(Pfizer) ^b ; leptospirosis (envelope), Duramune® Max (Fort Dodge) ^b
Recombinant protein	Desired gene cloned into organism that produces it in vitro, followed by harvesting and purification	A: Highly purified immunogen; higher potency possible D: Primarily stimulates humoral immune protection	Commercial: feline leukemia, Leucogen® (Virbac) ^b ; borreliosis, Recombitek® Lyme (Merial) ^b ; borreliosis, Prolyme® and Nobivac® (Intervet) ^b
Antidiotypes	Immunoglobulins produced against antigen-combining sites on immunoglobulin directed against the infectious agent	A: Highly specific immune response; stimulates cell-mediated immunity D: Foreign proteins potentially reactive	None
A, Advantage; D, disadvantage; FHV, feline herpesvirus-1; FIP, feline infectious peritonitis; CDV, canine distemper virus; FeLV, feline leukemia virus; CPV, canine parvovirus.

- b See [Appendix 3](#) for more information on particular commercial products.

1075

1076

Commercially available oral rabies vaccines with poxviruses as vectors have been employed to protect wildlife. Canarypox has been an effective vector in vaccines for canine distemper, rabies, and feline leukemia.^{207,559,561,562} Throughout the world, a canine canarypox virus–vectored distemper vaccine is commercially available for administration by injection (Recombitek CDV, Merial). Pups vaccinated with canarypox-rabies vaccine could be protected at a young age despite the negating influence of MDAs.⁵⁶¹ Parenteral canarypox-FeLV recombinant vaccine (Eurifel, Merial), expressing the envelope and *gag* genes, was protective against oronasal challenge with virulent FeLV.^{207,561} A needle-free injection system (VET JET®, Bioject Medical Technologies, Tualatin, Ore.) is licensed to administer a similar product (PureVax, Merial) transdermally.^{207,436} A recombinant baculovirus was used to express the VP2 capsid component of CPV, and the respective vaccine produced titers in dogs that were higher than those from commercially available inactivated vaccine.^{115,122} A canine adenovirus 2–based CDV vaccine expressing the H and F antigens was effective, in the face of MDAs, in protecting pups against a challenge with virulent CDV.¹⁶⁰

Various plant sources, *Agrobacterium tumefaciens* TL plasmid, cow pea mosaic virus, and potato virus C have been used as expression vectors for CPV-2 vaccination of dogs.^{212,383,408}

Nucleic acids (RNA or DNA), when inoculated as naked or plasmid-containing molecules containing complete gene coding, can stimulate production of immunogenic proteins by the host without being permanently incorporated into the host cell genome. Thus, unlike attenuated vaccines, nucleic acids are noninfectious and have no risk of causing disease. Nucleic acid vaccines are stable, resisting extremes in temperature, making their storage and preservation more practical and less expensive. They can be used to develop broader antigenic subtypes and induce both humoral and CMI responses. DNA vaccines appear to be most effective in stimulating long-lasting cytotoxic T cells and variable antibody responses against expressed proteins. Direct IM or intradermal (ID) inoculation of DNA from pathogenic organisms is a promising method for vaccination against some diseases.⁴⁷³ Practical limitations to use of these vaccines are that they may alter the genome of inoculated hosts and the numerous patent considerations on the technology used to create the final product. The nucleic acids are injected by inoculation devices, with or without substances such as liposomes or gold particles, which facilitate uptake by host cells. Second-generation DNA vaccines have been designed to contain genes encoding for cytokines or immunostimulatory molecules that act as biologic facilitators of the immune response. Without being able to deliver the genes and express them at sufficient levels at the correct site, the technology may not be commercially viable.²⁸

Classical DNA vaccines are injected IM and have little ability to stimulate S-IgA responses. Formulations with microparticles, cationic lipids, protein polymers, or biodegradable microspheres allow for oral or IN delivery and result in significant S-IgA production at the mucosal sites.⁵³⁶ Such DNA vaccines have been used in clinical trials in people, and unfortunately, they provide weaker responses as compared with conventional vaccines. Giving a combination of a DNA vaccine first, followed by a booster using a different type of vaccine for the same disease, can provide an accentuated immune response.

A CDV nucleic acid vaccine has been produced that causes expression of the nucleocapsid, fusion, and hemagglutinin proteins.⁸⁵ Three IM injections of 12-week-old dogs, at 4-week intervals, induced a humoral IgG response and protected dogs against challenge with virulent CDV. In subsequent studies, this vaccine was

Infectious Diseases of the Dog and Cat, 3rd Edition

found to break through maternal immunity 2 weeks after birth because it was effective in priming the immune system to subsequent vaccination after a conventional modified live virus (MLV) CDV vaccine at 9 weeks.²⁰⁶

100.4.3 Noninfectious

Noninfectious whole agent (inactivated or killed) vaccines are produced in a similar fashion to live vaccines. Because noninfectious vaccines fail to replicate in the host, the level of antigenic mass is a critical determinant in the efficacy of a particular product. Inactivated whole-agent products contain agents subjected to various forms of denaturation without destroying their immunogenicity. Heat and light treatments have been relatively ineffective because, in many cases, they destroy immunogenicity without complete inactivation. Chemical inactivation with formalin produces slight modification in antigenic composition of the product, reduction in immunogenicity, and severe irritation to the animal at the site of injection. Ethylenediamine and β -propiolactone are inactivating agents that overcome many of these disadvantages. Having greater antigenic mass and added adjuvants (see Adjuvants, later), inactivated vaccines have an increased tendency to produce local and systemic allergic reactions.

Noninfectious vaccines are stable and have no risk of producing vaccine-induced illness. They are sometimes considered safer for this reason. However, these vaccines do not mimic natural infection and therefore may not produce adequate mucosal immunity or CMI. In general, noninfectious vaccines must be given at least twice to produce an anamnestic response that equals one attenuated vaccination (Fig. 100-3). Full protection may not develop until 2 to 3 weeks after the last immunization. Despite this shortcoming, immunity that is stimulated by noninfectious products is commonly sufficient for clinical protection and routine use. After vaccination with noninfectious vaccines, many partially protected animals probably become infected when exposed to virulent agents. They develop a mild or subclinical infection that further boosts their immunity to the disease.

Purified subunit vaccines are composed of purified immunogenic components of infectious agents that are used in an attempt to increase the specificity and quantity of the immunogen while reducing its allergenicity.

The components are recognized by the host immune system as foreign and elicit an antibody-based immune response. Examples of subunit vaccines are Pfizer Leukocell® 2 (Pfizer, New York, N.Y.) vaccine for FeLV, which is produced by harvesting cell-free supernatants from cell culture; parenteral lipopolysaccharide (LPS)-extracted cell wall *Bordetella* vaccine such as Bronchicine® (Pfizer, New York, N.Y.); and a purified outer membrane protein, leptospiral vaccine (Duramune® Max, Fort Dodge, Fort Dodge, Iowa).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 100-3 Comparison of antibody response after inoculation with noninfectious (*top*) and live attenuated (*bottom*) virus vaccine. One dose of the live attenuated virus vaccine continues to drive the immune response. Two doses of noninfectious vaccine are required to produce a similar effect. (Modified from Mims CA. 1977. *The pathogenesis of infectious disease*. Academic Press, New York, N.Y. Used with permission.)

Recombinant protein vaccines, developed using DNA technology, also allow for in vitro production of large quantities of immunogenic proteins by introducing coding into bacteria, yeasts, and continuous cell lines. These differ from recombinant vectors in that the preformed antigen is produced in large amounts ex vivo and then administered to the animal as a purified component. The FeLV vaccine (Leucogen®, Virbac, Carros Cedex, France; Nobivac®, Intervet, Boxmeer, The Netherlands) consists of synthetic glycoprotein for FeLV (gp70) subgroup A expressed in *Escherichia coli*.³⁶² Recombinant outer surface protein A (OspA) protein vaccines are also available for vaccination of dogs for Lyme borreliosis (Recombitek® Lyme, Merial, Iselin, N.J.; ProLyme®, Intervet, Millsboro, Del.). Synthetic antigens can be produced by identifying the antigenic or genetic determinants using MABs. Once the nucleotide and amino acid sequences have been determined, the protein can be synthesized. Unfortunately, many antigenically active peptides by themselves are weak antigens that require adjuvants. Recombinant subunit protein vaccines have a similar duration of immunity (DOI) as inactivated whole-agent vaccines, which is shorter compared with live attenuated products. A synthetic peptide VP2 has been effective in protecting dogs against CPV-2 infection.³¹¹

Infectious Diseases of the Dog and Cat, 3rd Edition

100.4.4 Adjuvants

Adjuvants have been added to noninfectious biologics in an attempt to increase their duration and amount of immunostimulation to a level comparable to that of MLVs. Adjuvants are helpful in accentuating the immune response to killed whole organism or purified antigens. They can prolong antigen exposure, enhance antigen presentation, and increase cytokine and immune responses.³³⁵ By definition and in principle, adjuvants produce a heightened inflammatory reaction, which can sometimes be deleterious. Fever, anorexia, swelling, hyperesthesia, uveitis, arthritis, meningitis, and glomerulitis are potential complications of adjuvant used. Examples and properties of adjuvants used clinically and experimentally are listed in [Table 100-7](#).

Adjuvants are basically of two types: vehicles and immunomodulating compounds. *Vehicles* can be composed of metallic salts, microparticles, copolymers, polysaccharides, oils, liposomes, emulsions, saponins, and immunostimulating complexes (ISCOMs). The type of adjuvant selected for a particular vaccine depends on the route of administration, the type of infectious agent, and the host being vaccinated.⁵³⁵ Adjuvants for mucosal vaccines must withstand harsh environments and facilitate an IgA response. Liposomes and other lipid moieties such as ISCOMS or microparticles and nanoparticles are used to coat antigens at the same time they facilitate an immune response. For a further discussion of liposomes and ISCOMs, see the discussion under Immunotherapy in [Chapter 2](#).

Vehicles maintain antigen at a specific site and intensify the body's reaction to the antigen. Purified subunit or recombinant products are poorly immunogenic without inclusion of an adjuvant. Emulsified water-in-oil (Freund's incomplete adjuvant) and mineral gels or metallic salt adjuvants such as aluminum hydroxide, aluminum phosphate, gold salts, and alum have been used.

Aluminum-based adjuvants are frequently associated with granulomatous reactions at vaccination sites. These reactions have been linked with sarcoma development in cats (see Postvaccinal Complications). The amount of aluminum can vary from 350 ppm for some FeLV vaccines to 800 ppm for some rabies products.³⁵⁴ Highest levels are contained in rabies vaccines having a 3-year DOI. One-year vaccines have approximately one half as much adjuvant, and some 3-year vaccines are sold under separate labels as 1-year products. To reduce the amount of adjuvant load, 3-year intervals of vaccination are recommended where legally approved.

Immunomodulators, which are usually composed of mammalian proteins or microbial components, include substances such as muramyl dipeptides, copolymers, and saponins, which stimulate local secretion of cytokines. They may enhance CMI, provide for slowed antigen degradation and release, and stimulate the function of the mononuclear phagocyte system to produce IL-1. This cytokine stimulates T cells to release IL-2, which, in turn, potentiates cellular defense mechanisms. Some cytokines have been given directly in an attempt to boost the immune response (see discussion of cytokines under Immunotherapy in [Chapter 2](#)).

Saponins are plant-derived extracts that are glycosides with hydrophobic moieties. Quil A (Spikoside® Isotec AB, Luleå, Sweden) has been given alone and in combination with aluminum hydroxide in a variety of veterinary vaccines. Quil A stimulates both humoral immunity and CMI by enhancing recognition of both soluble and membrane-bound antigens. Quil A is also a component of ISCOMs. Combination of a modified live feline viral rhinotracheitis-calicivirus-panleukopenia (FVRCP) vaccine with an inactivated FeLV vaccine increased the serologic response in kittens compared with those given the MLV FVRCP vaccine alone.²⁰⁸ Presumably, adjuvants in the FeLV vaccine were responsible.

Infectious Diseases of the Dog and Cat, 3rd Edition

Adjuvants have also been evaluated in stimulating protective immunity at mucosal surfaces.³³⁴ Adjuvants such as cholera toxin β -subunits, muramyl dipeptides, saponins, and phorbol esters have been used. Combinations of antigens with these substances produce specific S-IgA responses.

Using modified bacterial toxins to deliver vaccine antigens allows for more specific stimulation of protective cytotoxic T-lymphocyte responses.⁵¹⁹ The inherent ability of these toxins to bind and enter host cells makes them excellent candidates for this purpose. For safety, the toxin's enzymatic activity must be inactivated before use. Besides cholera toxin, others from virulent bacteria such as *Bordetella pertussis*, *Pseudomonas*, *Bacillus anthracis*, and *Listeria monocytogenes* have been used.

One disadvantage of adjuvants is that they may evoke local tissue reactions, granulomas, or abscess formations at the site of injection. Systemic manifestations of polyarthritis, uveitis, and autoimmune reactions have been documented in vaccinated people. Another concern is the potential development of vaccine-associated injection-site sarcomas (see Postvaccinal Complications).

Antiidiotypic antibodies are immunoglobulins produced against antigen-combining sites on specific immunoglobulins directed against the infectious agent. The antiidiotypic antibody actually resembles the antigen itself and stimulates T cells in a manner similar to that of a vaccine. Although veterinary vaccines of this type are only in experimental stages, antiidiotypic vaccines have the advantages of being produced by genetic manipulation and are safe because they lack the risk of the infectious agents contaminating attenuated vaccines.

100.4.5 Alternative Routes

New immunization strategies have been developed that make the deliver of vaccines possible without the use of needles or syringes. Originally developed for DNA vaccination, transdermal administration is achieved by using devices that generate high-pressure aerosols and inoculate the vaccine solution with minimal pain or apparent injury at the site of inoculation.⁵ Lower vaccine volumes can be used with this technique. Transdermal needle-free inoculation is commercially available for animal vaccination, specifically FeLV vaccination in cats²⁰⁷(see [Appendix 3](#)), and is likely to expand as newer products are licensed.

1077

1079

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-7 Comparison of Vaccine Adjuvants^a

ADJUVANT	COMPOSITION AND EXAMPLES	ADVANTAGES/EFFECTS	IMMUNE EFFECT	DISADVANTGES AND COMPLICATIONS
Metal salts	Aluminum hydroxide, gold salts	Safety	Stimulate Th2	Granulomas and potential neoplasia?
Oil emulsions	Oil-in-water and water-in-oil emulsions with surfactant	Strong response, can prolong antigen exposure	Humoral response	More granuloma and injection site inflammation
Liposomes	Vesicles of cholesterol and phospholipids	Safe	Humoral response and stimulate CTL	Weaker response without co-administered immunomodulators
Microparticles	Particles of biodegradable polymers such as cyanoacrylates	Long-term antigen release with dissolution	Humoral and CMI response, can use for topical administration	Microencapsulation may alter antigen properties
Saponins	Chemical extracts of the tree <i>Quillaia saponaria</i> (e.g., Quil A)	Relatively safe, currently used in many veterinary vaccines	Strong Th1, Th2, and CTL responses	Hemolysis with inadvertent IV administration
ISCOMs	Lipid moieties containing saponins, cholesterol and phospholipids	Relatively safe, used in a few veterinary vaccines, many preclinical trials	Strong Th1, Th2, and CTL responses	Toxic only at high doses
Copolymers	Nonionic hydrophobic petroleum-based polymers	Relatively safe	Humoral and some CTL responses	Local reactions since not biodegradable
Polysaccharides	High molecular-weight dextransphagocytosisreaction	Nonirritating locally	Block phagocytosis and slow antigen degradation	Systemic hypersensitivity reaction with repeated use
Proteins	Diphtheria or tetanus toxoid, bovine serum albumin, KLH	Relatively safe	Improve antigen recognition	Systemic hypersensitivity reaction with repeated use
Bacterial products	<i>Propionibacterium</i> spp., muramyl dipeptide, cholera toxins, LPS components, <i>Bacillus anthracis</i> toxin	Potent immunostimulants	Strong humoral and CRL responses	Can induce more severe sensitivity reactions
Cytokines	IFN- γ , IL-1, IL-2, GM-CSF, IL-12	Can direct specific immune response	Response depends on cytokine used	Often species specific in composition and effects; may promote autoimmune or hypersensitivity reactions
Complement derivatives	C3d fragment	Can direct specific immune response	Response depends on fragment used	Theoretical but unproven humoral hypersensitivity or autoimmunity

CTL, Cytotoxic lymphocytes; CMI, cell-mediated immunity; Th1, helper lymphocyte-1 (CMI); Th2, helper lymphocyte-2 (humoral); IV, intravenous; ISCOMs, immunostimulating complexes; KLH, keyhole limpet hemocyanin; LPS, lipopolysaccharide, IFN, interferon; IL, interleukin; GM-CSF, granulocyte-macrophage colony-stimulating factor.

Infectious Diseases of the Dog and Cat, 3rd Edition

a Adapted from information presented in Spickler AR, Roth JA. 2003. Adjuvants in veterinary vaccines: modes of action and adverse effects, *J Vet Intern Med* 17:273–281.

Mucosal application is used for a large number of commercial immunogens. S-IgA, produced by mucosal-associated lymphoid tissue, is effective in local protection against mucosal infection or penetration by infectious agents. Commercially available vaccines for respiratory infections in dogs and cats and feline coronaviral (FCoV) disease in cats make use of this locally protective immune response. IN vaccines are commercially available, depending on the product. Alternate mucosal delivery methods are also being considered to reduce side effects of parenteral inoculation, stimulate local immunity, and increase effectiveness. Orally administered vaccines using microencapsulation or chimeric plant viruses are in development. The chimeric plant–virus vaccines are made by recombinant technology, and immunogenic protein genes are inserted into plant viruses that are often administered in food plants or grains by enteral routes (see previous discussion, Live Agent Recombinant Vector Vaccines).

When mucosal response to vaccine is evaluated, S-IgA should be used instead of serum IgA levels. Some secreted IgA does enter the blood following an immune response to a surface antigen exposure, and this adds to the total increase in blood IgA that is measured. Because of the ease of measuring serum IgA, vaccine manufacturers have often used this method as a means of determining protection; however, this method can be misleading.

Microencapsulation involves placing antigens into hydrogels or microspheres to protect orally administered antigens from gastrointestinal (GI) degradation. This approach sustains the antigenic stimulation and allows them to be exposed to the intestinal lymphoid tissues. Biodegradable microspheres are inert synthetic polymers (e.g., poly-D, L-lactide-co-glycolide) used to coat antigen and are similar to those used in absorbable suture material. Lipid microcarriers have been used to increase the immune response to topically applied vaccines. The type and size of the coating determine the duration of the antigenic stimulus. The primary and secondary waves of antigen release can be modified with coatings to simulate repeated vaccination after single-dose administration. Microspheres also have a potential usefulness in oral vaccines in that they protect against antigen degradation by gastric acid, allowing the antigens to reach intestinal lymphoid tissues in Peyer's patches. IP administration of adjuvanted vaccines may also have a regional effect on stimulating local intestinal lymphoid tissues.

Dermal vaccination involves administering vaccines in sprays and patches on the skin surface. Topical immunization has the potential to make vaccine delivery safer, with fewer reactions and better compliance.⁴³⁹ The skin-associated lymphoid tissue include keratinocytes, Langerhans cells, and T lymphocytes within local nodes. Keratinocytes establish the physical barrier while producing a variety of cytokines when they are exposed to antigens. Langerhans cells, located at the basal layer of the epidermis, capture and process antigens. They migrate via efferent lymphatics to paracortical T-cell areas of draining nodes and present these to naïve T cells. Antigens applied onto bare skin penetrate the continuous stratum corneum via intracellular or intercellular routes. The skin barrier can be made more permeable by hydration. Topical administration of cholera toxin (CHT) onto hydrated skin can confer protection against lethal mucosal toxin challenge in animals.¹⁹⁵

In addition to skin, the mucosal application of CHT or heat-labile enterotoxin, from gram-negative bacteria with other antigens, acts as an adjuvant. Adjuvants used to stimulate mucosal immunity (such as IL-1 or CHT) can induce both helper lymphocyte-1 (Th1) and helper lymphocyte-2 (Th2) immune responses, with mucosal delivery resulting in a predominant Th2 response. Vitamin D₃ precursor, 1 α -dihydroxy D₃, is a strong mucosal adjuvant that directs trafficking of dendritic cells in mucosae and causes a predominant S-IgA response. With

Infectious Diseases of the Dog and Cat, 3rd Edition

or without adjuvant, IN vaccination gives better IgA levels than do IM injections. A significant number of vaccines that incorporate these antigens are under development. Because the skin and mucosae of various animals are physiochemically different, current research involves finding efficient delivery systems that will allow consistent antigen delivery.²¹⁶

100.5 CONTROVERSIES CONCERNING ANNUAL VACCINATION AND INDIVIDUALIZED PROTOCOLS

Despite their tremendous benefit, vaccines are not always innocuous. The practitioner must weigh the potential for adverse consequences and financial limitations with the potential risk of infection against the inherent protection provided by individual products.^{466,533} Vaccine-induced illness has become a more significant concern given that its prevalence, although low, supercedes that of the diseases for which the vaccines are intended. Certain breeds and families of dogs have a higher prevalence of postvaccinal reactions (see Postvaccinal Complications, later). With routine standard protocols, some animals will be vaccinated too frequently or for diseases for which they have no risk or for which vaccines are of questionable benefit. There are other animals for which the risk of infection is so great that more frequent or earlier vaccination, or both, is needed. Use of multivalent vaccines is convenient and cost effective; however, at times, it may limit customization of vaccine schedules for animals when exceptions are needed.

Recent protocols and recommendations from veterinary organizations in North America and Europe have indicated that vaccination intervals of animals over 1 year of age should be increased beyond the annual basis.* The consensus of these groups asserts that no one schedule is optimal for all animals. Because of increased awareness of vaccine reactions, vaccination schedules must be individualized for each patient. Yearly boosters can no longer be recommended for all animals. Annual clinical examinations rather than vaccination should be emphasized for pets. A summary of these recommendations can be found in [Tables 100-8 and 100-9](#).

100.5.1 Overvaccination

With current vaccines, a series of at least three injections for kittens and puppies, ending at 12 and 16 weeks, respectively, can be recommended. One year later, a booster can be given, but subsequent boosters can be given triennially.

Annual vaccination of dogs and cats is a convenient but arbitrary circumstance. However, concerns have been raised that annual vaccination of dogs and cats may be too frequent. In a survey of private practice veterinarians and their clients in the United States, more than 96% of veterinarians recommended annual vaccination for distemper, hepatitis and parainfluenza, and parvovirus infections.⁴⁰⁷ Clients of these same veterinarians recognized that their dogs were receiving rabies (86%), distemper (84%), and parvovirus (84%) vaccinations. Fewer realized that antigens for hepatitis (58%), parainfluenza infection (55%), and leptospirosis (53%) were included. Veterinary opinion, not public pressure, is responsible for the antigenic content and frequency of vaccines given to pets. Recommendations for annual revaccination boosters were established in the late 1960s as an educated guess by experts in the field.²⁵⁴ The assumption was that annual vaccination would not hurt and would provide a means for a periodic preventative medicine program for animals.⁵⁰² In general, the trend has been to combine all vaccine antigens within a single product.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-8 Recommended Booster Vaccination for Dogs Based on Lifestyle and Habits^a

CANINE CLASSIFICATION	HABITS	FREQUENCY, BOOSTER TYPE
Kennel-group housing	In large animal holding facility such as a boarding or breeding kennel, humane society, laboratory research colony, or animal control housing	Annual: CDV, ICH, CPV, L, CPiV, Bd Optional: CHV, Bab, Gia, CCV, Lyme Triennial: R ^b
Outdoor enthusiast	Most of the time outdoors running unrestrained; unsupervised roaming and supervised or unsupervised hunting or fieldwork	Annual: CDV, ICH, CPV, L, CPiV, Bd, CCV, ^c Lyme ^c Triennial: R ^b
Outdoor socialite	Some of time outdoors; may contact other strange dogs on a periodic basis	Annual: L, CPiV, Bd, ^c R ^b Optional: CCV, ^c Lyme ^c Triennial: CDV, ICH, CPV, R ^b
Indoor socialite	Multiple-dog household, mostly indoors or confined but frequent contact with other known dogs through feeding, elimination, boarding, showing	Annual: L, CPiV, Bd, CCV ^c Triennial: CDV, ICH, CPV, R ^b None: Lyme
Indoor elitist	One- or two-dog household. Indoors mostly, but comes into contact with unknown dogs by occasional escapist activities	Triennial: CDV, ICH, CPV, R ^b Optional: L, CPiV, Bd ^c None: Lyme, CCV
Indoor pampered pooch	Strictly indoor, never comes into contact with other dogs; sits in the lap for hours at a time; rarely touches bare earth, a real couch potato	Triennial: CDV, ICH, CPV, R ^b None: L, CPiV, Bd, CCV, Lyme

CDV, Canine distemper; ICH, infectious canine hepatitis (canine adenovirus-2); CPV, canine parvovirus infection; L, leptospirosis; CPiV, canine parainfluenza virus infection; Bd, *Bordetella bronchiseptica* infection (bordetellosis [canine infections tracheobronchitis]); R, rabies; CCV, canine coronavirus infection; Bab, babesiosis; Gia, giardiasis; CHV, canine herpesvirus infection; Lyme, *Borrelia burgdorferi* infection (Lyme borreliosis).

- a An annual booster is given the first year after the primary immunization series of all puppies. Use these guidelines for subsequent boosters. These guidelines could vary based on the animal's source, breed, age, reproductive status, geographic location, boarding and travel, recreational or work use, disease prevalence or past diseases, or particular vaccine efficacy or complications. As an alternative to triennial vaccination, antigens can be separated with some being given each year.
- b Recommendations will be superseded by local public health laws. Rabies booster can be annual or triennial based on vaccine labeling.
- c Use of this vaccine also depends on prevalence in a given region.

With some viral infections, such as those caused by CDV, CPV-2, CAV-2 in dogs, and FPV and FCV in cats, serum antibody lasts for years without revaccination or exposure to virulent virus. Although such sustained response was initially attributed to MLV vaccination, it has been observed with some killed vaccines such as those for FPV. Specific-pathogen-free (SPF) research kittens that were vaccinated at 8 and 12 weeks of age had persistent antibody titers and were completely protected against FPV challenge 7.5 years later.⁵¹⁴ Protection against disease was not complete in that serum antibody titers declined beginning 3 to 4 years after vaccination, and clinical illness following FHV-1 and FCV challenge was 52% and 63%, respectively, less severe in vaccinated as compared with control cats. In another study,³¹² SPF cats were challenged between 9 and 36 months after vaccination, with one of three IN or parenteral commercially available vaccines

Infectious Diseases of the Dog and Cat, 3rd Edition

containing FHV-1, FCV, and FPV. Following challenge, all vaccinated cats were protected against virulent FPV that caused illness in all the control cats. Protection against clinical illness in FHV-1 and FCV challenge was partial as in the previous study. Similar extended DOI challenge studies have been published on components in multivalent canine vaccines.^{1,192} (See Duration and Degree of Immunity, later.) Antigens for CDV, CPV, and CAV₂ stimulate strong immune protection and dogs have been immune to challenge infection, which caused clinical illness in controls, after a 3-year interval.

Parvovirus diarrheal epidemics beginning in the late 1970s and breakthrough of protection from this infection with conventional products helped instill more frequent and extended vaccination protocols for pups and yearly boosters for adult dogs. Vaccination programs for cats changed in the 1980s as rabies outbreaks necessitated more widespread vaccination. The rabies vaccines changed to noninfectious adjuvanted products because of vaccine-induced disease that occurred with MLV products (see Vaccination, in Rabies, Chapter 22). In addition, a variety of noninfectious FeLV vaccines were introduced. These adjuvanted products have been suspected to be responsible for the increased prevalence of injection-site feline sarcomas (see later discussion). Despite documented adverse reactions to vaccines, the development of sarcomas in cats brought the concern regarding postvaccinal reactions and the questionable need for annual vaccination to the forefront.

1080

1081

Table 100-9 Recommended Booster Vaccination for Cats Based on Lifestyle and Habits^a

FELINE CLASSIFICATION	HABITS	FREQUENCY, BOOSTER TYPE
Cattery-group housing	In a multiple-cat, high-density environment, cats in direct contact and sharing litter boxes; stray or feral cats are being admitted on a periodic basis	Annual: FHV, FCV, FPV, R ^b , FeLV Optional: Gia, Bd, Chlam, FIP, FIV ^d Triennial: R ^b
Outdoor enthusiast	Most of the time outdoors; frequent contact with strange cats; multiple-cat open household, with new stray or feral cats being admitted	Annual: FHV, FCV, FPV Chlam, ^a R, ^b FeLV, ^c FIP ^d , Optional: Gia, Bd, FIP, FIV Triennial: R ^b
Outdoor socialite	Some of time outdoors; may contact other strange cats; fewer than three other cats in household	Annual: FHV, FCV, FPV, R, ^b FeLV Optional: Chlam, ^{c,d} FIP ^{c,d}
Indoor socialite	Multiple-cat household, mostly indoors or confined but frequent contact with other known disease-free cats when feeding, eliminating, boarding, showing	Optional: Chlam, ^d FeLV, ^{c,d} FIP ^{c,d} Triennial: FHV, FCV, FPV, R ^b
Indoor elitist	One- or two-cat household; indoors mostly, comes into contact with unknown cats by occasional escapist activities	Optional: R ^b , FeLV, ^{c,d} FIP ^{c,d} Triennial: FHV, FCV, FPV, R ^b
Indoor window watcher	Strictly indoor, never comes into contact with other cats; sits at the window for hours at a time	Triennial: FHV, FCV, FPV, R ^b None: Chlam, R, ^b FeLV, FIP, Bd, Gia

FHV, feline herpesvirus (feline rhinotracheitis virus [FRV]) infection; FCV, feline calicivirus infection; FPV, feline panleukopenia virus infection; Chlam, chlamydiosis; R, rabies; FeLV, feline leukemia virus infection; FIP, feline infectious peritonitis; Bd, *Bordetella bronchiseptica* infection (bordetellosis); Gia, giardiasis.

^a Annual booster is given the first year after the primary immunization of all kittens. Use these guidelines for subsequent boosters. These guidelines can vary based on the animal's source, breed, age, reproductive status, geographic location, boarding or hunting and travel, disease prevalence or past diseases, and particular vaccine efficacy or complications. FeLV-and FIV-infected cats should

Infectious Diseases of the Dog and Cat, 3rd Edition

only receive noninfectious vaccines. As an alternative to triennial vaccination, antigens can be separated with some being given each year.

- b Recommendations will be superseded by local public health laws. Rabies booster is given annually or triennially based on vaccine labeling.
- c Disease prevalence or serotesting, or both, will determine need for routine use.
- d Annual vaccination recommended for this optional product.

On the side of the argument for annual vaccination, pets may be more stressed and exposed to unsanitary conditions in their natural environment than animals in the research laboratories where challenge studies are performed. Dogs and cats may come into direct contact with other animals. Protection elicited by one product may not be used to predict the immune response generated by another brand of vaccine containing the same antigens. Furthermore, serotesting pets each year to determine whether boosters are needed rather than administering them may be impractical, expensive, and inaccurate (see Vaccine Efficacy, later). Annual or periodic vaccination allows for regular clinical examinations for detection and prevention of incipient illnesses. Up to 52% of dogs and cats brought to veterinary clinics for vaccination were found to have intercurrent disease, a factor that increased with advancing age.³⁴ Older dogs and cats have a noticeable decline in their immunity after 10 years of age.

Based on DOI studies on vaccine antigens, a compromise would be to extend booster immunizations every 3 years in adult animals for recommended (core) vaccines in dogs such as distemper, parvovirus enteritis, infectious hepatitis, and rabies and in cats for panleukopenia, viral respiratory infections, and rabies. Optional (noncore) vaccines in cats, which incidentally have shorter DOI intervals, are for feline leukemia, giardiasis *Chlamydophila* infection, and feline infectious peritonitis (FIP). In dogs, these noncore products are for Lyme borreliosis, giardiasis, and coronavirus and upper respiratory tract infections. If veterinarians elect to use revaccination intervals other than those indicated on the label, they should base their recommendations on the individual needs of the patient and sound immunologic principles.²⁵⁴ In the future, labeling of vaccines may indicate the specifics of challenge studies rather than a recommended 1-year booster interval. Recommended guidelines for vaccination boosters for dogs and cats with various backgrounds are summarized in [Tables 100-8](#) and [100-9](#), respectively.

1081

Overvaccination has also been questioned in the vaccination of neonates. The onset and frequency of vaccination and number of vaccine antigens have intensified as a result of disease outbreaks and the licensing of multivalent vaccines. In general, vaccines should not be given to animals under 6 weeks of age, and for some diseases, the animals should be older. MDA breakthrough at younger ages would likely occur only if the animal was colostrum deprived, or if IN vaccination was used. The immune system of pups and kittens is compromised during the first 2 weeks of life because of hypothermia. MLV vaccines, especially those for parvoviruses, have the potential for damaging tissues with rapidly replicating cells during this developmental period. Once vaccination is initiated, by at least 6 weeks of age, the subsequent interval of vaccination in this primary series should never be more frequent than every 2 weeks, with a 3- or 4-week interval being more desirable. The 2-week interval must be considered when the prevalence of disease in the animal's environment is high. For noninfectious vaccines, with the exception of those for rabies, at least two vaccines must be given, even in the absence of MDA. Many components of combination vaccines are not required during the initial vaccination series. When their need is justified, optional components (e.g., for respiratory diseases, leptospirosis, borreliosis, feline leukemia, coronaviral infection) should be given later in the series. This application will help maximize the immune response and reduce the chance that allergic reactions will develop in animals when susceptibility to severe consequences is greater.

1082

Infectious Diseases of the Dog and Cat, 3rd Edition

100.5.2 Vaccine Efficacy

Immunity after vaccination takes several days to develop, but it may last for years. After first-time or primary exposure to an antigen, the initial protection is usually provided by interferon (IFN) and later by an immunoglobulin response. The primary response is slower in onset than a secondary or an anamnestic response and initially is predominantly composed of IgM. A secondary response that follows reexposure to the antigen is characterized primarily by IgG.

Fortunately, veterinary vaccines, unlike their human counterparts, can be more extensively tested in the species for which they will be used, and appropriate challenge tests can be performed. The efficacy of a vaccine is determined by subsequently exposing vaccinated and unvaccinated animals to the same challenge dose and by measuring the incidence and severity of clinical disease that follows. Both humoral and CMI responses are important in protection from infection. Vaccines have an important role in stimulating both mechanisms. Unfortunately, humoral immune responses have often been measured after vaccination and thus equated with protection of an animal from infection. Some animals may actually be protected even in the absence of a serologic response. The significance of an absolute antibody titer is meaningful only when standardized serologic procedures are used and when this absolute titer is related to titers of protected animals following challenge infections. The correlation between antibody titers and protection from disease is good for self-limiting systemic infections such as with CDV, CPV, and FPV (Tables 100-10 and 100-11). Absolute titers may vary among laboratories and methodologies, making interlaboratory comparisons difficult.^{205,532,570} For FHV, FCV, and FPV, serologic titers have been correlated with resistance to challenge.^{312,514} In contrast, protection against many respiratory and GI mucosal surface infections is based on secretory rather than serum immune responses. Protection against persistent intracellular infections is more dependent on effective CMI. Challenge of the animal with a virulent agent is therefore a more reliable measure of vaccine efficacy. Cellular memory of past exposure to an antigen may persist long after serum antibody titers decline.

The development of tissue culture of viruses has greatly improved both the quality and the means of manufacturing veterinary vaccines. Commercial production, licensing, and marketing of biologics is rigidly controlled by the U.S. Department of Agriculture (USDA), the Ministry of Agriculture in the United Kingdom, the Bureau of Animal Health in Australia, the Department of Agriculture in Canada, and similar bureaus in other countries. Current testing guidelines include DOI, potency, and safety studies. Vaccines are evaluated for safety as demonstrated by tests for sterility, toxicity, and adventitious agents. Efficacy of products marketed in the United States is subsequently confirmed by challenge studies. The USDA has published procedures for evaluating efficacy of protection for many of the licensed veterinary vaccines (<http://www.aphis.usda.gov/vs/cvb>). Vaccine manufacturers are not required to test their products against those of competitors or evaluate them for interactions when their products are used in conjunction with those of other companies. Furthermore, they are not required to show challenge protection against infections produced by heterologous strains of the infectious agent under consideration. Generally, use of a vaccine from one manufacturer followed by boosting with another vaccine antigen is considered to be anamnestic. However, it should not be presumed that vaccines produced by different manufacturers, for the same antigen, are of equal efficacy. It cannot be assumed that the level and DOI will be identical for all brands. Differing strains are of especial concern for canine leptospirosis and borreliosis, and feline calicivirus, FeLV, and FIV infections.

After vaccines are studied in the laboratory on experimental animals, they are subjected to field testing by a limited number of practicing veterinarians before they are released for general usage. Many products had been

Infectious Diseases of the Dog and Cat, 3rd Edition

initially marketed without complete knowledge of DOI or adverse side effects. Manufacturers are receptive to reports of complications encountered by practicing veterinarians and, in turn, keep the veterinary profession informed of continuing efficacy studies and potential complications (see Postvaccinal Complications, later). For a listing of available vaccines and manufacturers in the United States, see [Appendix 3](#).

100.5.3 Duration and Degree of Immunity

DOI is important in determining the timing for booster vaccinations. With the exception of rabies vaccines, DOI of many marketed vaccines sold in the United States is not available because most challenge studies were performed 2 to 4 weeks after the last vaccination in a series. Manufacturers in the United States were under no legal obligation to demonstrate longer DOI for already-licensed antigens. In other countries, such as in Europe, vaccine licensing requires proof of DOI. Presently in the United States, USDA guidelines now require actual DOI challenge studies for vaccines containing “novel” antigens for which no other products are available such as *Borrelia* or FIV. Animals are held in isolation for the labeled period and are subsequently challenged or tested for serum antibody titers. Findings of longer-term studies must be comparable to challenge studies obtained a few weeks after vaccination. Although the minimum DOI must be determined, manufacturers are not obligated to establish the maximum duration. [Table 100-12,A](#) and [12,B](#) summarizes the studied DOI for many vaccines used in dogs and cats.

The DOI or efficacy of a vaccine to withstand challenge infection is expressed in terms of *preventable fraction*, which accounts for the proportion of vaccinated animals that do not develop a disease after challenge compared with those unvaccinated animals that do develop the disease. The number represents the fraction of animals that were truly protected by the vaccine. The formula is calculated as follows:

1082

Infectious Diseases of the Dog and Cat, 3rd Edition

1083

Table 100-10 Comparison of Canine Infections Prevented by Vaccination

CANINE DISEASE	TYPE INFECTION	PERSISTENCE	ORGANISM DETECTION METHODS ^a	PREFERRED ANTIBODY MEASURES ANTIBODY DIAGNOSIS	PROTECTION
Distemper	Self-limiting	CNS, retina	Direct FA: blood, conjunctival smear PCR: serum, urine, CSF	IgM-single; IgG fourfold change	Yes, VN preferred standard; Indirect FA and ELISA also used
Adenovirus-1 infection	Self-limiting	Occasionally liver	Direct FA: liver, kidney Cytology: intranuclear inclusions	IgM-single; IgG fourfold change	Yes, VN standard
Parvovirus infection	Self-limiting	None	ELISA: stool PCR: stool Direct FA: intestine	IgM-single; IgG fourfold change; Indirect FA preferred	Yes, HI standard; VN, ELISA also used
Leptospirosis	Self-limiting	Kidney, liver	Direct FA: tissues Immunoperoxidase: kidney	Agglutinin: single tentative Agglutinin: change best	Yes, neutralizing best Agglutination: short lived, low
Borreliosis	Self-limiting	Connective tissues	Direct FA: tissues PCR: tissues	C6 protein ELISA	OspA by immunoblot is best
Babesiosis	Persistent	Erythrocytes	PCR: whole blood Direct FA or cytology: smears	IgG: past exposure or active infection; ambiguous	No protection
Bordetellosis	Mucosal	Airway commensal	Direct FA: secretions or tissues	None	S-IgA, hard to quantify
Coronavirus infection	Mucosal	Intestinal mucosae	Direct FA: intestine	None	S-IgA, hard to quantify
Parainfluenza virus infection	Mucosal	Airway commensal	Direct FA: secretions or tissues	None	S-IgA, hard to quantify
Adenovirus-2 infection	Mucosal	Respiratory tract	Direct FA: airway secretions	None	S-IgA, hard to quantify
Herpesvirus-1 infection	Mucosal	Trigeminal and other neurons	Direct FA: mucosae during active infections	None	S-IgA, hard to quantify, virus latency
Giardiasis	Mucosal	Duodenum	Direct FA or immunoassay: stool	None	S-IgA, hard to quantify
Rabies	Persistent		Direct FA: CNS tissue	None	Yes, RFFIT, FAVN, neither infallible

CNS, Central nervous system; FA, fluorescent antibody; PCR, polymerase chain reaction; CSF, cerebrospinal fluid; VN, virus neutralization; ELISA, enzyme-linked immunosorbent assay; HI, hemagglutination inhibition; OspA, outer surface protein A; S-IgA, secretory IgA; RFFIT, rapid fluorescent focus inhibition test; FAVN, fluorescent antibody virus neutralization.

^a Other than by isolation of the organism.

Table 100-11 Comparison of Feline Infections Prevented by Vaccination

FELINE DISEASE	TYPE	PERSISTENCE	PREFERRED ANTIBODY DIAGNOSIS	ANTIBODY MEASURES PROTECTION
Panleukopenia	Self-limiting	None	IgM-single IgG-rise	Yes, VN preferred
Feline leukemia virus infection	Persistent intracellular	Lymphoid, myeloid	None, antigen used	Yes, VN standard; not available
Feline immunodeficiency virus infection	Persistent intracellular	Lymphoid	Yes-ELISA	No
Feline enteric coronavirus infection	Mucosal	None, occasional gut shedders	None	S-IgA
Feline infectious peritonitis	Persistent intracellular	Phagocytes	IgG-indirect FA	No
Feline calicivirus infection	Mucosal, generally	Airway commensal	None	S-IgA
Feline herpesvirus infection	Mucosal	Airway commensal	None	S-IgA
Bordetellosis	Mucosal	Airway commensal	None	S-IgA
<i>Chlamydomphila</i> infection	Mucosal	Airway commensal	None	S-IgA
Rabies	Persistent		None	Yes, but not infallible

VN, Virus neutralization; ELISA, enzyme-linked immunosorbent assay; FA, fluorescent antibody; S-IgA, secretory IgA.

$$\frac{\text{Prevalence (\% of disease in nonvaccinates)} - \text{Prevalence (\% in vaccinates)}}{\text{Prevalence (\% in nonvaccinates)}}$$

100.5.4 Serologic Testing and Challenge Studies to Determine Efficacy or Duration of Vaccination Responses

The concern about overvaccination has renewed interest in the use of antibody measurements instead of annual vaccination. Testing an animal's serum antibody titer has been proposed as a measure of protection against infections; however, such interpretations have limitations. Serologic responses are monitored in some instances for extended periods, but, unfortunately, serum antibody titers do not represent an absolute measure of protection in all types of infectious diseases. Additionally, it cannot be assumed that an animal with low serum antibody titer is unprotected or that animals with high serum antibody titers are protected. Therefore serologic monitoring must be done with discretion.

The type of antibody measurement is important in determining whether an animal is susceptible to infection. For example, serum neutralization (SN) and hemagglutination inhibition (HI) titers correlate with resistance to parvovirus infection. ELISA kits have been developed to detect antibodies against infectious agents. However, discrepancies can be found between measured antibody titers and protection because ELISAs are generally more sensitive and may detect other classes of antibodies.³¹² Only ELISAs that have been correlated with challenge studies should be used. Furthermore, failure to detect serum antibodies does not necessarily indicate that animals are not protected, especially if adult cats have been previously vaccinated.³¹² However, to err on the side of caution, overvaccinating animals with low or no measurable antibody titers is not considered a problem. Serologic testing should never be used to determine the level of protection of immunosuppressed animals or neonates with MDAs.

Infectious Diseases of the Dog and Cat, 3rd Edition

The type of infection produced by an agent is important in determining whether antibody titers will correlate with protection. Organisms that spread extracellularly in body fluids during the course of infection are most susceptible to the effects of circulating antibodies. In these infections, adequate antibody titers can provide sterile immunity. When immunity is sterile, it provides complete protection against infection. In such instances, challenge with a virulent or attenuated infectious agent results in no replication of the organism and no change in the serologic titer. Serum antibody titer measurements may provide valuable insight into the degree of protection for extracellular spreading systemic infections such as with canine and feline parvovirus infections and infectious canine hepatitis (ICH) and canine distemper.*

The absolute values of titers for protection against these diseases vary depending on the laboratory and method used. Antibody titers of sufficient magnitude indicate presence of an immune response and correlate with sterile immunity against infection. Cut-off titers are determined by correlating challenge protection studies or low prevalence of infection with measured antibody titers in the population studied. The absolute value of cut-off titers for protection will vary depending on the laboratory and method used. One problem is that not all laboratory assays have been validated. Practitioners should carefully evaluate whether the assays they are requesting have been correlated with reference laboratories that have measured challenge protection.

For mucosal infections such as bordetellosis, canine coronaviral enteritis, and FCV and FHV-1 infections, S-IgA concentrations are more important than are serum antibody titers. For persistent intracellular infections, such as FIV and FeLV infections and FIP, CMI is critical. Antibody titers are best used to document these infections rather than as a measure of protection. These intracellular organisms can replicate in cells regardless of the concentration of extracellular antibodies. Serum antibody measurements have no relevance with respect to protection against these infections. However, cell-mediated immune responsiveness is difficult to measure objectively in a clinical setting.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.5.4.1 Dogs

HI titers for CPV and SN titers for CDV were measured in 122 dogs ranging from age 1 to 13 years that were vaccinated between 271 and 1665 days prior.³⁷⁴ These two assays are generally considered the gold standard of antibody measurement for the respective diseases. Twenty-five percent of the dogs had a less than protective CDV titer, and 27% had a less than protective CPV titer, showing that a majority of dogs are protected, even with a delay in annual revaccination. In another study, sera from 1441 dogs in the United States, ranging from 6 weeks to 17 years of age, were tested for indirect fluorescent antibodies (FA) to CPV and CDV.⁵⁷⁵ In this study, positive seroreactivity was correlated with protective HI and SN titers performed by a reference laboratory. The results indicated a high prevalence of antibody response to CDV (96.6%) and CPV (95.1%). Of the 468 dogs for which vaccine histories were available, the interval between testing and prior vaccination was 1 to 2 years for 281 dogs, 2 to 7 years for 142 dogs, and less than 1 year for 45 dogs. Dogs 2 years age or older were evaluated for their antibody titers to CDV, CPV, CAV-1, CAV-2, and canine parainfluenza virus (CPiV) before and after vaccination, with a delay of up to and beyond 48 months since a previous vaccination with the same vaccine used previously.³⁹⁷ The percentage of dogs that had titers at or greater than the threshold values for being protected or that responded to revaccination with a greater than or equal to fourfold increase in antibody titer was 98.1% for CDV, 98.1% for CPV, 98.4% for CAV-1, 99% for CAV-2, and 100% for CPiV. Serum antibody titers to CDV, CPV, and CAV were measured in dogs from the south of England that had not been vaccinated for a range of 3 to 15 years.⁴⁸ Protective titers were found in 95% to CPV, 71% to CDV, and 82% to CAV. The high prevalence of titers to CPV was presumably caused by natural exposure in the environment. In a majority of dogs, a significant increase in antibody titers after booster vaccination with the three MLV antigens was not found, which suggests that the dogs were protected from infection with the MLV vaccines despite the variable delay in vaccine boosters. This finding is important because studies determining whether dogs or cats develop a greater than or equal to fourfold increase in antibody titer following vaccination show that the antibody titer had decreased sufficiently to allow the immune response to occur. Even though the antibody response had waned, life-long memory cell immunity is still present in these animals, and they will respond more rapidly than will the naïve animal. Unfortunately, the antibody blockade also explains why it is difficult to produce hyperimmune sera in dogs against infections in which antibody is protective, such as canine and feline parvoviral infection and canine distemper.

1086

1087

An MLV combination CDV, CPV, CAV-2, and CPiV vaccine was evaluated for DOI protection in pups given two vaccines at 7 to 8 and 10 to 11 weeks of age, with challenge 55 to 57 months after initial vaccination.¹ All vaccinates were protected against clinical disease following parvovirus and CAV-1 experimental challenge, and 90% were protected against CDV infection. None of the control animals were protected. This result would suggest at least a 4-year DOI for these core fractions of the vaccine. Similarly, a 3-year DOI challenge study has been conducted for a vaccine containing MLV combination distemper, adenovirus-2, and parvovirus-2.^{192,315} Dogs were vaccinated at 6 weeks of age or less and 3 weeks later. Groups of dogs were challenged independently for each antigen 3 years later (intracerebrally for CDV and oronasally [ON] for CAV-1 and CPV-2). All vaccinates were protected against infection with CDV and CPV-2 while all controls were ill. In the CAV-1 challenge, only 25% of vaccinates showed mild illness while all of the controls were severely affected.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.5.4.2 Cats

Information correlating serum antibody titers with protection against challenge infection is available for FPV, FHV-1, and FCV infections. With FPV, serum antibody titers measured by virus neutralization (VN) or ELISA can be used to measure resistance to infection. SPF laboratory kittens, vaccinated with inactivated products, were protected against challenge 7 years after the initial series.⁵¹⁴ Measured titers following vaccination, which have been correlated to challenge studies, have been used to predict protection.^{312,514} In a serologic evaluation, cats 2 years of age or older were tested for antibody titers to FPV, FCV, and FHV before and after MLV vaccination with the respective antigens.³⁹⁸ There had been a delay of up to 48 months or more since the last vaccination. The percentages of cats with titers at or above the threshold values, or responded to revaccination with an equal to or greater than fourfold increase in titer were 96.7% for FPV, 97.8% for FCV, and 88.2% for FHV. Notably, vaccine protection for FHV-1 and FCV is not complete; instead, it lessens the severity of infection on subsequent challenge.

A 12-month DOI study was conducted for FeLV vaccine in which kittens were vaccinated at 9 and 12 weeks of age.²¹⁸ The preventable fraction after challenge was 63%. Although VN antibodies were not increased following FeLV vaccination, they were increased following challenge with virulent virus in cats that were protected from infection. Other animals that did not develop VN antibodies after challenge became persistently viremic.

100.5.4.3 Rabies

Evidence for long-term immunity following rabies vaccination is based on challenge compared with serologic data. SN titers of 0.5 IU/ml have correlated with protection against challenge with virulent rabies virus in dogs and cats. This level is currently the cut-off titer for protection, as designated by the World Organization for Animal Health, Office of International Epizootics (see [Chapter 22](#) and [Table 99-3](#)). The rapid fluorescent-focus inhibition test (RFFIT), a modified VN method, and the fluorescent antibody virus neutralization (FAVN) methods have supplanted the standard SN test as a measure of protection following rabies vaccination. See [Appendix 5](#) for a list of some laboratories that perform these assays. Generally, many countries require a rabies immunization at least 3 to 6 months before importation with a minimum acceptable antibody titer and implantation with an identifying microchip. The required interval between vaccination and titer measurement varies among countries. A protective titer is a minimum of 0.5 IU/ml for the RFFIT or FAVN, and this value corresponds to a protective level determined with the SN titer. If the titer is insufficient, then a booster dose of vaccine with a followup titer is indicated. In the United Kingdom, the guidelines for importing pets involve the Pet Travel Scheme (PETS). A physical description of the animal and its vaccination history are available along with submitted serum. In a group of 1002 serum samples, 48 failed the blood test for importation, and all of these failures had received only their primary vaccination.⁶⁶ Subsequent analysis of failing animals at two laboratories showed that the failure rate for dogs was 4.12% and 5.16% and for cats was 2.85% and 2.67%. Significant differences in response rates were noted between the vaccine brand, between one or two doses of vaccine (dogs only), and between 4 to 5 weeks after vaccination. In cats, neutered animals had less risk of failing the serologic response. This finding suggests that animals that fail the criteria should be revaccinated with another product and the sampling be performed between 4 to 5 weeks after vaccination, should these criteria be suitable for the importing country. For cats, neutering may be of benefit if it is not of concern to the owner.

Infectious Diseases of the Dog and Cat, 3rd Edition

PETS was introduced as an alternative to quarantine for dogs entering the United Kingdom from rabies-free countries. Although quarantine was effective, animal welfare concerns were that isolation of animals was detrimental to the well being of pets and their owners. However, in addition to preventing rabies, the quarantine procedures have detected a large number of exotic diseases that might have entered the country unchecked.³⁵⁹ For further information, see Quarantine to Reduce Spread of Exotic Infections, [Chapter 94](#).

100.5.5 Effect of Age on Immune and Vaccine Responses

Dogs' and cats' immune systems are fully mature by 6 months of age. Therefore a booster vaccination is recommended after 1 year has lapsed from the primary immunization given during the early postnatal period. With some systemic extracellular spreading organisms, in which antibody is protective, such as CPV, CDV, and FPV infections, one vaccination may produce long-term immunity lasting many years and perhaps for the life of the animal.

Decline in the immune response to vaccination with advancing age may be a concern for the timing and frequency of inoculation of older dogs and cats. Aging is a multifactorial process, involving genetic control and a gradual decline of the immune, neuroendocrine, musculoskeletal, cardiac, and renal systems. In tissues, oxidative changes in cells and nucleic acids are responsible for many of these changes, and antioxidant nutrients may be beneficial in slowing this decline.⁴⁹¹

Compared with mice and humans, relatively little is known about the effect of age on the immune system of dogs. Concentrations of IgA have been shown to be increased in serum and saliva of aged dogs.¹⁸⁸ No

1087

difference in the concentration of serum IgG was found between young and aged German shepherd dogs.⁵⁴⁸

1088

Older Labrador retrievers have decreased lymphocyte stimulation to mitogens and increased percentages in total T cells but a decreased percentage of CD4+ cells.^{199,222} In dogs of various breeds, 32 young (3.15 ± 0.8 years) and 33 old dogs (12.1 ± 1.3 years) were vaccinated against distemper, parvovirus, and rabies.²⁴¹ No differences in postvaccination titers against any of the viruses between old and young dogs were noted. Whether such titers would persist after a 3-year vaccine interval is uncertain.

Few studies have been conducted concerning the aging of cats and their immune responses. Cats are considered young adults between 2 and 5 years of age, old adults at 7 to 8 years of age, and geriatric after 10 to 12 years of age. Geriatric cats had higher serum IgA and IgM but lower leukocyte counts and lower absolute values of T cells, B cells, and natural killer cells compared with young adult cats.⁶⁹ In geriatric cats, prevention of obesity by chronic restriction of caloric intake is correlated with a slowing of the aging process. However, within 4 days, acute nutrient deprivation in cats causes a reduction in lymphocyte stimulation, lymphocyte numbers, and lowered CD4+/CD8+ ratios.¹⁷² Following reinstitution of feeding, older cats (over 8 years) took three times longer to return to previous values as compared with young felines. Monocyte-cell function, as expressed by phagocytic activity and major histocompatibility complex (MHC) class II expression, was reduced in old versus young clinically healthy cats during short-term nutrient deprivation.⁵²² Vaccine studies were conducted in a group of 28 aged cats that were fed a diet with or without enrichment (omega-6 or omega-3 fatty acids). Cats with the supplement had an enhanced T-cell response to a bacterial immunomodulatory drug but had a diminished CMI response, as well as a reduced response to a viral-directed vaccine challenge.⁴⁹¹ This finding suggests that diet manipulations of fatty acids may alter the immune response of aged cats and potentially their vaccine responsiveness.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.5.6 Combination Vaccines

Commercial production of combined vaccines has made vaccination protocols less expensive and more convenient for both the veterinary professionals and pet owners. Interference testing, required for licensing, helps assure the veterinarian that antigens in multivalent products will produce immunity equal to individual antigens administered separately without risk of complications. Separate vaccine products may result in exposure to more extraneous proteins and allergenic components than the same antigens in combination; however, using combined antigen products may contain more total adjuvants than using products with only the desired components. Chemicals or adjuvants intended for one product may interfere with the effectiveness of another. As a general guideline, to prevent potential allergic or neoplastic complications, as few inactivated antigens as needed should be used during routine booster immunization. Veterinarians should administer these antigens as they believe necessary by profiling patients and giving the antigens as multivalent products when possible. The only disadvantage is that more than one multivalent combination vaccine may be needed in inventory.

100.5.7 Vaccination Failures

Vaccination does not equal immunization. Even with all factors taken into consideration, no vaccine stimulates an immune response in 100% of the population to which it is administered. Compared with the degree of severity of illness in unvaccinated animals, some licensed vaccines may reduce severity of clinical disease or the number of ill animals after challenge infection rather than provide complete protection. Even with vaccines that are highly protective, biologic variation is responsible for vaccine breaks in a low percentage of vaccinates. Protection of 70% of the population may be effective in reducing the prevalence of diseases when communicability is low, such as has occurred with rabies. However, vaccination is unacceptable in preventing rapidly transmitted diseases such as CPV enteritis. Depending on the disease, the acceptable efficacy of protection allowed for most vaccines is between 65% and 95%, meaning a certain percentage of animals will be unprotected in any vaccinated population. Unfortunately, from an individual animal standpoint, one vaccine break constitutes a failure.

Veterinarians are often blamed for animals developing disease after apparently adequate vaccinations. The animal was possibly incubating the disease before vaccination. Because of the high resistance of agents such as parvoviruses, acquisition of the infection can occur around the home environment. Puppies and kittens from animal shelters are often exposed to high levels of pathogens before vaccination. Other factors, however, are under direct control of the veterinarian. Many of these vaccine breaks may be caused by inattention to precautions that should have been taken during the vaccination procedure. Dogs and cats may contact high concentrations of pathogenic agents, such as parvoviruses, for the first time when they enter the veterinary hospital for vaccination. This exposure may occur in the hospital waiting room or ward area because of improper traffic flow or inadequate disinfection or isolation procedures for animals that are already infected. Vaccination of animals with existing mild illness or immunodeficiencies may not be contraindicated. In such situations, inactivated or other noninfectious products are recommended. For further information, see later discussion of Postvaccinal Complications and specific vaccine-induced illnesses, and see [Chapter 95](#) concerning immunodeficiency disorders.

The many causes of vaccination failure in dogs and cats are summarized in [Table 100-13](#). A few of the more pertinent features are discussed in this section. Not all vaccines will effectively immunize those patients to which they are given because of inherent host factors discussed previously, as well as difficulties with the vaccine or errors made in the process of administration. Vaccination in the presence of MDA is the most

Infectious Diseases of the Dog and Cat, 3rd Edition

common cause of vaccine interference in young animals and has been discussed previously. Other potential causes are considered later in this text.

Care and handling of vaccines is important in the animal's immune response as inactivation of a live product negates the animal's immune response. Directions for proper storage and handling as indicated on the product label should be strictly followed. Directions given by the manufacturers for handling of vaccines should always be followed because of the labile and occasionally harmful nature of biologic products and the liability risk to the veterinarian. Refrigeration is essential for almost all biologics, and inadvertent freezing may damage many products and inactivate live agents. Sunlight is damaging to many vaccines because it inactivates many viruses and bacteria. Stock should always be rotated to ensure that vaccines are used before the expiration dates. If lyophilized products are used, vaccines should always be mixed with the diluents provided and administered soon after reconstitution.

Needle size and composition may be important in the immune response. For most vaccines in small animals, a 22-gauge, 1-inch needle is best. Theoretically, this size places the agent in the SC site with a minimal amount of leakage from the injected area. Vaccines marketed for individual use should never be mixed in the same syringe because of potential incompatibilities. In addition, injecting multiple vaccines at the same site in the animal is not advised. In one study, when individual vaccines were combined and given SC at one site, the antibody responses were inferior compared with the responses when antigens were given at separate sites.¹⁰⁸ For this reason, only licensed combination products, which have been screened for compatibility, should be administered, and different products should never be mixed. The potency of attenuated products requires that they replicate, and inadvertent inactivation will reduce their effectiveness.

1088

1089

Table 100-13 Causes of Vaccination Failure

HOST FACTORS	VACCINE FACTORS	HUMAN ERROR
Immunodeficiencies	Rendered noninfectious during handling	Improper
Maternal antibody interference	Improper storage	Exposed at time of vaccination visit
Age: very young or very old	Vaccines do not protect 100% of population (biologic variation)	Concurrent use of antimicrobials or immunosuppressive drugs
Pregnancy	Disinfectant used on needles and syringes	Simultaneous use of antisera
Stress, concurrent illness	Wrong strain	Too frequent administration (<2-week interval)
Pyrexia, hypothermia	Excessive attenuation	Disinfection of skin (uncertain)
Incubating disease at time of vaccination	Overwhelming exposure	Wrong route of administration
Cytotoxic drugs or glucocorticoids		Delay between vaccines in initial series
Anesthesia (uncertain)		Omit booster vaccination
Hormonal fluctuations		Concurrent surgery or anesthesia
General debilitation, malnutrition		
Overwhelming exposure		

Aseptic methods should always be used in rehydrating vaccines, complete doses should be used, and unused opened diluents should be discarded. Most vaccines have adequate particle numbers to overcome possible reductions in antigen mass or organism numbers that occur during handling and storage.

Serial numbers of vaccines and sites of vaccination should be entered in medical records to assist in tracking vaccine breaks or vaccine-induced illnesses. Used bottles or those containing expired biologics should be considered a biohazard and should always be disposed in a safe manner.

Infectious Diseases of the Dog and Cat, 3rd Edition

Splitting doses of vaccine is *never* advised. Some veterinarians split doses for smaller animals to reduce proportionally the amount of extraneous proteins that might cause allergic reactions (see discussion of type I immunologic complications, Postvaccinal Complications). Reducing antigen levels voids implicit warranties of the manufacturer and shifts the liability to the veterinarian should a break in protection occur. The only recognized reduction in vaccine dose that has been recommended is in the IN vaccination of neonatal kittens for upper respiratory tract disease. In this instance, a few drops are administered in the nostrils of each kitten rather than giving an entire dose.

Cytotoxic agents or glucocorticoids may be associated with a decreased response to vaccination, depending on the dose and duration of treatment. When glucocorticoids are given long term, alternate-day therapy is less likely to cause immunosuppression. Although glucocorticoids are less likely to interfere with booster vaccinations, they are not recommended when the primary immune response to a particular antigen is being elicited. Moderate doses of prednisolone were administered to previously unvaccinated 13-week-old puppies for a 3-week period before vaccination for CDV.⁴⁰⁴ Doses of 1 or 10 mg/kg were given every 12 hours for the first week, once daily for the second week, followed by alternate-day therapy for the last week. The dogs were challenged with virulent virus 3 days after vaccination. Although in vitro lymphocyte stimulation testing showed a depressed response compared with that in control dogs, all vaccinated puppies receiving glucocorticoid therapy were immune to challenge.

Antibody responses to measles and CDV vaccination have also been studied in dogs that were more severely immunosuppressed with concurrent methotrexate and antithymocyte sera.⁵²⁵ Dogs immunosuppressed before CDV vaccination developed vaccine-induced systemic illness and encephalitis and died. Dogs immunosuppressed after CDV vaccination and later challenged with virulent CDV resisted challenge, but they had no increase in neutralizing antibody titer.

Dexamethasone, at a daily dosage of 0.25 mg/kg (equivalent to 1.25 mg/kg prednisolone), was given to dogs before and after their first vaccination with rabies vaccine.⁴⁶ No difference was found in the serum antibody titer of treated dogs compared with untreated animals.

Tetracycline, alone or in combination with niacinamide, has been used as an effective treatment of some cases of immune-mediated skin disease in dogs. Treatment of dogs with this combination did not interfere with antibody responses following vaccination against canine distemper and parvovirus infection.³⁹⁹

Changes in *body temperature* may influence the immune response. Elevated rectal temperature, artificially induced by high environmental temperature and humidity, has been shown to inhibit the serologic response of 8- to 12-week-old puppies to canine distemper vaccination. Puppies with elevated rectal temperatures (39.8° C [103.6° F]) that were kept under these conditions developed clinical illness after subsequent challenge with virulent CDV, whereas those with lower rectal temperatures were protected.⁵⁸⁹ The serologic response after vaccination for ICH was not affected by these conditions. Hypothermia is also known to decrease the measured in vitro CMI response of dogs, and probably cats, to vaccination.⁵⁰⁷

Anesthesia and surgery may have an indirect effect on concurrent vaccination. General anesthesia or surgery causes a suppression of the response in lymphocyte-stimulation testing, but the clinical significance of such results is probably minimal, and the serologic response is unaffected.²⁸³ Vaccination before and after surgery had no effect on the humoral or CMI vaccine response to CDV or CPV-2 in dogs and did not predispose them

Infectious Diseases of the Dog and Cat, 3rd Edition

to vaccine-induced illness.³⁹⁰ However, vaccination while under anesthesia is not recommended in case a hypersensitivity reaction develops that may go undetected.

Inactivation of modified live vaccine is less commonly a cause of vaccine failure because of the current manufacture and lyophilization of vaccines, refrigerated storage, and use of heat-sterilized disposable syringes rather than chemically disinfected syringes. Vaccines should be injected into visibly clean skin sites. Topical disinfection of the injection site in animals is questionable inasmuch as the hair is not routinely clipped before this procedure. Should routine practices result in local contamination, this may interfere with the injection procedure. Little evidence has been found to show that topical disinfectants themselves will alter the viability of SC inoculated products. 1089 1090

Vaccine interference can occur whenever attenuated antigens are administered at too-frequent intervals. Administering several attenuated vaccines simultaneously is better than giving them 1 to 4 days apart because of the blocking effect that the first vaccine may have on the second. This interference may be related, in part, to the production of INF by infected cells. Whenever possible, modified live vaccines should not be administered in the presence of other infectious diseases for this reason. Postponement of vaccinations for at least 2 to 3 weeks after illness or before sequential vaccinations with the same or a different product has been shown to be sufficient to overcome this interference. Animals with preexisting fever, debilitation, or multisystemic illness should not be vaccinated because immunization may fail and vaccine-induced illness or further immunosuppression is possible. Some researchers have suggested that immunosuppression occurs with use of CPV-2 vaccine strains because they induce lymphopenia, lymphocyte depletion, and suppressed lymphocyte stimulation in response to mitogens, but these responses are likely just a reflection of the expected response to a live agent. In multivalent vaccines, product licensing requires that combined antigens produce the same degree of protection as when they are given separately. In some cases, especially in naïve animals, administering multiple antigens may interfere with the response to each antigen alone. For this reason, in addition to the potential for allergic reactions, the authors (CEG and RDS) do not recommend using *Leptospira* or inactivated coronaviral vaccines in pups younger than 9 weeks of age during their primary vaccination series.

Delayed completion of a primary vaccination series is another potential cause for vaccination failure. Many times, delayed completion is the result of poor client compliance or client relocation. Under such circumstances, a delay of longer than 2 to 3 months between vaccines or delayed presentation for the first visit, should be corrected by administering at least two injections, 2 to 3 weeks apart, even if animals are beyond the age of MDA interference. Should the brand or formulation (recombinant versus inactivated versus attenuated) of vaccine be significantly different, or should the vaccination status be unknown or uncertain, a similar protocol of two vaccinations should be followed. Multivalent combination products are recommended in older animals receiving their primary vaccination series. Whatever protocol is used, some veterinarians prefer to administer rabies vaccine on the last visit in the series to help ensure compliance.

In some circumstances, *the route of vaccination* is also critical in maximizing the immune response because MLV rabies, feline respiratory, and canine measles vaccines are more effective when given IM rather than SC. For MLV rabies vaccines, which have been discontinued in most countries, this discrepancy may be explained by the fact that vaccine virus replicates better in innervated muscle as opposed to less innervated subcutaneous tissue. For other products, the difference may be related to greater blood supply or better tissue environment. Unfortunately, IM, versus SC, vaccination is more painful and is associated with a higher risk of postvaccinal type I immunologic reactions (see Postvaccinal Complications, later).

Infectious Diseases of the Dog and Cat, 3rd Edition

100.6 LIABILITY RELATED TO VACCINATION

Since 1996, legal statutes in the United States involving the USDA have freed vaccine manufacturers from liability regarding vaccine-induced complications, unless they are caused by improper manufacture of their vaccines. Veterinarians can no longer shift the liability of complications to the vaccine manufacturer. As a result, consumer claims regarding vaccines will be focused on veterinary malpractice or the failure of veterinarians to adhere to common standards. The question will be: did the veterinarian act in a manner comparable to what would be expected by a practitioner with equal experience and training? This is termed practicing according to a specific *standard of care*, and it applies to the decision concerning which vaccines to administer to each animal. Standard of care means what a practitioner of equal experience and training would deliver under similar circumstances. Only rabies vaccination is dictated by local public health laws. Several organizations have published recommendations regarding vaccine protocols for dogs and cats (Table 100-14). Although the standard for vaccination of dogs and cats is undergoing substantial reconsideration, the adoption of suggested guidelines by the veterinary community will have the greatest impact in determining the standard of care.

An important consideration with respect to future liability is the principle of *informed consent*. Veterinarians are expected to educate their clients concerning infectious disease risks for their pets, to inform clients of the risks and benefits of particular vaccines, and to handle and administer the products in accordance with the manufacturer's guidelines and commonly accepted standards of practice (Table 100-15). Veterinarians should obtain written informed consent from their clients. This consent means veterinarians should provide information to the client regarding the advantages, alternatives, and any risks of vaccines in lay terms. The final decision of the client is made to approve or disapprove of vaccination. The information can be provided as written guidelines for the practice that the client reads but should also be reinforced by commentary during the examination and vaccination process. Whether or not clients sign any statement that they were properly informed, the decision of the client and veterinarian regarding the pet's vaccination protocol should be recorded at the time of the visit. Spelling out the guidelines for future vaccination of the pet would seem appropriate at that time so that a plan can be followed with or without modification in the future. Given that no specific rules or guidelines exist, veterinarians are now subject to greater litigation than they were in the past. The medical record is an important tool to document the type of vaccinations given and information regarding the veterinarian's suggestions and owner's decisions. Information regarding vaccination needs should be altered on a yearly basis depending on the animal's individual health and environmental risks. At the time of each vaccination, the date, vaccine type, manufacturer, expiration date, and lot or serial number should be recorded. The site of administration should also be documented, and for cats, standard recommendations exist. Serologic results or prior adverse events should also be well documented. A signed consent form from a client that indicates awareness of discussed vaccine risks and suggested regimens is also judicious.

The manufacturers' responsibilities end with ensuring efficacy, purity, potency, and safety of their products. However, the number of animals that can be tested during preliminary trials is limited. Therefore safety is never absolute, and the veterinarian must consider balancing efficacy and the reduction of disease with the incidence of adverse events. Other than reporting of possibilities of anaphylactic reactions (see Type I hypersensitivity, later), vaccine labels have provided little information with regard to potential vaccine reactions. License requirements for newer products marketed in the United States have included listing of associated vaccine-related events. Because of differences in the timing of licensing, not all competitive products have the same level of safety information.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-15 Standard of Care for Veterinarians with Respect to Vaccination

1. Did the animal need the vaccine?

Consider: degree of contagion, severity of illness, permanence of immunity, waning antibody titer, prevalence of disease, outbreaks of illness, zoonotic risk.

2. Did the veterinarian select the proper antigen(s) for the patient?

Consider: pet lifestyle and exposure risk, predisposing breed or immune factors, onset and duration of protection, potential side effects.

3. Was the proper product selected for the intended antigen?

Consider: vaccine testing, challenge interval after vaccine and duration of immunity studies, field versus laboratory strain challenge, heterologous or homologous strain protection, academic institution opinions, age and breed of challenged animals, reported adverse reactions in field studies.

4. Was the vaccine given in a proper manner and location?

Consider: use as prescribed by manufacturer, record site and route of administration, use aseptic means, justified interval of administration.

5. Was informed consent obtained from the client before vaccination?

Consider: use of a permission form as documentation, education regarding disease particulars, not overstating vaccine safety, educating on risk of potential complications, educating on vaccine benefits and efficacy, outlining alternatives to vaccination, always having a written record of the consent.

6. Were adverse events monitored, documented, and reported?

Consider: vaccinating earlier in the examination process to allow for adverse events before discharging the animal, reporting adverse events to manufacturer, to the U.S. Pharmacopeia or other reporting service, documenting any adverse reactions in the written record and taking precautions for avoiding them in the future.

7. Were mistakes made that increased the risk to the patient or liability of the veterinarian?

Never doing the following: reducing a vaccine dose in an effort to minimize potential reactions, exaggerating claims relative to efficacy of a product, minimizing the potential for side effects of a particular vaccine, vaccinating for diseases for which a risk of infection cannot be justified, combining separate vaccine products before administration, vaccinating an animal that is clinically ill, vaccinating an animal with a known previous reaction without precautions.

100.7 POSTVACCINAL COMPLICATIONS

The benefits of vaccination of dogs and cats for serious diseases outweigh the risk of complications. However, because the prevalence of these diseases has decreased through vaccination, the prevalence of vaccine reactions may supersede that of their use in disease prevention. Despite claims of many antivaccination advocates, epidemiologic analysis does not show a correlation between vaccination within the last 3 months and ill health in dogs.¹³⁸ In the United Kingdom, an Adverse Reaction Surveillance Scheme has been evaluating adverse vaccine reactions since 1985.¹⁹⁸ In the period from 1995 to 1998, a total of 3188 adverse reactions have been reported; however, of the 841 for which sufficient information was available (369 dog, 472 cat), only 64 (7%) reactions were deemed vaccine related, 149 (18%) possibly related, and 628 (73%) probably unrelated. Even if all 841 events were considered an annual occurrence, this is only 0.004% of the 6 to 8 million vaccines given in the

Infectious Diseases of the Dog and Cat, 3rd Edition

United Kingdom annually. Although the prevalence of vaccine-induced reactions is low, some precautions may be in order for routine vaccination of animals with underlying disease or immune aberrations. Many immune-mediated and nonimmune complications are severe enough to restrict or eliminate the routine periodic use of particular vaccines in predisposed animals. Repeated annual revaccination of veterinary patients cannot always be justified with respect to all the components included in currently available combination products. Veterinarians should be aware of potential complications caused by each vaccine component so that particular antigens can be deleted from subsequent boosters if problems arise. They should consider educating clients, either verbally or in writing, of potential vaccine complications to facilitate early recognition and treatment. For vaccine guidelines and for reporting such reactions in the United States, see [Table 100-14](#). For a summary of the immunologic and nonimmunologic complications described next, consult [Table 100-16](#). For a summary of preventive measures to avoid vaccine-induced complications, see [Table 100-17](#). For a list of manufacturers to report specific vaccine or drug reactions, see [Appendix 3](#).

100.7.1 Immunologic Complications

Hypersensitivity reactions that are known to develop after vaccination in certain dogs and cats are types I, II, III, or IV hypersensitivities reactions, or any combination of these (see [Table 100-16](#)).

100.7.1.1 Type I

Type I reactions involve an interaction between cytophilic IgE and antigen, with resultant degranulation of circulating basophils and tissue mast cells releasing large amounts of heparin, chemotactants, prostaglandins, histamines, and biogenic amines into the systemic circulation. Anaphylaxis may occur after the use of any vaccine, although it is most commonly associated with the use of adjuvanted or multivalent products containing large amounts of foreign protein, such as inactivated rabies vaccine, canine coronavirus (CCoV) vaccine, FeLV vaccine, *Leptospira* bacterin, and parenteral *Bordetella* vaccine. Potentiated parvoviral products containing large amounts of antigen have also been incriminated. Foreign proteins, such as fetal bovine serum (FBS), used in cell culture, can cause type I hypersensitivity reactions. With the advent of inactivated and adjuvanted viral vaccines for rabies in cats and dogs, feline respiratory disease, FPV, and FeLV infections, an increasing prevalence of type I hypersensitivity reactions has been noted, especially in cats. Miniature dachshund pups and some of the other miniature breeds have a disproportionally high reaction rate. Ferrets have a similar tendency to develop this reaction, even when CDV or rabies vaccines are administered that are licensed for use in that species.²⁰⁰

In the dog, clinical signs include facial edema (“big head”), pruritus, hypotensive shock, weakness, dyspnea, and vomiting with or without diarrhea that can be hemorrhagic.⁴²⁰ Local or systemic reactions may occur in young puppies within 1 to 24 hours after their second or third vaccination and may result in acute clinical signs described previously, as well as death. Puppies that survive such episodes should not be revaccinated with known allergenic components through the remainder of their initial vaccination series. For example, if the affected animals are allergic to leptospiral antigen, they should not be revaccinated with the leptospiral fraction until they are at least 16 weeks of age. At this time, the veterinarian should administer antihistamines as a precautionary measure before giving the vaccines. In addition, the patients should be hospitalized and monitored for 1 to 2 hours after the vaccine is given.

Cats show facial pruritus, hypersalivation, vomiting, diarrhea, dyspnea, collapse, and respiratory distress from acute pulmonary edema, usually within minutes to hours (under 24 hours) of vaccination. Diarrhea is usually watery but may become hemorrhagic if it is severe or persistent. Even with recovery, diarrhea may persist in some cats for several days thereafter. Respiratory distress, exhibited by dyspnea and cyanosis, is

Infectious Diseases of the Dog and Cat, 3rd Edition

the most severe reaction. A majority of cats will respond favorably to 0.2 ml IV of 10-fold diluted epinephrine (1:10,000) and parenteral antiinflammatory doses of glucocorticoids, but those with severe progressive respiratory symptoms or hemoptysis usually die.

When anaphylaxis is a problem for an animal, the veterinarian is advised to (1) modify the vaccination schedule to reduce the number of antigens given simultaneously, (2) switch to MLV instead of inactivated adjuvanted products, and (3) use SC or IN (when available) rather than IM inoculations, which decrease the rate of uptake of the product into the systemic circulation. Syringe aspiration is essential before injecting any parenteral vaccine to determine whether a blood vessel has inadvertently been penetrated. Animals should be vaccinated early during the office visit to allow an adequate observation period. Clients should also be advised to keep their pets inside and under observation for at least 1 hour after arriving home following vaccination. Antihistamines (e.g., diphenhydramine, 1 mg/kg given SC or IM 15 minutes before vaccination) should always be given to these reactors before subsequent vaccinations, and vaccine antigens should be administered separately, when available, to allow identification of the problematic component. Measurement of antibody titers to certain infectious agents might determine whether and when revaccination is necessary (see Vaccine Efficacy, previously). Skin testing animals by ID inoculation of 0.1 ml of the suspected vaccine may also elicit a type 1 hypersensitivity to offending products. The site should be observed for at least 1 hour for development of urticaria (wheal), and saline and histamine controls should be used for comparison. Not all animals that develop a positive ID skin test result will have signs of hypersensitivity after vaccination. For example, many dogs develop an immediate hypersensitivity reaction to *Leptospira* antigen months or years after vaccination, but only a certain number of those dogs will develop a clinically relevant adverse reaction (anaphylaxis, facial edema, bloody diarrhea). Inbred atopic dogs have been shown to develop enhanced antipollen IgE responses when vaccinated with CDV, CAV-1, and *Leptospira* vaccines just before, but not after, exposure to pollen extracts.¹⁷³ In another study, vaccination of some dogs for rabies increased serum concentrations of total IgE and induced specific IgE for vaccine antigens, including those in tissue culture.²⁴⁰ Aluminum adjuvant in the vaccine was suspected as the cause for the nonspecific increase. Despite the persistence of IgE in some dogs, none showed evidence of allergic disease after vaccination. However, because of this immunopotential, recommendations suggest that atopic dogs receive their booster vaccinations during nonallergic seasons or disease-free intervals.

1092

1093

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-16 Postvaccinal Complications Associated with Canine and Feline Biologics

TYPE OF PROBLEM	MECHANISM OF PRODUCTION	RESPONSIBLE VACCINES
Immunologic		
Type I	Immediate hypersensitivity; allergy, anaphylaxis	<i>Leptospira</i> bacterin; inactivated adjuvanted rabies, FeLV and respiratory vaccine
Type II	Cytotoxicity (hypersensitivity or autoimmunity):	
	Hemolytic anemia	MLV CPV vaccine
	Thrombocytopenia	MLV CDV vaccine
Type III	Immune complex (hypersensitivity):	
	Uveitis	MLV CAV-1 vaccine
	Generalized serum sickness	Passive immunization
Type IV	Cell-mediated (hypersensitivity or autoimmunity):	
	Granuloma	BCG immunotherapy
	Encephalitis	Nervous tissue-derived rabies vaccine
	Polyradiculoneuritis	Inactivated neonatal mouse brain rabies vaccine
Nonimmunologic		
Local reaction at injection site, cutaneous granulomas, or sarcomas (especially cats)	Adjuvants, preservatives, inactivators	Bacterins such as for <i>Bordetella</i> and <i>Leptospira</i> ; inactivated adjuvanted viral vaccines such as for rabies and FeLV
Systemic fever and malaise	Local lymphoid replication of MLV products	Any MLV vaccine
Neurologic complications	Viral	MLV rabies and CDV vaccine
Abortion, infertility, congenital malformation	In utero or early neonatal infection	Any MLV vaccine during pregnancy Parvoviral vaccines during neonatal period
Clinical disease in vaccinates	Incomplete attenuation or local administration of attenuated vaccines	IN vaccines: Feline calicivirus, herpesvirus (IN or parenteral product); canine parainfluenza virus (mild) or canine <i>Bordetella</i> vaccine (mild)
	Feline limping	MLV caliciviral vaccine
	Polyarthritis in Akitas	Combined MLV or inactivated adjuvanted vaccines
Postvaccinal shedding	HOD and juvenile cellulitis	MLV CDV vaccine
	Virus localization	CPV-gastrointestinal, CAV-1 vaccine-renal, CAV-2 vaccine-respiratory
Postvaccinal encephalitis	Immunosuppressed animal or relatively unattenuated virus enters the nervous system when immune defenses are poor	CDV vaccine, measles vaccine, MLV rabies
CPV, Canine parvovirus; CDV, canine distemper virus; CAV-1, canine adenovirus-1 (hepatitis); BCG, bacille Calmette-Guérin; CAV-2, canine adenovirus-2 (respiratory); MLV, modified live virus; HOD, hypertrophic osteodystrophy; FeLV, feline leukemia; IN, intranasal.		

Infectious Diseases of the Dog and Cat, 3rd Edition

100.7.1.2 Type II

Type II hypersensitivity, or autoimmunity resulting in cellular injury, has been suspected or reported after MLV vaccination in dogs. This reaction involves binding of antibody with or without complement with subsequent damage to host cells. Autoimmune hemolytic anemia (AIHA) and autoimmune nonregenerative anemias (autoimmunity to erythrocyte precursors) have been suspected to occur after MLV CPV vaccination in dogs. This phenomenon might also occur after natural infections but has rarely been reported. One-fourth of dogs studied with AIHA had been vaccinated with polyvalent products within 1 month of onset in one study.¹³⁴ The dogs with this association had lower platelet counts, increased trend toward intravascular hemolysis and spontaneous microagglutination, and higher mortality compared with the other affected animals. The vaccine components may have induced autoantibody production or activated the immune system to destroy erythrocytes with preexisting surface autoantibodies. Other studies have not found this suspected association,²⁹⁷ and although inciting controversy, the subject of vaccine-induced autoimmunity requires further study in dogs and cats.⁴³⁵ Vaccines, as with certain drugs, infections, and other factors, are known to serve as triggers in development or exacerbation of autoimmune disease in genetically susceptible humans.⁹³ Killed products with bacterial antigens are most likely to serve as a nonspecific trigger because the immune enhancing effects of adjuvants and bacterial cell walls. Attenuated agents are thought to invoke the process through molecular mimicry in which “like antigens,” those similar between antigens in the organism and host, cause immunologic cross-reactivity against certain host tissues.

1093

1094

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-17 Contraindications to Routine Vaccination of Dogs and Cats

DISEASES OR CONDITION	VACCINES TO AVOID	RECOMMENDED ALTERATIONS
Genetic immunodeficiencies (see Chapter 95): Weimaraners and Akitas	MLV vaccines, especially Rockborn or Snyder Hill CDV	Inactivated or other noninfectious products
Acquired immunodeficiencies (see Chapter 95): FIV, FeLV, cancer, chemotherapy, cytotoxic or myelosuppressive drugs ^a	Modified live vaccines	Onderstepoort or preferably recombinant CDV
Immune-mediated diseases: uveitis, glomerulitis, polyarthritis, polyradiculoneuritis	Annual vaccination	Inactivated or other noninfectious products
Immune-mediated diseases: hemolytic anemia or thrombocytopenia	MLV parvoviral or combination vaccines	Triennial rabies and minimize other antigens
Type I hypersensitivity vaccine reaction: dachshunds	Inactivated, adjuvanted vaccines, IM administration	Triennial vaccination
Mild or one-system disease, fever	Modified live vaccines	Modified live vaccines (see text for additional precautions)
Pregnancy or lactation	Modified live vaccines	Control disease or use noninfectious vaccines
Vaccine-induced sarcoma	Inactivated, adjuvanted vaccines	Inactivated or other noninfectious products
Chronic feline ulcerative gingivostomatitis and faucitis (see Chapter 89)	Inactivated adjuvanted calicivirus vaccines	Nonadjuvanted inactivated or noninfectious products, modified live vaccines, triennial vaccination Reduce vaccine booster frequency, or use modified live vaccines when necessary

MLV, Modified live virus; CDV, canine distemper virus; FIV, feline immunodeficiency virus; FeLV, feline leukemia virus; IM, intramuscular.

a Methotrexate, azathioprine, cyclophosphamide in dogs or cats; or extended use of chloramphenicol, sulfonamides, trimethoprim, dapsone, griseofulvin, or sulfadiazine in cats.

Transient thrombocytopenia also was reported after MLV combination vaccines in dogs.^{126,550} Thrombocytopenia, which developed in most vaccinated dogs, was mild (more than 100,000 and fewer than 200,000 platelets/ μ l) and subclinical. Despite transient thrombocytopenia, no change in platelet function was detected. Whether this form of thrombocytopenia is caused by autoimmune or infectious mechanisms is uncertain. Only animals with concurrent congenital or acquired bleeding tendencies may be expected to show hemorrhagic tendencies. Veterinarians may want to delay elective surgery on animals with known bleeding tendencies for a 2-week period after vaccination. Severe immune-mediated thrombocytopenia can also occur within 1 to 2 weeks after vaccination of some dogs. These animals have overt petechiae and hemorrhagic tendencies, with platelet counts less than 50,000/ μ l. Glucocorticoid therapy is usually required for several weeks thereafter to increase the platelet count, and subsequent boosters may have to be avoided or minimized to prevent a recurrence of the problem in affected dogs. Dogs with autoimmune disease disorders should probably have antibody titers evaluated in lieu of revaccination.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.7.1.3 Type III

This hypersensitivity reaction, also known as serum sickness, is associated with immune complex formation and deposition and is responsible for the anterior uveitis that occurs in some dogs receiving the MLV CAV-1 vaccine and rarely with CAV-2 vaccines. This local type III, or Arthus, reaction results from virus-antibody complex formation within the eye (see Pathogenesis, [Chapter 4](#)). The process often resolves spontaneously unless secondary complications such as glaucoma develop.

Generalized serum sickness is the result of widespread immune complex deposition throughout the walls of the microvasculature of certain structures, such as the renal glomeruli, joints, and uveal tracts. Usually, this complication is seen only after the administration of large amounts of hyperimmune serum or globulin. Because passive immunization is used infrequently in dogs and cats, the prevalence of serum sickness is minimal, which has developed in a dog as a complication of *Propionibacterium acnes* immunotherapy (see

1094

1095

[Chapter 2](#)).³²⁹ Glomerulonephritis and amyloidosis can result from chronic or repeated antigenic exposure. One example would be vaccine-associated polyarthritis in Akitas (see Vaccine-Associated Disease in Young Akita Dogs, later). This finding is one reason why human beings are not given booster doses annually, as is the practice in veterinary medicine. Both amyloidosis and glomerulonephritis have been experimentally produced in animals after desensitization therapy protocols using repeated injections of large quantities of foreign antigen. Although concern exists, neither disease has been attributed to repeated administration of biologics in immunocompetent dogs or cats. See later discussion, and [Chapter 95](#), for further discussion of vaccine-induced complications in immunodeficient dogs and cats.

100.7.1.4 Type IV

Cell-mediated, or type IV, hypersensitivity reactions can occur after BCG is used as an immunostimulatory compound (see Immunotherapy, [Chapter 2](#)). Large, exuding granulomas may develop at the site of injection. Historically, postvaccinal encephalitis was an allergic reaction that occurred after nervous tissue-derived rabies vaccinations were given.

100.7.1.5 Polyradiculoneuritis

Known as coonhound paralysis in dogs and Guillain-Barré syndrome in humans, polyradiculoneuritis is an immune-mediated inflammation of nerve roots that has been seen after a variety of vaccines were given to dogs and cats.^{187,201,501} Coonhound paralysis is an immunologic disease caused by antigens in raccoon saliva that cross-react with the basic myelin protein of peripheral nerves to which dogs become exposed after direct contact with raccoons. As with other immune-mediated diseases, a genetic predisposition for coonhound paralysis exists. Although various vaccines can be incriminated, the highest frequency of polyradiculoneuritis has occurred after some lots of suckling mouse brain-derived inactivated rabies vaccines were used.²⁰¹ The central nervous system (CNS) of the newborn mouse, normally devoid of myelin, is well adapted to the production of large quantities of rabies virus needed to produce inactivated vaccine. Apparently, the nervous tissue of older mice was inadvertently used in production of the vaccine, or peripheral or cranial nerve myelin was accidentally included. This circumstance resulted in transient acute lower motor neuron (LMN) paralysis 1 to 2 weeks after vaccination in a proportion of dogs, similar to what is seen in experimental allergic neuritis.

Infectious Diseases of the Dog and Cat, 3rd Edition

Polyradiculoneuritis is similar whether it is caused by a vaccine or raccoon bite exposure. Rapid and progressive LMN weakness develops, usually beginning in the pelvic limbs and progressing forward. Pain sensation remains intact, and animals are hypersensitive to muscle palpation. Cranial motor nerve abnormalities such as facial paralysis may be observed. Occasionally, animals may have difficulties in swallowing and breathing or autonomic dysfunction that can lead to death.

The diagnosis of acute polyradiculoneuritis can be presumed based on marked diffuse muscle atrophy, preserved pain, and presence of hyperesthesia. When the equipment is available, electromyographic changes show fibrillation potentials characteristic of LMN denervation, and nerve conduction velocities are variably reduced, depending on the degree and location of myelin loss. Clinical improvement with demyelination alone begins within 2 weeks of onset of paralysis, and recovery to normal occurs in 1 to 2 more weeks. With axonal injury, recovery may be delayed for several months or may be incomplete. Subsequent exposure to the inciting cause may result in more severe and prolonged paralysis. Although glucocorticoid therapy has minimal effect on the course of this disease, one of the authors (CEG) has found that one dose of cyclophosphamide (50 mg/m²) given early in the course of illness may alleviate the severity of recurrent illness.

100.7.2 Local Reactions

Many complications have been associated with either local irritation or production of disease by canine and feline biologics. Local reactions after vaccination include pain, erythema, swelling, irritation, loss of hair, change of hair color, and abscess formation. Erythema, swelling, and irritation typically occur within 30 minutes to 1 to 2 weeks after inoculation. Onset of the other findings occurs within days to weeks. Pain can be caused by many components in the vaccine, such as stabilizers, high or low pH, high osmolality, adjuvants, or preservatives. Swelling is most frequently noted with the noninfectious products containing adjuvants or with the bacterial products owing to bacterial cell wall and foreign protein derived from the culture media. Parenteral *Bordetella*- and *Leptospira*-adjuvanted bacterins and adjuvanted-inactivated viral vaccines for rabies, FeLV, and feline respiratory diseases have most commonly been incriminated. Local reactions that enlarge or persist 2 to 3 months after vaccination should be evaluated by needle aspiration or biopsy, especially in cats because they may develop into injection site-associated sarcomas (ISS).

100.7.3 Contamination

Local and systemic inflammatory reactions have occurred from the inadvertent inclusion or growth of pyrogens in vaccines. Multidose vials contribute to this problem. *Pseudomonas*, other psychrophilic bacteria, and fungi can grow even during refrigerated storage. High amounts of endotoxin in early inactivated whole cell, parenteral *B. bronchiseptica* vaccines caused systemic manifestations in dogs, such as depression, shivering, tremors, and vomiting,⁵⁶ and produced local reactions and abscesses. Newer products with reduced levels of endotoxin have alleviated this complication as has the development and extensive use of modified live IN vaccines. Individual syringes and needles should be used for all vaccines given to dogs and cats. When insufficiently cleaned injection devices have been reused, inadvertent transmission of attenuated viruses has occurred.³⁵⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

100.7.4 Adventitious Agents

Most viruses are grown in cell culture that must contain serum, which is almost always obtained from bovine fetuses. FBS has on several occasions been the source of contamination with viruses such as bovine viral diarrhea virus (BVDV), blue tongue virus, bovine parvovirus, and probably others. Vaccination of pregnant animals is not advised but is done under some circumstances. Blue tongue virus grew undetected in one killed commercial release of canine vaccine and caused abortions, cardiac failure, and respiratory distress in pregnant bitches vaccinated in the last trimester of gestation.^{6,594} Necropsy findings were sanguineous pleural effusion, serous pericardial effusion, pulmonary congestion, splenomegaly, and enlarged mesenteric lymph nodes. Histologic features were multifocal vasculitis in parenchymal organs, interstitial pneumonia, multifocal myocardial edema, and myofiber degeneration.¹⁵⁶ No reported illness was found in nonpregnant dogs, and no lesions were present in the aborted pups.⁵⁸ The virus was isolated from maternal organs and from a repository of the incriminated lot of vaccine.

Mycoplasmas and mycoplasmal DNA detected by polymerase chain reaction (PCR) have been found in some commercial veterinary vaccines.²⁹⁹ BVDV was found to contaminate an MLV multicomponent product, but no adverse reactions were reported from its presence. Parvoviruses, including bovine and porcine viruses, have been found as contaminants in vaccines.

1095

100.7.5 Focal Cutaneous Granulomatous Reactions and Alopecia

1096

Adjuvants used in noninfectious vaccines potentiate the immune response by creating a depot effect, which sequesters antigen and stimulates a sustained inflammatory reaction. Certain bacteria, especially gram-negative bacteria such as *B. bronchiseptica*, can serve as an adjuvant in multicomponent vaccines. As a result of certain adjuvants, firm dermal or subcutaneous nodules may form at sites where vaccines are given to dogs or cats.²²⁵ These nodules typically regress after 2 to 6 weeks, but other vaccines such as certain FeLV and *Giardia* vaccines cause similar reactions. Such reactions have been more commonly reported after inactivated rabies vaccination of dogs and cats.²²⁵ Vaccines may also produce visible hyperpigmented alopecic macules in the overlying dermis of breeds without undercoats, such as the poodle, Bichon Frisé, and Briard.⁴⁰ Nonadjuvanted products such as the recombinant canarypox rabies–vectored vaccine (Purevax®, Merial, Duluth, Ga.) do not cause this adverse reaction.

Histologically, the nodules created by adjuvanted rabies vaccine were characterized by a local nonsuppurative vasculitis with rabies antigen–specific fluorescence in the wall of the blood vessels. Central necrosis of tissue is surrounded by a granulomatous reaction with influx of macrophages and variable numbers of lymphocytes, plasma cells, and eosinophils. Lymphocytes are numerous, in many cases forming follicles. Globular gray-brown material within the necrotic zone and in macrophage cytoplasm represents residual vaccine adjuvant. Macrophages may transport this material to distant sites, perpetuating and disseminating the reaction. Dogs or cats exhibiting such reactions may be more likely to develop anaphylaxis on subsequent boosters should vaccine be inadvertently absorbed systemically at a rapid rate. Additionally, concern has been expressed that cats that are predisposed to inflammatory reactions may be more likely to develop vaccine associated ISS.³⁴⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

100.7.6 Injection Site–Associated Sarcomas in Cats

ISS were reported initially in 1991; however, increased sarcomas at sites where vaccines are normally injected were observed at the mid to late 1980s following the introduction of killed aluminum-adsorbed rabies and FeLV vaccines. These sarcomas have been presumed to originate at areas of persistent inflammation produced by these vaccines.^{483a} Other sources of trauma in cats can also lead to sarcoma development.¹³⁰ Feline oncornavirus and papillomavirus infections do not appear to be involved in a cat's susceptibility.^{143,286,288} However, sarcomas have been reported in cats following the use of other adjuvant-containing vaccines and other injectable products.²²⁵ Injection of benzathine penicillin, parasiticides (lufenuron), or even repository glucocorticoids or absorbable sutures have been associated with this reaction.* Deep-tissue sutures and penetrating injuries of the eye have resulted in sarcoma development in cats. Cats are the only species in which traumatic ocular sarcomas have been reported. The occurrence of ISS is not unique to the cat given that other species (e.g., dog, ferret, humans) had reportedly developed them at injection sites but at extremely lower frequency.^{387,551}

The component thought to be associated with postvaccinal inflammation is the adjuvant.^{346,352,354,508} However, anything that stimulates a strong inflammatory reaction might cause an ISS. The inflammatory reactions to deposited aluminum and other proprietary adjuvants cause tissue reactions. These reactions consist of proliferation of fibroblasts and myofibroblasts, as well as infiltration of lymphocytes and macrophages and other cells.³⁴⁷ These cells, in turn, release multiple cytokines, growth factors, and other molecules, which increase reactive oxygen species that, in genetically susceptible animals, may lead to transformation of certain cell types, resulting in a neoplastic disease. In addition to fibrosarcomas, cats have developed osteosarcomas, liposarcomas, rhabdomyosarcomas, chondrosarcomas, and malignant histiocytomas, among other neoplasms, at vaccination sites. Depending on the brand of vaccine used, in cats vaccinated with inactivated rabies vaccine, 80% to 100% develop local inflammatory reactions. Inflammatory reactions with the rabies vaccines were larger than that observed with FeLV vaccines. No local inflammation was evident at nonadjuvanted FeLV vaccine sites. Despite the common microscopic occurrence, the prevalence of these grossly visible and palpable swellings at 21 days postvaccination were reportedly as high as 11.8 out of 10,000 vaccine doses.¹⁹⁶ Some researchers believe that this inflammatory response is a prerequisite for sarcoma development, although this theory is controversial. These swellings usually subside within 3 months. Tumors usually arise between 3 months to 3.5 years after vaccination, with 1 year as a median time.

ISS likely result from hyperinflammatory responses in mesenchymal tissue at the site of inoculation. ISS can also originate at other sites, presumably as a result of migration of aluminum-containing macrophages. In such tumors, increased MHC class II and lymphocytes expressing CD11b and CD3 prevail.⁸⁰ Platelet-derived growth factor (PDGF) levels are increased in sarcomas. PDGF comes from macrophages and lymphocytes at the site of tissue injury and is a normal response to wound healing. In addition, in inflammatory tissues that become neoplastic, P53 (tumor-suppressor gene) is upregulated following DNA damage, resulting in tumor proliferation.²³³ In cell culture, DNA damage is caused by all types of adjuvant-containing products but not with live feline respiratory vaccines.³⁸¹ Because of the DNA damage, and the difficulty of resecting malignant fibrosarcomas, once a tumor is removed, the chance of reoccurrence is 42%.

Compared with cats receiving adjuvanted-inactivated rabies vaccines,^{345,508} reactions were less frequent or inconsistent after FeLV vaccination, especially with nonaluminum-adsorbed and nonadjuvanted products.

Infectious Diseases of the Dog and Cat, 3rd Edition

Nonadjuvanted rabies vaccines, especially the canarypox virus–vectored rabies product, produced little to no inflammatory changes when they were administered to rats,³⁴⁷ cats, ferrets, and mink.⁸⁰ Postvaccinal inflammation occurs to the same degree whether the vaccine is given SC or IM; however, the location of the inflammation is in a deeper location with the latter route. Massaging a vaccine site changes only the shape, but not the volume, of the postvaccinal inflammation.³⁵¹ Sarcoma occurrence is not restricted to vaccines containing only aluminum salts adjuvants. Vaccines other than those for rabies or FeLV have also been incriminated⁶⁷ because anything that produces inflammation in the tissues of susceptible cats may result in development of ISS.

Although inflammation is common at most sites of adjuvanted-inactivated vaccine administration, ISS development is rare. A genetic susceptibility component among cats is suspected given that only a few cats develop sarcomas at sites of vaccination. Related cats have had more prevalent tumor development. Cytogenetic studies may provide more insight into this predisposition. Lymphocytes in ISS associated with vaccines are positive for PDGF and other proinflammatory cytokines.²²⁶ The expression of C-jun, an oncogene coding for a protein (AP-1) that is associated with cellular oncogenesis in vitro in vaccine-associated ISS, is strong.²²⁶ These sarcomas contain altered MAB reactivity to p53 nuclear protein, a critical regulator in the cell cycle.^{80,233}

The estimated prevalence of occurrence in the United States based on biopsy submissions was 1 in 10,000 vaccinated cats, although it may be as high as 1 in 1000 vaccinated cats.* In an epidemiologic survey of practicing veterinarians, the estimated prevalence was 2.1 cases per 10,000 cat visits or 3.6 cases per 10,000 cats.¹⁰⁵ In the United Kingdom, where vaccination practices differ, where rabies and FeLV vaccines are less used, a range of incidence of 0.021 to 0.61 sarcomas for every 10,000 doses used was reported.^{184,534} Repeated yearly boosters may increase the risk. Unnecessary vaccines or boosters are not advised. In a multicenter case-control study of ISS risk, no single vaccine brand or manufacturer within an antigen class was found to be associated with sarcoma formation.²⁷⁶ Unfortunately, almost all vaccines administered to cats in this study contained an adjuvant or involved use of multidose vials; therefore the risk of these parameters could not be accurately determined. One important risk factor that was associated with sarcoma development was administration of cold vaccines.

Three methods for reducing the prevalence of sarcomas that involve the veterinarian, the owner, and the vaccine manufacturer have been suggested (Table 100-18). The site of sarcoma development has been most commonly in the interscapular area, presumably because this is a preferential location for veterinarians to inoculate cats. The interscapular area should be avoided because neoplasms in that location are difficult to remove, and drainage of inflammatory reactions is poor, resulting in sequestered adjuvants. Recommendations have been made to give vaccinations at specified sites to enable future tracking of reactions and at extremities where they can be more easily observed and removed. Rabies vaccine should be given SC in the right rear leg as distal as possible on the extremity; feline leukemia vaccine is given on the left leg at a corresponding site. Other products are given on the trunk just on either side of midline. Despite the potential of sarcoma development, the public health benefits of continuing rabies vaccination outweighs any complication. However, the development of newer, safer rabies products will hopefully reduce the risk of ISS associated with vaccines. Restricting FeLV vaccination presents another acceptable alternative. Nonadjuvanted leukemia products can be used, animals not at risk should not be vaccinated, and animals at risk can be vaccinated twice as kittens, possibly again at 1 year of age, then never again without an increased risk of becoming persistently infected with FeLV. Noncore parenteral vaccines that are known to induce local granulomas should be given to cats only when it can be shown to be necessary and when it will provide a significant benefit.

Infectious Diseases of the Dog and Cat, 3rd Edition

Recommendations can also be made to monitor vaccination sites because early detection and removal of sarcomas offer the best chance for a cure (Table 100-19). After inoculation, the owner should monitor vaccine sites for a 12-week period. Most masses that develop within 3 weeks of vaccination are granulomas that will resolve in 1 to 2 months, although some will persist. Should the mass enlarge during the observation period, wide local excision should be performed. Removal of the early reactive granulomatous mass may reduce the overall immune response to the vaccine but more importantly will reduce the chance of sarcoma development. If the mass continues to enlarge past the 3-month period, progressive enlargement is probably related to a growing sarcoma. If this condition is suspected, the patient should be referred to a specialty practice for a needle or incisional wedge biopsy. Alternatively, only extremely wide and deep mass removal should be considered. Excisional biopsy (lumpectomy) alone after this period is rarely curative. Even wide surgical excision has often resulted in a 30% to 70% failure rate. Radical surgery combined with local irradiation has been advised.^{94,291} Sarcomas are usually locally invasive; however, metastasis has been reported in up to 22% of cases.^{154,234,489,494} Few cats receiving surgical therapy alone survive longer than 2 years. When the tumor is located on the limbs, the time to first recurrence was longer than that with tumors on the trunk. Although combined surgery and drug therapy, with or without radiation therapy, has been beneficial, many cats succumb despite this approach.³⁴⁸ A review of the management of these tumors has been published.³⁷³

* References: 64, 67, 153, 175, 196, 276, 330.

* References: 155, 275, 330, 346, 373.

100.7.7 Systemic Illness

Systemic illness characterized by fever and malaise may also occur from self-limiting infection with modified live vaccine within local lymphoid tissues without systemic spread. This illness, which commonly does not last longer than 1 to 2 days after vaccination, often explains the transient anorexia and depression noted in recently vaccinated animals. Rarely are antiinflammatory drugs, antipyretics, or other supportive therapies indicated. MLV FPV vaccine resulted in severe clinical disease characterized by fever, diarrhea, and leukopenia in kittens infected 60 days before with FIV.⁶² An IN trivalent vaccine containing MLV FPV was thought to cause viral enteritis in cats co-infected with *Salmonella*.¹⁶⁶ The vaccine has been reformulated; however, IN vaccination for FPV is not as effective as parenteral vaccination is against FPV and should not be relied on for primary vaccination. Thus parenteral FPV monovalent products should always be used in conjunction with IN FHV-1 and FCV vaccines, whether or not an IN vaccine contains MLV FPV.

Attenuated *Chlamydomphila* products can cause systemic illness in a low number of cats within 1 to 3 weeks after vaccination. Clinical signs include fever (41° C [106° F]), lethargy, weakness, anorexia, and stiffness. Short-term therapy with glucocorticoids or analgesics may help alleviate these clinical signs.

Inadvertent parenteral inoculation of attenuated *B. bronchiseptica* and CPiV vaccine intended for IN use has caused localized pain and swelling, pyrexia, vomiting, mature leukocytosis, hypercholesterolemia, hypoalbuminemia, increased alkaline phosphatase and alanine aminotransferase activities, and hyperchloremia in an affected dog.⁵⁶⁹ Diffuse hepatocellular necrosis was found with liver biopsy. In another case observed by one of the authors (CEG), the illness was fatal. Management of these local and systemic reactions and acute hepatic necrosis involves symptomatic therapy with daily application of warm compresses to the injection site, systemic antiinflammatory drugs as needed, and antibacterial drugs such as gentamicin, tetracycline, or trimethoprim-sulfonamide. Parenteral treatment with gentamicin, and SC fluids at the injection site, early in the course of illness is thought to be very important in management of this potentially fatal condition.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.7.8 Neurologic Complications

Neurologic disease has been the most commonly documented postvaccinal reaction described in dogs and cats. This finding may be related to the overt nature of neurologic illness and to the decreased immunocompetence of the CNS against MLV agents. Rabies encephalomyelitis has been reported after vaccination with MLV vaccines. Most licensed rabies vaccines for dogs and cats throughout the world are noninfectious, although an MLV vaccine has been licensed in Europe. MLV rabies vaccines should never be used in exotic carnivores because of the uncertainty that exists with respect to species-related susceptibility to vaccine-induced disease. In fact, no MLV vaccines should be used in exotic carnivores unless it is absolutely necessary and it is known that they will not cause disease in the species.

Vaccine-induced rabies in dogs and cats after MLV vaccination begins with paralysis in the inoculated limb within 7 to 21 days and progresses bilaterally, in an ascending fashion.^{36,38,444} Affected cats have had progressive LMN paralysis with unusual extensor rigidity of the limbs. Pain sensation and reflex function were decreased in an ascending fashion. Progression to forelimb and intracranial involvement was more common in affected cats, whereas dogs usually recovered completely within 17 days to 2.5 months. Injection in the cervical musculature, closer to the brain, has been associated with a much greater prevalence of neurologic complications. A peculiar feature of the paralysis in some cats is a sign of hyperextended limbs rather than flaccid paralysis. Animals with vaccine-induced rabies do not represent a health hazard because the virus is attenuated and is not shed in the saliva. Because of the difficulty in distinguishing the vaccine virus from virulent virus, expert virologists and public health officials should be contacted for recommendations concerning disposition of an affected animal (see [Chapter 22](#) and [Appendix 4](#)). Vaccine-induced rabies should not be a problem when inactivated vaccines are used unless they inadvertently contained live virus.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-18 Practices That May Reduce the Occurrence of Postvaccinal Sarcomas in Dogs and Cats

VETERINARIANS

1. Profile pet and administer annual booster vaccines only for those agents for which pet is at risk for exposure. Vaccines used should be based on the needs of each patient. Do not overvaccinate.
2. Serotest, when applicable (see text), to determine if vaccines are needed.
3. Use MLV recombinant vector products, nonadjuvanted noninfectious, or IN, when available and effective.
4. Use SC vs IM route. Both can cause tumor formation; however, tumor development is detected earlier with SC.
5. Administer different vaccines at widely spaced sites, and use a consistent location for subsequent boosters.
6. Rabies right pelvic limb, leukemia left pelvic limb, and FHV-C-P on the lateral trunk or over the forelimb on either side
7. Do not administer vaccines at the interscapular space.
8. Massage vaccine sites immediately after inoculation to help disperse adjuvant (uncertain benefit).
9. Map and record these sites, vaccine brand, and serial numbers.
10. Advise owners of risk and need for monitoring vaccine sites. Inform them of risk of local and systemic vaccine reactions.
11. Reduce use of vaccines containing aluminum-based adjuvants.
12. Identify core vaccines (see text) and assess risk for noncore diseases before vaccinating.
13. Use single-dose rabies vaccines, and always mix well.
14. If multidose containers are used, mix them well before using to disperse adjuvants evenly.
15. Reduce use of combined multivalent products that compound the amount of adjuvants per dose.
16. Reduce the frequency and number of unnecessary vaccinations such as for FeLV.
17. Consider reducing the frequency of booster vaccines in adults. After the first annual booster, consider triennial boosters.
18. Bring vaccine to room temperature before using.^a
19. Consider use of monovalent boosters and stagger these over annual visits rather than all antigens yearly.
20. Consider offering preventive health measures rather than vaccination for yearly visits.
21. Consider use of topically applied MLV vaccines for respiratory diseases in high prevalence areas.
22. Surgically remove swellings that persist at vaccine sites beyond 90 days.
23. Report all vaccine-associated sarcomas to the United States Pharmacopeia (<http://www.usp.org>; 800-487-7776).

OWNERS

Infectious Diseases of the Dog and Cat, 3rd Edition

1. Monitor vaccine sites for increased swelling.
2. Reduce animal co-mingling and improve sanitation to limit exposure and need for repeated boosters.
3. Return for annual physical examination regardless of need for vaccination.

MANUFACTURERS

1. Establish DOI for products for proper booster frequency.
2. Develop vaccines for nonparenteral routes.
3. Reduce, alter, or eliminate sarcoma-inducing adjuvants.
4. Develop and market monovalent vaccines.

VETERINARY ORGANIZATIONS AND ASSOCIATIONS

1. Work with local governments to ensure rabies vaccine requirements are compatible with existing licensed product recommendations and DOI.
2. Continue to update and publish guidelines regarding vaccine practices.
3. Support funding for studies to determine or document safety and efficacy of current vaccines.
4. Encourage manufacturers and governing agencies to institute consistent, effective, and readily available reports on vaccine-induced adverse events.

MLV, Modified live virus; *IN*, intranasal; *SC*, subcutaneous; *IM*, intramuscular; *FHV-C-P*, feline herpesvirus (feline rhinotracheitis virus [FRV])-calicivirus-panleukopenia; *FelV*, feline leukemia virus; *DOI*, duration of immunity.

Recommendations from: The Feline Sarcoma Task Force, American Association of Feline Practitioners (Ref), and the Committee for Veterinary Medicinal Products, European Union (*Anon Vet Rec*, 2003).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-19 Postvaccinal Sarcoma Recommendations

Diagnostic Monitoring:

Site monitoring: record the location, shape, and size (in three dimensions) of all masses occurring at injection sites.

All masses occurring at injection sites are assumed malignant until proven otherwise.

Further diagnostics and management needed if the swelling:

Persists more than 3 months after vaccination

Enlarges to greater than 2 cm diameter

Increases in size after 1 month

If a mass displays any of the above criteria:

Perform diagnostic incisional wedge or needle (tru-cut) biopsy (not aspirates)

Therapeutic Plan:

Stage the tumor and screen the patient by performing a CBC, serum chemistry profile, urinalysis, and thoracic radiographic exam.

Additionally screen for FeLV and FIV, from a prognostic rather than etiologic concern.

Consult an oncologist for multimodal treatment planning.

When possible, use computed tomography or magnetic resonance imaging to evaluate the location and spread of tumor in the body.

Never perform a “lumpectomy” or “shell out” the tumor.

Even aggressive surgery is often incomplete, unless *very* early.

Radiation or chemotherapy may be needed in conjunction with surgery.

Submit the entire mass removed for histopathology.

Infectious Diseases of the Dog and Cat, 3rd Edition

Report all histopathologically confirmed vaccine-associated sarcomas to the product's manufacturer and the U.S. Pharmacopeia Veterinary Practitioner's Reporting Program, 12601 Twinbrook Parkway, Rockville, MD 20852. Voice phone 800-487-7776; fax 301-816-8532 or <http://www.usp.org/prn>.

Recheck the cat by followup physical examination every month for the first 3 months and every 3 months for at least 1 year.

CBC, Complete blood (cell) count; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus.

Information was adapted from the recommendations of the Vaccine-Associated Feline Sarcoma Task Force.

Encephalomyelitis has been reported after CDV vaccination in dogs, especially in very young pups or immunosuppressed dogs (see Canine Distemper, earlier, and Prevention, [Chapter 3](#)). Postvaccinal distemper has been reported after immunosuppression of dogs with cytotoxic chemotherapy (see previous discussion, Vaccination Failures, and Canine Distemper, later) and in association with virulent CDV infection (see Canine Parvoviral Enteritis, later). Atrophy of the Purkinje's cells and cerebellar dysfunction developed in three of six pups given MLV measles vaccine at 6 weeks of age¹⁵⁷; however, this observation seems unusual in that measles virus does not generally replicate to any extent in the dog. MLV FPV vaccines and CPV vaccines should not be administered to animals younger than 4 to 5 weeks. Cerebellar degeneration and myocarditis may develop in kittens and puppies, respectively, from virulent parvovirus. MLV vaccine might also cause cerebellar disease in very young (under 3 weeks) immunosuppressed dogs or cats.⁴⁹⁷ Cases of cerebellar hypoplasia from vaccinating pregnant cats or dogs with attenuated parvoviral vaccines are rare because most veterinarians are aware of this contraindication. Parenteral vaccination with one of the first licensed, attenuated CCoV vaccines was associated with disseminated vasculitis and meningitis in dogs that was similar to FIP in affected cats.^{364,598} The authors have observed a modified live CDV Rockborn strain vaccine to cause an increased frequency of CDV postvaccinal encephalitis when it was added to a combination product that previously had a low or no postvaccinal complications.

100.7.9 Prenatal and Neonatal Infections

If MLV vaccines are given during pregnancy, vaccine infections can result in fetal malformation or death or infertility and abortion in the dam. Neonatal infection can also occur after the use of MLV CPV or FPV vaccines in puppies or kittens younger than 4 weeks. Although some vaccines may be safe, the general recommendation is to avoid giving MLV vaccines to pregnant females. Furthermore, unless specified on the label as safe for use in pregnant animals, noninfectious vaccines should not generally be given to pregnant animals because systemic allergic reactions might develop that might jeopardize the pregnancy.

100.7.10 Respiratory Disease

Clinical illness can develop as an expected postvaccinal event when IN vaccines are used for FCV, FHV-1, CPiV, CAV-2, and *B. bronchiseptica* infections. The mild clinical syndrome is usually self-limiting, but the organisms may produce respiratory tract inflammation, a carrier state, or may spread to other susceptible animals. In general, cats are more severely affected compared with dogs. The onset and level of secretory immune responses with IN vaccines are superior to those of parenteral vaccines. However, the clinical disease that these vaccines can produce has restricted their use by veterinarians because clients become concerned even when mild clinical signs are present. Parenteral MLV feline respiratory vaccines inadvertently or accidentally released into the environment or on the haircoat or aerosolized during administration can cause

Infectious Diseases of the Dog and Cat, 3rd Edition

similar or more severe postvaccinal reactions because they are not attenuated as do the strains intended for IN inoculation. In some purebred catteries where genetic immunodeficiencies exist, the use of MLV respiratory vaccines may have to be avoided because of the potential of vaccine-induced respiratory disease. Feline chronic ulcerative gingivostomatitis and faucitis (see [Chapter 89](#)) are likely caused by hypersensitivity to persistent FCV infection. Routine annual boosters, especially of adjuvanted noninfectious products, are not recommended in affected cats. In some cases, one of the authors (CEG) has observed activation of oral ulceration after vaccine boosters of carrier cats.

1099

1100

100.7.11 Febrile Limping Syndrome of Cats

This problem is noted in kittens after the use of products containing attenuated FCV. The illness usually occurs in kittens younger than 6 months of age and within 21 days following a vaccination.^{110,111} Animals are lame, anorectic, and febrile as early as 7 days after immunization. Pyrexia is commonly present, and some cats show concurrent signs of respiratory disease with or without oral ulceration. Kittens show a shifting-leg lameness and hyperesthesia that cannot be localized to a particular joint. The clinical signs resolve with symptomatic therapy of fluids, antibiotics, and analgesics; complete recovery is noted in 3 to 4 days. One theory suggests that vaccinated kittens may have been incubating field virus at the time of vaccination, which triggers a hyperimmune response and resultant immune-mediated polyarthritis. However, the more likely premise is that vaccine virus spreads to the joints from viremia following inoculation, with a subsequent inflammatory response. Similar lameness occurs in lower frequency in unvaccinated cats that become naturally infected with FCV.

Lethargy, mental depression, anorexia, and lameness have been reported in cats within 7 to 21 days following vaccination with attenuated *Chlamydophila* products. Because the clinical disease is mild and the reaction to vaccination is often more severe, the routine use of *Chlamydophila* vaccines is not recommended.

100.7.12 Vaccine-Associated Disease of Young Akita Dogs

Families of closely related Akita dogs have developed immune-mediated polyarthritis 3 to 29 days after receiving MLV vaccines and less frequently or less rapidly after receiving noninfectious vaccines^{129,603} (see also [Chapter 95](#)). Such defects in their immunity are expected because Akitas are highly inbred from a relatively small gene pool. By 16 weeks of age, the dogs usually developed signs consisting of cyclic fever, joint pain, neutrophilic leukocytosis, and nonregenerative anemia. Elevated levels of hepatic enzymes, creatine kinase, and azotemia have been observed. Joint fluid analysis reveals nonseptic, purulent polyarthritis. Treatment with glucocorticoids helps alleviate the clinical signs, but relapses are frequent, and higher continuous doses of glucocorticoids may be needed. Unfortunately, long-term high doses of glucocorticoids may lead to iatrogenic hyperadrenocorticism. Dogs usually have to be euthanized by 2 years of age because of progressive systemic inflammatory disease, amyloidosis, and renal failure as a result of glomerular amyloidosis. The disease may be an immune-mediated disorder induced by an immunodeficiency with increased susceptibility to vaccine organisms or coincidental exposure to other environmental or commensal microflora. The condition shows many similarities to the syndrome of recurrent fever, polyarthritis, and renal amyloidosis in Chinese Shar-pei dogs (see [Chapter 95](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

100.7.13 Vaccine-Associated Hypertrophic Osteodystrophy and Juvenile Cellulitis, Especially Noted in Weimaraners

A syndrome has been observed after administration of combination vaccines, including MLV CDV, characterized by fever, limb swelling, radiographic changes typical of hypertrophic osteodystrophy (HOD), and variable systemic manifestations such as coughing from pneumonia, lymphadenomegaly, diarrhea, pyoderma, and oral ulceration.^{128,221} Reactions usually develop after the second dose of vaccine given between 8 to 20 weeks of age.¹²⁷ Signs usually begin 1 to 27 days after vaccination, with a mean of 10.5 days. The most commonly affected signalment has been young (2 to 5 months of age) Weimaraners, and less frequently, other large-breed dogs, and occasionally small-breed dogs. Typical cases of juvenile cellulitis have been associated with this syndrome.³⁵⁷ In one of the author's (CEG) experience, some dogs with juvenile cellulitis may have radiographic evidence of HOD, even when concurrent dermal lesions are the predominant manifestation. The simultaneous occurrence of these two syndromes following CDV vaccination suggests that they may be related to infection with attenuated distemper vaccine virus in an immunocompromised host. However, infection with virulent CDV in dogs incompletely protected by vaccination cannot be excluded. Virulent CDV has also been associated with metaphyseal osteodystrophy in dogs (see [Chapter 3](#)), and primary immunodeficiencies have been established in Weimaraners that may make some dogs more susceptible (see [Chapter 95](#)). This syndrome usually occurs following the administration of the second dose of MLV CDV-containing vaccine in the puppy series. Leukocytosis is the main laboratory abnormality, although neutropenia has been observed. Low plasma protein and low levels of IgG and IgM have been observed. Treatment with antiinflammatory dosages of glucocorticoids (0.5 to 1.0 mg/kg/day prednisolone) over 1 to 3 weeks at a gradually reduced level is adequate to cause resolution of signs. This syndrome has occurred most commonly with vaccination with the Rockborn, Snyder Hill, and certain Onderstepoort strains of vaccines. Subsequent immunization of affected dogs or any vaccinations of Weimaraners, with less virulent Onderstepoort strain or recombinant canarypox virus–vectored distemper vaccine, is recommended (see [Table 100-17](#)). One alternative that appeared to reduce this reaction in Weimaraners was to separate the parvovirus from the distemper-adenovirus-*Leptospira* immunogens into an every-other 2-week interval.²²¹ Dogs in the group receiving the separated antigens reacted only after administration of the second distemper vaccine, and then only at that time. Pups given both distemper and parvovirus and the other immunogens in combination on a 4-week-interval schedule developed varying degrees of the HOD reaction after each dose in the vaccine schedule. Dogs that reacted to the vaccine did not develop measurable antibody titers, if at all, until after the immunization protocol was completed. They also had low levels of IgG before immunization.

Given that certain families of Weimaraners are prone to develop this reaction, they should be vaccinated differently; they should also be serotested 1 month after the vaccination series is complete to ensure successful immunization for CDV and CPV. An alternative vaccination method that may be tried if MLV CDV is causing the problems is to use only the canarypox virus–vectored CDV combination product because it contains no live CDV and is as effective as MLV CDV after 3 doses of vaccine given over a period of 9 to 12 weeks starting at 6 weeks of age. One other recommendation is to restrict the use of combined antigen products, such as with *Leptospira* bacterin, in these dogs during their primary vaccination series because they may suppress an already tenuous immune response.

100.7.14 Shedding of Vaccine Agent

Shedding of vaccine virus, which occurs with the IN MLV products, also occurs after administration of parenteral vaccines such as MLV canine-origin and feline-origin parvoviral vaccine (feces), CAV-1 vaccine

Infectious Diseases of the Dog and Cat, 3rd Edition

(urine), and CAV-2 vaccine (respiratory secretions). This shedding may serve to vaccinate other susceptible animals of the same species that come in contact with infected secretions. However, caution must be exercised when mixed animal species are vaccinated, especially when exotic and wildlife species are in contact with a vaccinated animal that is shedding virus. Although the potential exists, reversion to virulence for the target species has not been demonstrated with any virus that is shed as a result of vaccination with commercially available veterinary vaccines.

1100

1101

100.7.15 Influence on Drug Disposition

A potential influence of vaccines or viral infections on drug disposition exists in that they induce IFN synthesis, which, in turn, inhibits hepatic enzyme systems. This factor might prolong the effects of drugs eliminated by oxidative metabolism, such as aminophylline, barbiturate, lidocaine, propranolol, chloramphenicol, tylosin, griseofulvin, and trimethoprim. However, no studies have been performed to demonstrate this potential effect.

100.7.16 False-Positive Test Results

Bovine serum or other proteins in cell culture can cause reactions that give false-positive ELISA results, especially when adjuvanted noninfectious products were used. These results have been found in serotests for antibody in the diagnosis of toxoplasmosis, FIP, and FIV infection after routine use of CHV, FCV, and FPV vaccines. Vaccines for feline respiratory disease or panleukopenia are often grown in Crandell-Reese feline kidney (CRFK) cells. To determine if cross-reactivity exists, kittens were vaccinated with either CRFK or feline renal tissue (FRT) extracts or with one commercially available product including either an intranasal or one of three parenteral vaccines.^{313,314} Cats vaccinated with the CPFR or FRT extracts or parenteral vaccines had seroconversion and developed measurable serum antibodies to FRT. Cats vaccinated SC had greater antibody responses to CRFK cells than did those that were vaccinated IN. Whether this laboratory finding has a bearing on development of renal disease in cats is uncertain. Routine vaccination in research beagle dogs with multivalent and rabies vaccine was associated with an increase in species-specific tissue autoantibodies.⁵¹⁶ In beagles, the increase was in antibovine thyroglobulin antibodies, while in pet dogs, an increase was noted in anticanine thyroglobulin antibodies after vaccination. Whether these increases are an artifact of cross-reactivity or an indicator of stimulating thyroid autoimmunity is uncertain.

100.7.17 Immunosuppression

Some concern has been expressed regarding deleterious effects of attenuated vaccines on the immune response, especially during primary vaccination of naïve animals. To be effective, attenuated vaccine antigens have to produce transient infection themselves, which leads to immunologic activation and sometimes potential immunosuppression. Polyvalent vaccines can cause lymphopenia and suppress the response of lymphocytes to mitogens when testing is performed within the first week after vaccination. Individual antigen components do not cause this problem as frequently as do combined immunogens, and in one report in dogs, combined CDV and CAV antigens were incriminated.⁴⁴⁹ When vaccine antigens are combined, they are required to have testing, which shows that the combination does not suppress the immune response to the same antigens given separately. Evidence suggests, however, that use of attenuated vaccine agents along with concurrent, potentially virulent infectious agents may lead to greater susceptibility to disease caused by either agent. One of the authors (RDS) has observed some dogs with localized demodicosis developed generalized disease 2 weeks after vaccination with combination products. Clinical salmonellosis and suspected concurrent parvoviral enteritis were observed in a cattery with endemic *Salmonella* infection after vaccination with IN

Infectious Diseases of the Dog and Cat, 3rd Edition

modified live FPV, FHV, and FCV vaccine.¹⁶⁵ Vaccine-induced distemper encephalitis has been observed in MLV CDV–vaccinated 3-week-old pups that were co-infected with virulent CPV (see [Chapter 8](#)). Under certain circumstances, inactivated vaccines have also been suspected to cause transient immunosuppression. When bacterins for *Leptospira* are used in combination early in the primary vaccination series of pups, they may reduce the serologic response to the viral antigens compared with that of pups not receiving them.

100.7.18 Human Health Risk to *Bordetella bronchiseptica* Intranasal Vaccine

B. bronchiseptica, a cause of respiratory disease in dogs and cats, can infect people as a zoonotic infection (see [Chapters 6](#) and [16](#)). Most cases of human infection with this organism have been in immunocompromised individuals. Young children, elderly, and human immunodeficiency virus (HIV)-infected people with acquired immunodeficiency syndrome (AIDS) have been most susceptible. Infections have usually involved the respiratory tract or contamination of surgical or traumatic wounds. The attenuated IN vaccine for *Bordetella* was suspected to cause respiratory infection in a 14-year-old boy.⁴⁴ A veterinarian inadvertently sprayed the face of a boy (while the boy was restraining his dog) with an aerosol that contained both CPiV and *B. bronchiseptica*. The boy developed a paroxysmal cough beginning 5 days after the event, and clinical signs persisted for 3 to 4 months. The boy was treated with antibiotics and recovered. No cultures were performed of his respiratory system; however, with subsequent investigation, two morphologically distinct isolates of *B. bronchiseptica* were cultivated from the vaccine. Because no other cases of respiratory illness were observed in the boy's school or family contacts, the infection was presumably caused by the vaccine. For this reason, veterinarians should reconsider the manner in which they administer IN vaccine to their patients. When possible, the animal should be restrained by hospital personnel rather than clients. If clients are present during administration, avoid having infants, pregnant females, elderly adults, or known immunosuppressed individuals within a distance of 2 to 3 meters. An alternative would be to have them leave the room, or the animal should be taken to another area to administer this product.

100.8 VACCINATION RECOMMENDATIONS FOR SPECIFIC DISEASES

The diseases to be discussed are those for which vaccines are commercially available. Specific chapters on each disease should be consulted for additional information. Overall recommendations for canine and feline immunization protocols are summarized in [Appendices 1](#) and [2](#), respectively. [Appendix 3](#) lists veterinary biologics available in many countries.

100.8.1 Vaccination of Exotic Carnivores

Many nondomestic carnivores are vaccinated for diseases of dogs and cats with commercially available canine and feline vaccines. In general, one of the authors (RDS) recommends that unless absolutely necessary, MLV products should not be used in exotic species because they may cause clinical illness, and in addition, a potential always exists for reversion of the attenuated strain to virulence in a foreign host. Only noninfectious rabies vaccines should be used in these animals. Oral recombinant-vectored vaccines are available for wildlife, and a parenteral rabies canarypox virus–vectored rabies product is available for cats. The killed and recombinant rabies products should be tested and used only after safety and efficacy can be demonstrated in the specific exotic species. Because of the risk of vaccine-induced distemper, a concern has been expressed for vaccinating nondomestic carnivores with MLV/CDV vaccine; however, noninfectious whole viral products have been ineffective. Chicken embryo–derived CDV vaccines appear to be safer in this regard for species such as the domestic ferret, but they can cause disease in the black-footed ferret. The product of choice is the recombinant canarypox virus–vectored CDV vaccine that has been proven safe and effective in ferrets.⁵⁴² In

1101

1102

Infectious Diseases of the Dog and Cat, 3rd Edition

the United States, the USDA-Animal and Plant Health Inspection Service (APHIS) has proposed allowing wolves and wolf-dog hybrids to be inoculated with the same vaccines used for dogs.¹¹ Similarly, proposals to give the same consideration to Bengal-cat hybrids have been offered. Vaccinating these animals creates legal and ethical issues for veterinarians and public health officials. In jurisdictions where these animals are not legal pets, they should not be vaccinated; however, veterinarians may decide to vaccinate in areas where ownership is allowed. The owner must receive notice, preferably in writing and as part of informed consent, that efficacy of vaccines is not proven in these animals. Susceptibility to canine and feline infections and recommendations for vaccinating wild or exotic carnivores are summarized in [Table 100-20](#).

100.8.2 Vaccination Requirements for Transport of Animals

Interstate shipment of animals that are affected with or have recently been exposed to infectious diseases is prohibited within the United States. Each state has established guidelines that normally include a physical examination and current rabies vaccination. General information is available in the current regulations of the USDA (<http://www.usda.gov>), APHIS (<http://www.aphis.usda.gov>), Department of Agriculture in Canada (<http://www.agr.gc.ca>), Bureau of Animal Health in Australia (<http://www.aahc.com.au>), Ministry of Agriculture in the United Kingdom (<http://www.defra.gov.uk>), and similar bureaus in other countries.

In the European Economic Community (EEC), animals may move between member countries provided they show no signs of disease, are identified by tattoo or microchip, are vaccinated using a World Health Organization–approved vaccine certified by an official veterinarian, and are accompanied by an animal passport clearly identifying the individual.²¹

Amendments have been added to regulate the importation of animals into rabies-free areas such as the United Kingdom and Ireland. An animal originating outside the EEC is required to have an import license and a minimum of 6-months post import quarantine in approved facilities. Animals from EEC member nations must originate from a registered holding facility and must have been born and kept in captivity from birth, with no contact with wildlife. The animals must be identified with a microchip and be vaccinated against rabies at least 6 months before shipping and be at least 12 weeks of age at the time of vaccination. After vaccination, an internationally agreed on serologic test such as the RFFIT or FAVN must demonstrate a protective rabies titer of at least 0.5 IU/ml. If the test is carried out after the first vaccination, it must be between the first and third months after vaccination. Further changes in this law are being considered.²² For information regarding serologic testing and proof of rabies immunization for transport of animals, see previous section of Rabies and in [Chapter 22](#).

100.8.3 Rabies Vaccination Recommendations for Dogs and Cats

Rabies vaccines have been extremely effective in reducing the prevalence of this disease in dogs. As a result, the incidence of human disease has decreased substantially, whereas the relative incidence of feline rabies has increased. The first vaccines for rabies, derived from nervous tissue of infected animals, evoked severe autoimmune reactions in the CNS. Subsequently, more purified, extraneurally produced MLV vaccines were cultivated in avian embryo and tissue culture media. Unfortunately, certain MLV vaccines produced postvaccinal rabies in dogs and cats (see previous discussion of Neurologic Complications). Because of this problem, the trend has been to switch from MLV to inactivated rabies vaccines. No MLV rabies vaccine is currently available in the United States, but a genetically attenuated MLV rabies vaccine has been licensed in Europe, and MLV vaccines are available in a large number of countries throughout the world (see [Appendix 3](#)). All MLV rabies vaccines must be given IM at one site in the thigh. MLV requires fixation to nerve endings to be effective, and these are more plentiful in muscle compared with subcutaneous tissue.

Inactivated rabies virus vaccines provide an adequate duration and level of protection but not necessarily comparable to that of MLV products. Inactivated rabies vaccines must contain high viral content, and adjuvants, such as aluminum hydroxide, need to be added. Combination products containing rabies antigen have been licensed for cats but one of the authors (RDS) believes strongly that rabies should be given only as a monovalent vaccine. These modifications, required to make inactivated rabies immunogenic, may be

1102

1103

Infectious Diseases of the Dog and Cat, 3rd Edition

associated with a greater degree of allergic and neoplastic reactions, especially in cats (see Postvaccinal Complications, earlier). In general, inactivated rabies virus vaccines given IM often give stronger immune responses than those given SC, but the former is associated with more systemic allergic reactions. A canarypox virus–vectored recombinant feline rabies vaccine (Purevax Feline Rabies®, Merial, Athens, Ga.; see [Appendix 3](#)) that produces few local inflammatory reactions is effective in cats. The product is currently licensed only as a 1-year product.

For recommendations on rabies vaccines used in the United States, the *Compendium of Animal Rabies Vaccines* published by the National Association of State Public Health Veterinarians should be consulted (see [Appendix 4](#)). In summary, both dogs and cats should receive their first rabies vaccine no earlier than 3 months of age. Rabies vaccines are frequently given on the last visit of the neonatal vaccination series ([Appendices 1 and 2](#)). Subsequent boosters are administered 1 year later, then either 1 or 3 years later, depending on the age of the animal, the vaccine manufacturer's recommendation, and the local public health laws. Although inactivated vaccines generally require at least two vaccinations in a series 2 to 4 weeks apart to offer full protection, rabies vaccines can provide adequate protection with one dose. The current challenge procedure for licensing of rabies vaccines involves giving one dose at 12 to 16 weeks of age, then waiting 1 year with the 1-year rabies vaccine and 3 years with the 3-year products. The animals are then challenged to demonstrate protection. One-year products often become licensed as 3-year products by showing that they provide the same protection 2 years later as they did at 1 year. Triennial vaccination with a 3-year product provides the same protection as does yearly vaccination with a 1-year product. Using 3-year products is preferred because they provide the same protection and reduce the chance of an adverse reaction. Only a few states, cities, or local municipalities require that rabies vaccines be given more often than once every 3 years after the booster at 1 year. Because of the confusion it might cause in diagnosis and management, rabies vaccination is not recommended for wild animals that are kept as pets; however, when needed, only noninfectious or recombinant-vector products should be considered.

Rabies vaccination of cats is mandatory in some counties in the United States and discretionary in others. The vaccine requirements vary from annual to triennial. Unlike the situation in dogs, licensing is not tied to vaccination, and few county governments require that cats be licensed, even where mandatory feline rabies vaccination exists. Therefore as guided by the Council on Biologic and Therapeutic Agents report of the American Veterinary Medical Association, in many situations, veterinarians have the task of recommending rabies vaccination of cats to their clients based on the regional variation of disease, different feline lifestyles, risk of reaction of a particular breed, and preference of the owner and veterinarian.²⁹⁶

100.8.4 Canine Vaccination Recommendations

See [Appendices 1 and 3](#).

100.8.4.1 Canine core vaccines

Since the 1970s and especially the 1980s, annual vaccination has been the routine practice for immunization of dogs. The prevalence of many diseases for which the vaccines were developed has been decreased significantly. Evaluation of early vaccines showed that not all pups maintained sterilizing antibody titers (protection from infection) to CDV after the initial series. However, it was not known at that time that CMI played an important role in protection from disease and that sterile immunity was not necessary for protection from disease. Therefore annual boosters were recommended because serologic testing was more difficult and costly compared with revaccination. However, the lowered frequency of infection and information on adverse reactions recently has prompted the question, “Are we vaccinating too

Infectious Diseases of the Dog and Cat, 3rd Edition

often.² The too-frequent administration of boosters and potential for development of hypersensitivity or other reactions creates a medical dilemma. For this reason, veterinary scientists and professional veterinary groups have categorized vaccines into core vaccines and optional (noncore) vaccines, with individual customization based on the animal and its environment (see [Appendix 1](#)).^{295,441} Components considered *core* vaccines for dogs are canine distemper, canine adenovirus, canine parvovirus type 2, and rabies virus; they are recommended for all dogs. Noncore vaccines are vaccines used to prevent or manage diseases such as infectious tracheobronchitis, leptospirosis, coronaviral enteritis, Lyme borreliosis, and giardiasis that are of lesser severity, for which less effective vaccines are available, or to which the pet may have limited exposure based on geographic or utilitarian factors. These products should be given only to animals at risk, and they often need to be given on an annual or more frequent basis based on potential for exposure.

100.8.4.1.1

Canine distemper

(Also see Prevention, [Chapter 3](#).) Immunity to CDV is based on humoral (antibody) and CMI responses. However, the magnitude of the antiviral antibody response in the host determines whether a dog is protected from infection or if it will develop the epithelial or neurologic form of the disease (see [Chapter 3](#), and Serologic Testing, previously). Passive administration of serum antibodies to CDV can be used to protect animals from becoming infected (passive sterile immunity). Only MLV vaccines and live recombinant–vectored CDV vaccines are highly effective in protecting dogs against CDV. However, these vaccines are not homogenous with respect to the degree and duration of neutralizing antibodies that are produced following vaccination.⁴⁸⁴ Noninfectious vaccine gives incomplete and short-lived protection from CDV and is not licensed in most countries. MLV vaccination can also cause false-positive test results for viral detection in serum up to 4 weeks after vaccination.⁵²⁷

Distemper vaccination is performed in combination with other antigens, mainly CAV, CPV-2, and CPiV, at 3- to 4-week intervals, beginning at 6 to 9 weeks of age. Most currently used vaccines are able to break through MDA by the time the animal is 12 weeks of age. Distemper vaccines differ in their ability to immunize and break through MDA, even among the recombinant and conventional MLV products,^{472,484} but most are able to provide protection when given at or after 12 weeks of age. The Onderstepoort strain, which has been chicken-embryo adapted, later avian-cell adapted and later canine-cell adapted, are generally, but not always, less immunogenic than the canine cell–adapted Rockborn or Snyder Hill strains ([Table 100-21](#)) Improvements have made many of the MLV products comparable. Colostrum-deprived puppies should not be vaccinated with MLV distemper vaccine before 4 weeks of age. A canarypox virus–vectored vaccine may be considered at this age if a monovalent was available.

1103

1104

a Refer to [Appendix 3](#) for additional information on these vaccines and manufacturers.

Measles vaccine (MV) in combination with distemper has been recommended as the first vaccination given to high-risk puppies between 4 and 6 weeks of age. MV creates a heterotypic immune response in the presence of a high concentration of MDA to CDV, at a time when vaccination with MLV distemper vaccine alone would fail. Four- to 6-week or older puppies will respond to measles antigen, whereas only 50% or less may respond to CDV antigen. MV does not typically produce a humoral response to CDV such as the CDV vaccine virus, but it does prime the immune system to prevent disease. Distemper antigen has been combined with measles (MV-CDV) by one vaccine manufacturer (Pfizer, New York, N.Y.) with the assumption that it would produce a superior homotypic response in those puppies whose maternal immunity is weak. MVs should not be given to bitches if they are going to be bred or if they are 12 weeks of age or older, otherwise MDA to MV will be present in their colostrum if they are bred and have a litter after the first heat. This transfer of MDA will interfere with the effectiveness of MV subsequently given to the pups. By 12 weeks of age, MDA will have waned sufficiently that distemper vaccine alone should be effective. One of the authors (RDS) has demonstrated in unpublished observations that the monovalent recombinant canarypox virus–vectored CDV vaccine (Recombitek®, Merial, Duluth, Ga.) will immunize puppies with high maternal CDV antibody titers and thus can provide early protection from CDV and at an age when some conventional MLV vaccines fail to provide protection. Furthermore, with at least two additional doses in the vaccine series, the antibody response will then be at levels equal to that provided by conventional MLV vaccines.

At least one dose, if not two doses, of MLV CDV or recombinant CDV vaccine should be given whenever dogs older than 12 weeks are presented for their first vaccination. One MLV distemper vaccine provides strong protection in the naïve animal, even in the absence of MDA; however, a second vaccine will ensure more lasting protection. After the primary series, dogs should be revaccinated 12 months later or at 1 year of age. Similarly, in humans, a second booster for measles during the primary vaccination series has been shown to provide more sustained and better protection than a single vaccine does when children are immunized beyond the waning of serum MDA.^{114,182}

Vaccination of dogs with MLV CDV vaccine may even be effective in preventing disease when it is given within 3 to 4 days after initial exposure (not after onset of clinical signs) to virulent CDV (see Prevention, [Chapter 3](#)). MLV vaccine (monovalent product) should be given whenever exposure occurs, if the vaccination history is unknown. For animals older than 1 year, boosters for distemper need not be given more often than every third year. The evidence for this is supported by challenge studies with virulent virus and serologic testing following vaccination (see [Table 100-12](#)). In the absence of CDV,

Infectious Diseases of the Dog and Cat, 3rd Edition

two-thirds of dogs tested had protective antibody titers from 8 to 10 years after vaccination.⁴²⁵ One of the authors (RDS) has demonstrated that the DOI for CDV is a postvaccination minimum of 7 years as determined by challenge and up to 15 years by serology. With less protective vaccine strains, such as certain of the older Onderstepoort vaccines sold in Europe, immunity may wane with time (e.g., 3 or more years) in dogs that do not receive periodic boosters.³⁰² However, dogs over 2 years of age generally have better maintenance of their antibody titers than do younger animals.⁴⁸⁴ Adequate VN titers developed in 90% of vaccinated dogs. Dogs were protected against infection when challenged up to 5 to 7 years after vaccination.⁵⁰² Some distemper breaks have occurred when less protective distemper vaccines had been used, revaccination had waned, or low environmental exposure suddenly increased (see Vaccination, [Chapter 3](#)).^{47,140,194,219} As a systemic viremia that is susceptible to neutralizing antibody, distemper is one disease for which antibody titers are an effective means to determine susceptibility of a vaccinated animal to distemper. Seroconversion that occurs following vaccination indicates that the animal did not have sterile immunity and that the vaccine provided some additional booster protection.

Some concern has been expressed that outbreaks of CDV infection might be caused by poor immunity resulting from differences between field isolates and vaccine strains. Although genetic differences were found in naturally occurring strains,⁵⁰ cross-protection studies show similar protection, regardless of the isolate, and no variants have been reported that are antigenically different from the vaccine viruses. In Chicago, Illinois, an outbreak of distemper in dogs that were adopted into a community was traced to infected raccoons housed in the same animal control facility. A corresponding outbreak in the zoological garden was attributed to the wildlife outbreak and the wandering of raccoons onto zoo grounds. Analysis of the strains involved in epizootics of the zoological garden and dying raccoons over several years have shown genotypic and phenotypic variation of the viruses responsible for the outbreaks.³²⁴ Limited cross-protection studies in dogs done by one of the authors (RDS) showed protection between strains, suggesting that management in the animal control facility was responsible for these outbreaks, although further studies and monitoring are needed.

1104

1105

Distemper can rarely develop in a vaccinated dog; however, when virulent virus is present at high levels and the dog has other concurrent illnesses, is immunosuppressed, or is a genetic-poor responder or nonresponder, disease may develop. Individuals in every breed can be found that are unable to develop an immune response that will protect the animal from disease when it is challenged with virulent virus. This animal is not immunosuppressed; instead, it is an animal whose immune system cannot recognize important immunodeterminants (HA and F antigens) of CDV. One of the authors (RDS) estimates approximately 1 in 1000 to 10,000 dogs are nonresponders for CDV. Given that this trait is genetic, it might be higher in certain breeds and will surely be higher in certain families of dogs. Attenuated distemper vaccines give the strongest immunity and long-term protection; unfortunately, these vaccines have the greatest risk of producing postvaccinal reactions. One of the authors (RDS) also estimates postvaccinal encephalomyelitis at approximately 1 case per 10,000 doses for the more virulent CDV vaccine strains. Distemper vaccine-induced encephalomyelitis, also termed inclusion body polioencephalitis, usually develops 7 to 15 days after vaccination in immunosuppressed dogs or with particular lots or strains of vaccine (see [Chapter 3](#) and Postvaccinal Complications, previously). The illness, which can appear as an acute or more chronic progressive condition, is caused by a nonproductive CDV infection of neurons by vaccine virus.⁴⁰⁶ As a result, the illness usually affects gray matter in the diencephalon, mesencephalon, and medulla oblongata, although cortical and spinal cord involvement has been observed.⁹² Systemic signs are uncommon. Unlike conventional CDV infections,

Infectious Diseases of the Dog and Cat, 3rd Edition

the CNS progression may subside, and dogs may survive with clinical improvement or residual neurologic deficits.⁹² The Snyder Hill and Rockborn strains produce the strongest immunity but have the greatest risk of producing postvaccinal encephalitic disease. Care must be taken therefore to avoid vaccinating certain dogs for distemper with MLV vaccines, especially neonates younger than 3 months of age that have a known or suspected immunodeficiency disorder or are receiving immunosuppressive therapy. Care should also be taken in vaccination of exotic carnivores with MLV distemper vaccines because these can induce vaccine-induced encephalitis.¹³⁹ For further information on these topics, see Prevention, [Chapters 3](#) and [8](#).

A recombinant canarypox virus–vectored distemper vaccine expressing H and F antigens (Recombitek® CDV, Merial, Athens, Ga.) is available (see [Chapter 3](#)) that is safe and effective for all animals, including immunocompromised pups and wild carnivores. A similar product has also been licensed for ferrets.^{436,542} Initially, the duration of long-term immunity was uncertain with the recombinant vectors vaccines; thus yearly boosters have been recommended. However, studies by one of the authors (RDS) shows that when three doses of recombinant monovalent CDV product for ferrets are given at 2- to 4-week intervals to pups with high levels of blocking MDA, the antibody response is very high and above levels required for sterile immunity (greater than 1:20 VN titer). Furthermore, preliminary data from one of the author's (RDS) unpublished studies suggest that the recombinant product might provide a minimum of 3 years DOI. Therefore the recommendation for vaccination with the recombinant distemper combination might be similar to that for MLV vaccines (see [Appendix 1](#)).

100.8.4.1.2 Infectious canine hepatitis

(Also see [Chapter 4](#).) Serum antibody against CAV-1, derived from MDA, passively administered serum, or produced following vaccination, is protective against this cytolytic, systemically spreading virus. Vaccination against this disease has brought about a dramatic reduction in the occurrence of this once widespread and potentially fatal illness. Few, if any, cases of hepatitis are seen in older animals (older than 6 months of age), which suggests long-term protection following MLV vaccination or recovery from natural infection. Vaccines containing MLV-CAV-1 were originally produced; however, in the 1970s, it was replaced with the safer, antigenically related CAV-2, and now most products contain this latter antigen. CAV-1 vaccines were evidently associated with more allergic uveitis than naturally occurring CAV-1 infection. Where CAV-1 antigen is found, it is generally an inactivated product. In areas where vaccination rates are high, ICH is rarely seen in domesticated dogs. Yet, although the disease is rare, a continual reservoir exists in wildlife and outbreaks or isolated cases can still occur when vaccination of puppies is delayed or incomplete. For this reason, CAV-2 is considered a core vaccine.

The shedding of MLV CAV agents and high viral stability has been responsible for inadvertent but beneficial vaccination of many dogs for this disease. However, regulations in many countries require that vaccine viruses are not shed. For this reason, inactivated CAV-1 and CAV-2 vaccines have been available in some parts of the world. Vaccination for ICH is usually performed in combination with that for distemper, CPiV, and CPV-2, beginning at 6 to 9 weeks of age. When using inactivated product, a booster dose must be given annually, whereas in many cases, the MLV products produce longer immunity of at least 3 years (see [Table 100-12](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

100.8.4.1.3 Canine parvoviral enteritis

(Also see Prevention, [Chapter 8](#).) Vaccination for CPV enteritis is essential because CPV is as contagious or is more contagious compared with CDV and is more stable in the environment. Exposure to virus is likely early in life, and as soon as pups are susceptible, they may become infected from a contaminated environment. Even before their first vaccination, pups from vaccinated dams can have virulent CPV in their stool, as demonstrated by PCR.⁴⁹² Before weaning, replication of enteric virus in pups is likely being suppressed by MDA protection in the sera and locally from their dam's milk.

One of the authors (RDS) has demonstrated that infectious virus survives for at least 1 year in sandy or clay soils. This information provided an explanation as to how the virus infected new litters of gray timber wolves (*Canis lupus*) in northern Wisconsin for a significant number of years after repopulation programs were put in place. The soil in the wolf den remained infected year after year. This finding means that more than 90% to 95% of dogs in a given population may have to be successfully immunized to prevent spread of infection.

Vaccines are produced from a variety of CPV-2 isolates and genotypes, but all are antigenically related. Both inactivated and MLV vaccines are available ([Table 100-22](#)). As with other diseases, MLV CPV vaccines offer a longer DOI and, more importantly, stimulate immunity much sooner than do killed vaccines. Postvaccinal shedding of vaccine virus occurs with MLV vaccines; however, it is of no clinical significance and may cause seroconversion in naïve contact animals and weak-positive parvovirus fecal-ELISA results²⁴⁷ (see [Chapter 8](#)). Unfortunately, fecal-oral spread or topical administration of MLV does not provide suitable protection against CPV because it does not reach lymphoid tissue in sufficient concentration compared with parenteral administration. Protection during primary immunization can be provided by one MLV CPV-2 injection or two doses of killed vaccine. In themselves, killed vaccines may not provide as long-term immunity as does MLV; however, under field conditions, the provided protection allows the pup's immunity to be boosted by subsequent exposure to virulent virus. In contrast to inactivated vaccines, MLV vaccines provide a high level of antibody and sterile immunity that not only prevents disease, but also prevents infection or shedding after challenge with virulent virus. For this reason, dogs that are housed in large groups should be vaccinated with MLV vaccines because they will not shed virulent virus should an outbreak occur.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-22 Comparison of Vaccines Available for Canine Parvovirus Infection^a

VARIABLE	INACTIVATED VIRUS	MODIFIED LIVE VIRUS (CONVENTIONAL)	POTENTIATED
Recommended for use in pregnancy	Yes	No	No
Shedding of vaccine virus	No	Yes	Yes, consistent
Protects contacts of vaccinates	No	Variable	Frequently
Positive test results for fecal vaccine virus	No	3–5 days	5–7+ days
Prevents shedding of virulent virus	No	Yes	Yes
Relative magnitude of humoral response	Low	High	High
Relative particle mass of vaccine	High	Low	High
Breakthrough of maternal antibody			
Start vaccinating (weeks)	9	6–9	5–8
Generally protected (weeks)	18–20	16–18	12
Stop vaccination series (weeks)	18–20	16–18	12–14
Stop vaccination in problem breeds ^b (weeks)	16–22	16–22	16
Single dose protects naïve dog ^c	No	Yes	Yes
Selected examples of products	Adenomune,	Parvocine	Progard, Nobivac (Intervet)
	Parvocine (BioCor)	Vanguard (Pfizer)	Vanguard Plus (Pfizer)
	Performer (Agri Labs)	Solo-Jec (Aspen)	Recombitek (Merial)
	Vanguard (Pfizer)	CPV/LP (Vaccinel)	Galaxy (Schering-Plough)
	ImunoVax (RXV)	Adenomune (Biocor)	Duramune (Fort Dodge) ^d
	Canlan (FD)	Parvoid (Fort Dodge)	NeoPar (NeoTech)
		Dohyvax (Fort Dodge)	Kavak (Fort Dodge)
		Parvovax (Merial)	Eurican; Primodog (Merial)
		Enduracell (Pfizer)	Quantam (Schering Plough)
		Tissuevax (Schering Plough)	Parvigen; Canigen (Virbac)
		Parvigen (Virbac)	

a Refer to [Appendix 3](#) for complete information on products in this table.

b Rottweiler, Doberman pinscher, American Staffordshire terrier, German shepherd dog.

c Assuming no interference from maternal antibody.

d Originally formulated product protects similar to potentiated products.

Vaccination for CPV enteritis might seem to be indicated earlier than 6 to 8 weeks of age when the prevalence of the disease is high or when puppies are colostrum-deprived. However, only inactivated products are generally recommended in puppies younger than 4 weeks because of potential damage by CPV-2 to rapidly dividing cells, such as those in the myocardium or cerebellum. MLV products are also

Infectious Diseases of the Dog and Cat, 3rd Edition

not recommended in immunosuppressed or pregnant dogs. Severely immunosuppressed animals or exotic species may develop disease from CPV-2 vaccine virus and should be given only inactivated products. If previously unvaccinated very young or immunosuppressed pups are in high-risk environments and require immediate protection, immune sera (see Passive Immunization, earlier) should be considered.

A parenteral CPV-2 vaccine has been licensed in puppies 4 weeks of age or older, as a monovalent or bivalent product (Progard® -CPv or -DPv and Nobivac® Puppy DP, Intervet, Millsboro, Del., and Boxmeer, The Netherlands, respectively). Ideally, bitches should be vaccinated with MLV CPV-2 products 2 months before breeding, and they should never be vaccinated with MLV while they are pregnant. If already pregnant with an uncertain level of antibody, the bitch can be given two doses of inactivated monovalent CPV-2 vaccine 3 to 4 weeks apart in the last trimester, but these products have not been approved for pregnant animals and vaccination-induced reactions can cause animals to abort or cause premature parturition. 1106 1107

Lack of vaccinations and incomplete vaccination series are important factors in the development of CPV enteritis. Vaccine breaks that occur with a seemingly *good* vaccine schedule in young dogs (younger than 2 years) are probably accounted for by MDA blockade. MDA may fall below protective levels, requiring earlier vaccination, in areas of high environmental contamination. Attenuated vaccine strains do not break through maternal immunity as effectively as virulent CPV resulting in a period of susceptibility. In the past, manufacturers claimed that their *conventional* CPV-2 vaccines would break through maternal immunity as early as 6 weeks of age with one dose. Generally, prevaccination titers were low in those litters reportedly protected at such young ages by conventional vaccines. Conventional products often failed to immunize pups until 18 to 20 weeks, even though MDA against a virulent virus was, in many cases, gone by 6 to 9 weeks of age.

Manufacturers have been able to overcome the susceptibility period when vaccines are ineffective by using more immunogenic strains, raising the virus titer per dose of vaccine, and lowering the serial passage, thus creating *potentiated* CPV-2 vaccines (see Table 100-22).^{72,317-319} Increased immunogeneity of these newer CPV products developed since 1995 (see next paragraph) has provided immunity in the majority of pups vaccinated at 12 weeks of age or older. The high efficacy of the new products in these puppies has resulted in a recommendation to give a complete series of vaccinations, with doses given every 3 to 4 weeks until pups are at least 12 to 14 weeks of age.³⁷² No need has been found to vaccinate to the 18 to 20 weeks required by the conventional CPV-2 vaccines. The *window of susceptibility* is rarely greater than 2 weeks. In contrast, certain breeds of pups or pups born to bitches with very high antibody titers may not respond to conventional CPV-2 vaccines until up to 20 weeks of age. The remaining conventional products on the market are those manufactured for some of the feed stores and catalog sales (over-the-counter products) and by Pfizer Inc. (New York, N.Y.) as Vanguard®.

As with distemper, certain breeds appear to be more clinically susceptible to CPV-2 disease; and in some breeds, more low responders and nonresponders to the CPV-2 vaccines exist. The incriminated breeds include Doberman pinschers, American Staffordshire terriers, Rottweilers, and German shepherd dogs.²⁵¹ One of the authors (RDS) estimates the nonresponders to CPV-2 at 0.1% and the poor responders at 1% to 5%, with that number higher in certain breeds and lower in others.

Because of the large amount of virus excreted by infected dogs, vaccination alone is often inadequate in breaking the CPV infection cycle, especially in a shelter environment. Pups may need to be isolated from birth to 12 weeks from viral exposure to control an outbreak. Pups should be kept away from parks,

Infectious Diseases of the Dog and Cat, 3rd Edition

boarding facilities, other litters, and shows until a dose of vaccine is given at or after 12 weeks of age. Simultaneous vaccination and infection with wild-type virus will generally result in disease, unlike CDV in which, because of a longer incubation period, the vaccine can be given up to 72 hours after infection and it can prevent disease.

Although combined vaccination with MLV CDV and CPV-2 vaccines has been rumored to cause immunosuppression, more controlled experimental studies have refuted these claims.^{449,450,555,556} Despite the safety of combined CDV-CPV products, some breeders have expressed some concern about using multivalent products for the first vaccinations of pups. However, alternating these antigens in an initial vaccination series will leave a pup highly susceptible to infection with either virulent CDV or CPV, depending on which is omitted. Another argument posed by breeders has been to give the vaccines alternatively on a weekly basis; however, spacing MLV inoculations too closely may cause vaccine interference. Instead, vaccines should be given at a minimum interval of 2 weeks, although 3- to 4-week intervals are desired. Caution should be used when vaccinating pups suffering from CPV-2 illness. A potential problem with CDV postvaccinal encephalitis exists if neurotropic MLV CDV vaccines are administered (see [Chapter 3](#)). Therefore Onderstepoort CDV strain or recombinant CDV vaccines are recommended for use when concurrent CPV outbreaks are occurring.

Dogs that have recovered from subclinical infection with virulent virus or those that have been vaccinated and produced immunity to MLV vaccines have DOI that lasts at least 7 years. Cases of CPV-2 infection in susceptible older dogs are uncommon, and therefore older dogs may not require annual boosters for CPV. Annual vaccination programs have continued because of the use of multiple antigen vaccines. Revaccination of CPV-immune dogs does not often cause a significant (fourfold) increase in their antibody titer. This finding indicates that preexisting antibody has neutralized the vaccine virus before it could stimulate immune cells. Therefore periodic vaccination on an annual or triennial basis may not improve already-established immune protection for this disease. Similarly, producing hyperimmune sera by repeated vaccination of blood donors that might be used for treating CPV-susceptible pups would also be difficult. In a study of 106 dogs vaccinated against CPV-2 within the last 1 to 4 years, only one dog had a fourfold increase in antibody titer after revaccination because the dog had a low HI titer (lower than 1:160) before a booster vaccination.⁵⁰²

A shifting of antigenic determinants and genetic composition of CPV-2 began taking place in approximately 1981 with the CPV-2a strain and again in 1985 with the CPV-2b strain. Despite marketing claims to the contrary, excellent cross-protection exists between the old strains in the vaccine and the new field isolates. Molecular virology has shown that the most common viral type now isolated is CPV-2b (see [Chapter 8](#)). Similarly, immunodiagnostic tests based on MAB to original isolates are still sensitive in detecting newer strains of virus. Significantly, CPV-2b can infect and cause clinical illness in cats (see Feline Panleukopenia, later, and [Chapter 10](#)). This finding is in contrast to the original 1970's CPV-2 isolate, which was unable to even replicate in susceptible cats.

Immunity in the vaccinated animal is provided by IgG-neutralizing antibody. Passively acquired antibody from colostrum completely prevents infection for variable periods after birth. Serologic assays including ELISA, HI, VN, and indirect FA tests have been developed to detect this antibody. The ELISA is frequently used for diagnosis of virus in feces, and a variety of in-office kits are available (see [Appendix 6](#)). Antibody titers should be determined in selected laboratories that perform HI or VN tests. Measurement of serum antibody titers is a useful tool to determine need for vaccination against CPV infection. Absolute titers vary between laboratories, depending on the method used and test conditions. Each laboratory should provide reference values, and if a laboratory does not perform HI or VN, they

Infectious Diseases of the Dog and Cat, 3rd Edition

should have quality assurance performed by outside reference laboratories testing many samples by HI or VN. An in-office ELISA has been developed, TiterCheck® (Synbiotics, San Diego, Calif.), which has been approved by the USDA and has been quality controlled with VN and HI.	1107 1108
---	--------------

100.8.4.1.4 CPV-1 infection

The so-called *minute virus of canines* may cause illness in very young puppies and reproductive disease (e.g., embryonic death, abortions) (see [Chapter 8](#)). CPV-1 outbreaks have been associated with neonatal and in utero mortality. CPV-1 is not related antigenically to CPV-2, nor does a vaccine exist or much evidence that CPV-1 causes disease in a significant number of animals. The lack of immunologic cross-reaction also means that CPV-1 will not be detected by immunologic tests intended for CPV-2 in feces or tissues.

100.8.4.2 Noncore vaccines

100.8.4.2.1 Canine infectious tracheobronchitis

(Also see Prevention, [Chapter 6](#).) Infectious tracheobronchitis, also known as kennel cough or canine infectious upper respiratory disease (CIURD), is incited by a large number of viruses, bacteria, and mycoplasmas. Viruses can include CPiV, CAV-2, CDV, and CHV-1; secondary opportunistic bacteria such as *B. bronchiseptica*, *Streptococcus* spp., *Pasteurella* spp., and *Mycoplasma* spp. are often incriminated in complicating infections. Viruses such as CPV-2 can also be involved, especially by causing immunosuppression from co-infection. Multiple agents are often involved in an individual animal's illness. Because of the multiplicity of agents and short-term immunity to mucosal infections, prediction of protection following vaccination with CAV-2, CPiV, and *B. bronchiseptica* is impossible. Serum antibody titers to *B. bronchiseptica* increase to greater levels with parenteral vaccination rather than via IN route.¹⁴⁴ However, serum antibody levels play an uncertain role in predicting protection against infections of the respiratory tract or other mucosal surfaces. S-IgA and other local innate and specific immune mechanisms, which are difficult to measure, transiently increase following IN vaccination. These factors may be more important for protection against respiratory tract pathogens than systemic responses. However, challenge studies indicated better protection in pups that were sequentially vaccinated with one manufacturer's products using modified live IN and killed IM products during the primary vaccination series as compared with vaccination with either product alone.¹⁴¹ Important to note is that the IM product used in this study is no longer licensed in the United States and has been replaced by a SC variety of different manufacture. Further studies on the use of SC products will be needed because they may not provide as strong a protection as afforded by IM injection. In contrast, in a large ongoing study in shelters by one of the authors (RDS) where 50% of the dogs receive parenteral vaccines and 50% receive IN vaccines, no significant differences have been seen between the vaccines and CIURD in any of the shelters. This result is not surprising given that this condition is a complex respiratory disease caused by many organisms that cannot be prevented by vaccines. Immunization against these infecting organisms can only help manage the disease and hopefully keep infected animals from developing severe pneumonia and possibly dying. Many dogs that are never vaccinated with kennel cough products resist the disease, as well as those vaccinated every 6 months to a year; thus probably even more factors are involved than those previously cited. These additional factors include genetics of the animal and anatomic differences among breeds or individuals. Severe kennel cough with death occurs regularly in racing greyhounds in spite of routine and constant vaccination with any and all commercial vaccines. However, if vaccines were not used, the morbidity and mortality rates may be even

Infectious Diseases of the Dog and Cat, 3rd Edition

higher. Some of the mortality in greyhounds that occurs in spite of vaccination has been attributed to other respiratory pathogens such as equine influenza virus (see [Chapter 25](#)) and group D streptococci (see [Chapter 35](#)).

Available vaccines include avirulent live cultures, given IN, and whole-cell bacterins and antigenic extracts given parenterally. MLV CDV and CAV-2 viruses, both of which can cause respiratory tract infections, are included in routine parenteral vaccines, and CAV-2 is available in some IN vaccines (see [Table 6-4](#) and [Appendix 3](#)). Modified live CPiV and killed *B. bronchiseptica* bacterin are available in some parenteral combinations. The DOI produced by respiratory vaccines against most primary respiratory pathogens, such as CPiV and *Bordetella*, has not been well established. One concern is that genetic differences exist between a number of field isolates and vaccine strains of *B.*

bronchiseptica.^{280,282,475} This finding may also help explain outbreaks of infection in vaccinated animals. In an attempt to obviate this problem, some vaccine companies have a variety of strains in their products, and the composition is periodically modified with current field isolates.

Parenteral canine respiratory vaccines usually do not produce protection until 2 to 3 weeks after the second vaccination. Originally, parenterally administered *Bordetella* bacterins contained large amounts of LPS (endotoxin), which produced fever, swelling, pain, or abscess formation at the site of injection. Newer parenteral products have modified whole cell or partially purified cell wall components that obviate some of the adverse reactions. Some reduction in efficacy and DOI has been associated with the purification process. Despite this disadvantage, administering parenteral products today is more convenient than are the older products that cause significant adverse reactions. Parenteral products produce higher serum IgG titers following vaccination.¹⁴⁴ However, this measure of protection is not as valid as is challenge infection. Parenteral products can be used for initial vaccination in the puppy series and subsequently in booster vaccinations. Vaccination with many parenteral products can begin at 6 to 8 weeks of age, depending on label recommendations. Because of the killed *Bordetella* component in parenteral vaccines, and to obtain adequate levels of S-IgA for all antigens, recommendations are that animals receive at least two doses 2 to 4 weeks apart for primary immunization.

IN vaccines, including both modified live CPiV and *B. bronchiseptica*, with or without CAV-2, have been developed in an attempt to increase the local immune response to vaccination (see [Table 6-2](#) and [Appendix 3](#)) and to reduce the local and systemic adverse hypersensitivity-like reactions from parenteral products. IN vaccine may be used to boost immunity before anticipated exposure, or at the time of unanticipated exposure, to infected dogs. IN *Bordetella* vaccine has been shown to protect against clinical illness and to reduce the shedding of organisms after challenge exposure.⁹⁸ Most animals were protected against infection by 4 to 14 days after vaccination with a single dose. IN CPiV and *Bordetella* vaccines show some protection from challenge infection beginning 72 hours after administration.^{197a} These vaccines can help prevent illness in a kennel outbreak or in pets before hospitalization or boarding. The clinical illness resulting from IN-administered canine respiratory vaccine is generally mild or unnoticeable compared with that of topically applied feline respiratory vaccines. Occasionally, vaccinated dogs will develop a persistent rhinitis or cough, and some immunosuppressed pups have had more severe lower respiratory tract infection. IN vaccines should never be used in dogs with preexisting respiratory tract disease.

Vaccines against canine ITB are recommended when an increased risk of respiratory infection is known or suspected. Naïve dogs should be vaccinated initially, with at least two parenteral or one IN vaccine at least 10 to 14 days before possible exposure at dog shows, kennels, or veterinary hospitals. With IN vaccines, the animal may be vaccinated immediately before exposure as a less desirable, but practical,

1108

1109

Infectious Diseases of the Dog and Cat, 3rd Edition

alternative. Puppies as young as 3 to 4 weeks can be given IN vaccine because it is not affected by MDA as are parenteral products, and it has been shown to be safer at these early ages. Some of the products are also recommended as safe for pregnant bitches, but no reason has been found to use them in the pregnant animal. Annual or more frequent boosters are recommended in animals who are at high risk. Up to 10 months of protection has been demonstrated for some products. In many instances, individuals who show dogs do not use any kennel cough products, and they report no more or less kennel cough than do their colleagues that vaccinate every 3 to 6 months (personal communications with breed association members). That natural immunization would be very high in dogs that routinely go to dog shows should be expected.

100.8.4.2.2

Canine coronavirus infection

(Also see Prevention of Coronaviral Infections, [Chapter 8](#).) Immunity to canine coronavirus (CCV) infections generally involves S-IgA. S-IgAs have been difficult to measure for CCV vaccines in the clinical laboratory. Reproducing clinical disease with a variety of CCVs in susceptible experimental dogs is also impossible; thus vaccine efficacy cannot be reliably demonstrated. Serum antibody titers, which are easier to measure, indicate a systemic immune response to vaccine or indicate exposure to CCV, but they do not necessarily correlate with protection. S-IgA has been increased in challenged vaccinated animals compared with unvaccinated controls. A large number of products have been licensed in the United States for protection against this disease (see [Appendix 3](#)), and most are inactivated; however, one MLV vaccine has been developed. Inactivated and parenteral modified live CCV vaccines provide no or poor S-IgA response. Neither MLV or killed products administered parenterally to dogs prevent viral replication and fecal shedding after challenge infection.^{437,467} Experimentally, MLV CCV vaccine given parenterally does prevent fecal shedding following challenge; however, the dogs still show seroconversion, indicating some replication in the host.⁴⁶⁸ Regardless of which vaccine is used, dogs do not develop sterile immunity following vaccination as they do transiently following natural CCV disease.⁵⁰² Therefore vaccination with CCV will not prevent the increase in virulence of CPV-2.

CCV produces only mild and self-limiting clinical illness, primarily in pups younger than 6 weeks of age. The disease is in no way comparable to CPV-2 enteritis. Combined infections with CPV-2 and CCV can be more severe than with either infection alone; however, CCV vaccination does not prevent the CCV from enhancing the severity of CPV-2 infection. Thus vaccination against CPV-2 is the predominant determinant in viral enteritis protection. Vaccination against CCV is not generally recommended in either puppies or older dogs. Discontinuing CCV vaccination in shelters, commercial kennels, and in pet dogs has not lead to an increase in enteritis or any change in enteric disease prevention in the unvaccinated animals.

Complications have arisen during the development of CCV vaccines in the past. The first MLV vaccine for CCV was licensed in the United States in 1983; however, it was removed from the market because of a 5% rate of postvaccinal vasculitis and meningoencephalitis similar to the lesions of FIP.^{364,598} Later, another manufacturer incorporated a new strain of modified virus into their vaccine. Unlike the previously marketed MLV CCV vaccine, the MLV vaccine strain produced no neurologic or systemic disease when administered alone. However, when it was placed in a combination product, it increased the neurovirulence of the CDV vaccine strain component, resulting in an increased risk of CDV vaccine-induced encephalitis.⁷⁷ Thus marketing of the combination product with this CDV strain had to be discontinued.

Infectious Diseases of the Dog and Cat, 3rd Edition

A combination of *Leptospira* bacterins and inactivated CCV antigen in the same vaccine has caused some difficulties. Increased allergic reactions have been found when adjuvants are present. Because of antigen degradation, adjuvants are required when inactivated components, such as *Leptospira* or coronavirus antigens, are in formulated liquid diluent fraction, rather than the lyophilized fraction of the vaccine, and are being used in lieu of sterile water diluent. To overcome allergic complications with leptospiral antigen fractions, manufacturers have had to purify the leptospiral products to remove foreign proteins. Similarly, allergenicity seems less of a problem if *Leptospira* bacterins are administered at another site in the animal at the same time as a multiple-component vaccine. If allergic reactions are noted, combined inactivated CCV vaccines and *Leptospira* bacterins should be avoided.

Infection in young pups between 2 to 10 weeks of age with CCV is common, but disease is rare. The reason that CCV occasionally causes disease is not known. Research is needed to determine whether the disease is caused by a genetically distinct variant that is highly virulent or that certain dogs are susceptible to disease caused by CCV, or both. Isolates of CCV that have been associated with disease in a small number of dogs caused no disease when given to susceptible 2-week-old pups. Furthermore, a combination of MLV CPV-2 vaccine viruses and the CCV isolates caused no disease when given to susceptible pups.^{501a} Dogs immunosuppressed with glucocorticoids and cytotoxic drugs appeared to be more susceptible to histologic changes in the GI tract when experimentally infected with some isolates of CCV. CCV should be considered a common inhabitant of the canine GI tract, similar to canine rotaviruses and reoviruses or *E. coli*. Under rare and unusual (and as yet poorly defined) circumstances, any or all of these infectious agents may cause some tissue pathology and disease. However, no indication exists that a vaccine will prevent that event; thus CCV vaccine is not recommended until it can be demonstrated that it prevents disease.

100.8.4.2.3 Canine herpesvirus infection

A subunit vaccine consisting of herpesvirus glycoproteins is available in Europe for vaccination of pregnant dogs against CHV infection (Eurican® Herpes 205, Merial, Duluth, Ga.; see [Chapter 5](#) and [Appendix 3](#)).^{395,463} The vaccine is recommended just before breeding and a second one 1 to 2 weeks before anticipated parturition. Specific CHV MDA is passed in the colostrum to newborn pups, providing them with early neonatal protection. In breeding kennels, vaccine use was associated with higher rate of pregnancy and lower puppy mortality before weaning. The potential effect on a breeding establishment would be to increase birth weight and weaning rate and to reduce CHV-1 mortality in pups. Some evidence suggests a reduction in fetal death as demonstrated by higher litter size for vaccinated, as compared with unvaccinated, dams. Because the vaccine is a subunit vaccine, no interference occurs with PCR or viral isolation methods.

100.8.4.2.4 Leptospirosis

(Also see Prevention, [Chapter 44](#).) Protection against *Leptospira* involves leptospiricidal or neutralizing antibodies to outer surface proteins or carbohydrates of the organism. Variations in the carbohydrate composition of the LPS are responsible for the variety of serovars²⁹⁸ and less than complete heterologous protection afforded by current vaccines or recovery from prior infection with another serovar. Complete protection generally requires homologous vaccine antigen.

Serologic tests used to diagnose leptospirosis generally involve agglutinating antibodies that may not always correlate with protective immunity. Agglutination titers, determined by the microscopic	1109 1110
---	--------------

Infectious Diseases of the Dog and Cat, 3rd Edition

agglutination test (MAT), measure IgM and some IgG levels and are better diagnostic measures of exposure or infection, rather than protection. MAT titers are generally low (no greater than 1:400) after vaccination. MAT titers of 1:100 or greater, which are considered protective following vaccination, are often not present to one or more of the vaccine serovars after primary immunization. When present after vaccination, MAT titers often decrease nonreactive (less than 1:100) within 2 to 3 months in pups receiving two doses and after 6 months in adult dogs vaccinated multiple times.³²⁰

ELISA antibodies have been measured on a limited basis for diagnostic purposes in which IgM and IgG can be specifically evaluated. ELISA-based antibodies are more sensitive for exposure to virulent or vaccine antigens and may last for periods beyond the protective period (see [Chapter 44](#)). Therefore these antibodies are not reliable in predicting protective immunity. More specific antibodies for protection are leptospiricidal titers; and although they are better indicators of immunity, they are difficult to measure. For these reasons, challenge experiments are needed to provide accurate information about duration of immunity.

A few manufacturers claim that their products provide varying degrees of protection from disease after challenge for up to 12 to 14 months. However, none of the present *Leptospira* vaccines consistently protect against infection, as measured by leptospiremia and shedding in urine, in dogs challenged with virulent organisms. In a short-term (1 month following vaccination) DOI study of 34 dogs comparing three commercially available vaccines, all control dogs shed spirochetes in their urine at various times for the first 3 weeks after challenge.¹⁰ In contrast, vaccinates were generally protected against spirochetemia and challenge. A few vaccinated dogs had transient spirochetemia, and organisms could be detected in the urine of a few dogs, although control unvaccinated dogs were more severely affected.

In one long-term challenge study, three groups of dogs were vaccinated with a bivalent product for *Leptospira* and challenged via mucosal and IV inoculation.²⁹³ Challenge was performed at 5, 27, and 56 weeks after vaccination. After challenge, all vaccinates were protected against renal shedding because organisms could be cultured from the urine of controls but not vaccinates. Histologic evidence of interstitial nephritis was found in the control but not vaccinated dogs. *Leptospira canicola* antigen was slightly more immunoprotective than that of *Leptospira icterohaemorrhagiae*. Protection against leptospiremia was complete at 5 weeks and partial at 27 weeks; however, 1 year after vaccination, 100% of dogs vaccinated for *L. canicola* and 33% of those vaccinated for *L. icterohaemorrhagiae* had transient spirochetemia. The vaccine was more consistently protective against urinary shedding of spirochetes after challenge for the three sampling times up to 56 weeks after vaccination. Based on the results for this one vaccine, efficacy of leptospiral vaccine seems poor for sterile immunity, and duration of strongest immunity is relatively short (approximately 6 months to 1 year) compared with that of some of the other vaccine antigens. Because these studies show a reduction in protection with time, a 1-year DOI with this vaccine would be a projected maximum.

As nonviable antigens, *Leptospira* products have to be administered at least twice over 2- to 3-week intervals to produce an initial immune response in a previously unvaccinated dog. Booster vaccination is recommended at yearly intervals but may be insufficient to maintain protective levels of immunity.

Leptospira bacterins for dogs most often contain inactivated whole bacteria or potentially purified cell wall antigens of *L. canicola* and *L. icterohaemorrhagiae*. Vaccination with these products is not recommended in animals younger than 9 weeks. In general, they are preferably administered at 12 weeks or older because of the allergenic nature of the vaccines. Anaphylaxis and other less-severe type I hypersensitivity reactions (e.g., facial edema, hives) may be present within 1 hour after the second or

Infectious Diseases of the Dog and Cat, 3rd Edition

third vaccination in puppies given the initial series (see previous discussion of type 1 immunologic complications). A prior allergic reaction to a combination booster in any dog is probably enhanced by *Leptospira* bacterin; therefore, it should be eliminated or administered separately in subsequent vaccinations. Similarly, *Leptospira* bacterins should be avoided in miniature dachshunds and pugs, breeds that have a high rate of allergic reactions. Combination of *Leptospira* bacterins with noninfectious adjuvanted vaccines increases the risk of anaphylaxis. *Leptospira* bacterin is usually marketed in a liquid form and is usually used to reconstitute the lyophilized components in combination vaccines. The liquid formulation of *Leptospira* vaccine has adjuvants that are omitted when this fraction is lyophilized and incorporated with the other vaccine components. Sterile diluent provided by the manufacturer may be substituted for the *Leptospira* fraction when a reason exists to omit it. When using *Leptospira* bacterin alone is appropriate, the liquid portion of the vaccine should be administered.

All of the available products contain serovars *L. canicola* and *L. icterohaemorrhagiae*. Manufacturers market vaccines against *Leptospira grippityphosa* and *Leptospira pomona* serovars, which have been associated with recent cases of canine leptospirosis. One quadrivalent *Leptospira* product (Duramune® Max 5+4L, Fort Dodge Animal Health, Fort Dodge, Iowa) is a partially purified outer membrane protein product (see [Chapter 44](#) and [Appendix 3](#)). Other manufacturers are considering adding these latter serovars to their vaccines. A quadrivalent bacterin containing serovars grippityphosa, pomona, icterohaemorrhagiae, and canicola (Vanguard Plus 5, Pfizer Animal Health, Exton, Pa.) is also available for this purpose. Newer subunit vaccines containing the immunogenic envelope of *Leptospira* are being evaluated to avoid the disadvantages of currently available products that cause adverse reactions. Leptospiral vaccines have been considered optional (noncore) by veterinarians in many areas because of the perceived rarity of the disease, short DOI, and risk of postvaccinal hypersensitivity.

When assessing the need for *Leptospira* vaccination, generally outdoor, sporting breeds, or large breeds (weighing more than 15 kg) are most affected during the summer or fall months.^{203,586} Therefore these breeds should be targeted for this vaccine, preferably in the spring to help provide more complete protection over the problematic period of summer exposure. The highest risk factor for disease prevalence is in rural areas and urban areas that are encroaching on rural environments.⁵⁸⁷ Dogs that visit rural areas also have a high inherent risk of exposure, which should not preclude vaccination of dogs that frequent buildings in urban areas with high rodent populations. One of the authors (CEG) is aware of a large number of cases of leptospirosis with serogroup *L. grippityphosa* infection in dogs used for police surveillance in urban areas.

100.8.4.2.5

Lyme borreliosis

(See also [Chapter 45](#).) Serum antibodies are not completely protective against *Borrelia burgdorferi* because the organism not only has the propensity to alter its outer surface proteins during the course of infection, but also has the ability to encyst. Vaccination induces production of OspA antibodies that are expressed by the organism while it is attached to the midgut of its tick vector. Antibodies to OspA interfere with the organism in the midgut of the attached tick before it can infect the host. These antibodies must be present in the serum at the time of tick attachment to be protective. Antibodies to OspA might be measured as an indicator of past vaccination and therefore might serve as a marker of some protection. Measurement of borrelicidal antibodies using live organisms gives a better indication of protection. Once the organism enters the host, outer surface protein C (OspC) antigens are predominantly expressed by the organisms.

1110

1111

Infectious Diseases of the Dog and Cat, 3rd Edition

Two commercial inactivated whole cell bacterins (Galaxy® Lyme, Schering-Plough, Union, N.J. and LymeVax®, Fort Dodge, Fort Dodge, Iowa) and two recombinant subunit OspA vaccines (RM Recombitek®, Merial, Duluth, Ga. and Prolyme®, Intervet, Millsboro, Del.) are available for protection against Lyme borreliosis (see [Table 45-6](#) and [Appendix 3](#)). Studies by the various manufacturers have shown protection when dogs were challenged at times ranging from 156 to 366 days after the second vaccination. Vaccines protect dogs from spirochetemia and clinical limping episodes after challenge with virulent organisms compared with unvaccinated control dogs. Although the numbers of dogs have been small, these vaccines appeared to offer advantages for high-risk dogs (predisposed to tick exposure) in high-prevalence regions; it cannot be recommended for routine vaccination. The vaccine interferes with accurate interpretation of serologic titers for months to years unless immunoblotting is used (see [Chapter 45](#)) or with the SNAP® 3Dx® Test (Idexx Laboratories, Westbrook, Me.) when C6 antibody is detected. Concern has been expressed regarding immune-mediated complications such as hypersensitivity reactions or accentuating polyarthritis from Lyme vaccine.³³⁶ These claims have not been adequately tested and might be less of a concern with recombinant OspA product. The human Lyme vaccine that was available for several years has been taken off the market because a small population of people with a certain human leukocyte antigen type developed nontreatable chronic arthritis. A similar problem may be present in vaccinated dogs, but additional studies are needed. Another concern is that the vaccines contain a limited number of strains that may not cross-protect against the known *Borrelia* spp. and serovars; however, further information is needed from field studies to show this is an issue of concern.

Despite the controversy that exists, *Borrelia* vaccines appear to be effective in challenge studies that have accompanied vaccine licensing. Because *B. burgdorferi* is virtually impossible to eradicate from tissues once infection is established,⁵⁴⁹ and because antibodies against OspA should be present at the time of tick exposure, pups determined to be at risk in endemic areas should be vaccinated *before* they have the opportunity for natural exposure. *Borrelia* vaccines are recommended, depending on the product, for use beginning at 4 to 9 weeks of age during the primary vaccination series and consist of two to three inoculations, 3 weeks apart (see also [Appendix 3](#) and [Table 45-6](#)). Revaccination of dogs at potential risk should *not* be postponed until booster age; instead, they should be vaccinated again at the beginning of the tick season. Concern has been expressed for both overdiagnosis and overvaccination for borreliosis in the veterinary community. If Lyme disease can be documented in dogs within a given geographic area, then this vaccine should be considered as one means of preventing the disease along with tick control measures. The vaccine should not be used outside these areas unless dogs will be traveling to endemic regions.

100.8.4.2.6

Giardiasis

(See also Prevention for Giardiasis, [Chapter 78](#).) Humoral immunity is important in the elimination of *Giardia* trophozoites from the host intestine. Increases in IgM, IgG, and IgA antibodies to surface and cytologic antigens of the parasite have been observed in the serum and GI mucosa between 10 to 17 days after infection.⁴²² However, certain hosts do not develop this humoral immune response, and CMI does not appear to be directly involved in immune clearance of the parasite. A *Giardia* vaccine has become commercially available in the United States for prevention of clinical illness and reduction of cyst shedding in dogs and cats (see [Appendix 3](#)). In challenge studies for licensing, pups were vaccinated SC at 3-week intervals. Placebo-inoculated dogs received only adjuvant. Challenge was at 6 months and 1 year. Vaccination reduced the duration and number of cysts shed and the severity of diarrhea. Control animals lost weight, while the vaccinated ones either maintained or gained weight. Trophozoites were abundant in the small intestine of control animals but absent in vaccinates. In one study of 13 dogs,

Infectious Diseases of the Dog and Cat, 3rd Edition

vaccination of symptomatic dogs was associated with a resolution of clinical signs and termination of oocyst shedding.⁴²³ However, no control dogs were used in that study. In another controlled field study to evaluate the vaccine for treatment of infected dogs, 20 dogs with antigen test–positive results for *Giardia* were divided in two groups and were given either *Giardia* vaccine or a saline placebo.⁹ No significant differences were found in the vaccinated control groups with respect to antigen test–positive dogs over a 20-week period. To date, the vaccine has not been adequately tested in dogs in the field to determine its efficacy, and *Giardia* rarely causes clinically significant disease, even though infection is common. The American Animal Hospital Association Committee⁴⁴¹ places *Giardia* vaccine in the “Generally Not Recommended” category.

100.8.4.2.7 Babesiosis

(See also Prevention, [Chapter 77](#).) Serum antibodies are indicative of exposure but not protection in evaluating immune responses of the host to intraerythrocytic parasites such as *Babesia*. A commercial vaccine against *Babesia canis* infection (Pirodog®, Merial, Lyon, France) is available in Europe (see [Appendix 3](#)). This vaccine contains antigens derived from cell culture of *B. canis*. Vaccination does not prevent infection but it appears to prevent many of its pathologic consequences.

100.8.4.2.8 Leishmaniasis

(See also Prevention, [Chapter 73](#).) An experimental vaccine containing the fucose mannose ligand antigen of *Leishmania donovani* combined QuilA saponin was effective in protecting dogs against experimental field challenge.⁵¹ Challenge was accomplished by placing dogs in highly endemic environments and evaluating them for the development of infection over 3.5 years. In challenged dogs, 25% of controls and 5% of vaccinates developed fatal clinical illness within the course of the experiment. A preventative fraction of 80% was calculated. Vaccines are not commercially available for this disease and further studies are needed to determine cross-protection among worldwide species of *Leishmania*.

100.8.5 Feline Vaccination Recommendations

(See [Appendices 2](#) and [3](#).)

100.8.5.1 Core vaccines

100.8.5.1.1 Feline panleukopenia

(Also see Prevention, [Chapter 10](#).) Antibody titers can be used to predict protection against infection with FPV. VN or HI titers are the reference method to elucidate titers.

Both inactivated virus and MLV vaccines are effective in preventing this disease. In the absence of MDA interference, at least two doses of inactivated vaccine are required in kittens to equal the protection afforded by one dose of MLV vaccine. At least two MLV or three inactivated vaccine doses should be given at 3- to 4-week intervals to kittens in the initial series at 8 to 9 weeks of age. The second MLV vaccine ensures that an anamnestic response will occur if the first vaccine was blocked by MDA, which is usually negligible by 12 weeks of age.

1111

Although FPV infection has been considered a disease of unvaccinated shelter kittens, it has been documented in *fading kittens* from well-vaccinated pedigree breeding catteries.³ Virus was detected in the feces by CPV-2 and FPV ELISAs. Further studies indicated that the virus was FPV and not CPV-2 and that vaccine breaks were occurring because of expo-sure of kittens to large amounts of virus in a contaminated environment.

Both parenteral and IN MLV FPV vaccines are available. The IN vaccine (Feline UltraNasal® FVRCP, Heska, Fort Collins, Colo.) is combined with the FHV and FCV components. As with CPV infection, parenteral vaccination offers stronger protection than IN vaccination because replication in lymphoid tissues is stronger following parenteral administration of parvovirus vaccine. Systemic immune response and serum antibody titers are more important than S-IgA in defense against systemic parvoviral viremia. However, IN vaccine may offer less risk of allergic or neoplastic complications, but MLV FPV has not been associated at a significant level with development of ISS; thus this should not be a consideration. Use of this combination IN vaccine was associated with an outbreak of panleukopenia in Persian kittens infected with *Salmonella* (see [Chapter 10](#))¹⁶⁶ and with outbreaks of FPV in several shelters. This result may be associated with some virulence with the topically administered product and the possibility of MLV virus causing either disease or immunosuppression or because topical (IN or oral) vaccination is not as effective as SC or IM administration in protecting against this disease. The topically administered vaccine involved in this episode was withdrawn from the market and was reformulated to deliver a smaller volume and to decrease postvaccinal complications.

Genetic modification of the CPV-2 virus to the CPV-2a and CPV-2b strains has been associated with an adaptation of these genotypes to infect cats and potentially produce disease identical to feline panleukopenia (see [Chapters 8](#) and [10](#) and prior discussion of canine parvoviral infection).^{257,391,402,571} To date, experimentally reproducing clinical disease in susceptible cats has not been possible with some of the most highly virulent CPV-2b strains that regularly cause up to 100% mortality in susceptible puppies. In two studies, CPV-2b isolation rates of 3% to 10% were found in naturally infected clinically ill cats, while the remainder of isolates were FPV.^{181,571} Feline FPV vaccines, canine CPV-2b vaccines, and killed mink enteritis virus (MEV) vaccines were all effective in preventing infection in cats challenged with virulent CPV-2b virus.^{501a} In these studies, challenge with virulent virus was performed within 1 month or less following vaccination; however, longer DOI studies are needed following heterologous vaccination.

After homologous vaccination with FPV vaccine, antibody titers and challenge protection persist for at least 7.5 years even after two doses of killed FPV vaccine in kittens⁵¹⁴ (see *Overvaccination*, earlier). MLV vaccines provide longer immunity, probably life long. After the initial series in kittens and an annual booster 1 year later, vaccination can be done every 3 years or less to minimize the number of boosters. MLV vaccines would be recommended over inactivated virus products when FPV is a significant concern (e.g., shelters, catteries, pet shops). Inactivated virus vaccines are preferred if a risk of producing vaccine-induced illness exists or if vaccination is absolutely required in pregnant queens. Newborn kittens are immunologically responsive to FPV by 7 days of age; however, MLV vaccine must be avoided before 4 to 5 weeks of age because of its potential for producing cerebellar damage or clinical disease. Colostrum-deprived kittens in a low-risk environment (pet cats) can receive vaccinations between 2 and 4 weeks of age, but inactivated virus vaccines should be used at this age. Routine parenteral MLV vaccination of 4- to 6-week-old kittens is recommended in endemic catteries or shelters to reduce the prevalence of disease. Homologous hyperimmune serum can be administered to provide

Infectious Diseases of the Dog and Cat, 3rd Edition

immediate protection to exposed unvaccinated kittens (see Passive Immunization, earlier). In a serologic study of feral cats by one of the authors (RDS), an unexpected finding revealed that 50% of the feral cats had never been infected with FPV, CPV-2, or MEV.^{212a} This finding was unexpected because these parvoviruses are extremely stable in the environment and remain infectious for at least 1 year or longer.

100.8.5.1.2

Feline viral respiratory disease

(Also see Prevention, [Chapter 16](#).) Feline respiratory disease complex (FRDC) or upper respiratory infections in cats are common, especially in catteries, multiple-cat households, shelters, and pet shops. As in CIUDC, FRDC involves infectious agents mainly FHV-1, many serotypes of FCV, a variety of bacteria, *Chlamydomphila*, and *Mycoplasma*, and is impacted by environmental factors (humidity, temperature, ventilation, gases), stress, and poor hygiene. Given that FRDC is rarely caused by only one of these factors, not surprisingly, vaccines cannot prevent disease in high-risk environments. Serum antibody titers were measured in SPF cats vaccinated with two doses of inactivated virus vaccine as kittens.⁵¹³ In this study, antibody titers began to decline by 3 to 4 years. The vaccines did not prevent cats from acquiring the infection (sterile immunity) but reduced the severity of clinical illness when they were challenged with FHV-1 or FCV 7.5 years after vaccination. Thus serologic assays may be used to measure evidence of immunologic memory but not equate with complete protection from these viruses.

FCV and FHV-1 vaccines are available as MLV and inactivated parenteral and as MLV IN products. IN products provide more rapid, superior local protection, and better breakthrough of MDA. Parenteral vaccination for respiratory infections produces a slower response to protection, usually requiring at least two doses of vaccine at a minimum of 3 to 4 weeks apart. In contrast, IN vaccine may provide protection within 48 hours in a susceptible cat but may typically produce a high incidence of mild contagious respiratory illness after vaccination, and viral shedding is common. Cats can become colonized with these attenuated strains of vaccine virus, which may provide them with a sort of premonition against infection with virulent strains.

Despite the rapid induction of S-IgA response afforded by the IN vaccine, veterinarians dislike the IN route of vaccination because of the high prevalence of vaccine-induced disease. Although IN vaccine has been recommended as a treatment for cats that suffer from chronic persistent respiratory infection, no studies have been conducted to document its effectiveness in resolving persistent infections. Parenteral products are less attenuated compared with IN vaccines. When giving parenteral vaccine, care should be taken to prevent accidental oronasal exposure of cats to aerosols or spilled vaccine. Following inhalation, postvaccinal respiratory disease may be more severe with parenteral products compared with IN products. A recommended method of administering IN vaccine to adult cats is to have an assistant raise the muzzle to 45 degrees. One hand of the administrator covers the eyes, and the other delivers the vaccine.⁵⁴

Protection afforded against the development of respiratory diseases is usually incomplete and temporary, whether parenteral or IN vaccination is administered because of the transient persistence of S-IgA on mucosal surfaces. However, the response to reexposure can be more dramatic than that of unvaccinated animals because of immunologic memory. Regardless of the vaccine interval, vaccines do not prevent infection, latency of FHV-1, or all manifestations of disease. Cats that contract respiratory viruses after vaccination should have milder clinical illness than they would have had without vaccination but that is not always the case. Severe outbreaks have occurred, even in households, catteries, and shelters where all animals have been vaccinated.⁵⁷⁴ Attenuated vaccine strains of FCV may colonize the vaccinated

1112

1113

Infectious Diseases of the Dog and Cat, 3rd Edition

cat's respiratory tract in a persistent carrier state, and FHV-1 will become latent because vaccines cannot prevent latency with wild type FHV-1 strains.

For the last 30 years, the majority of FCV vaccines have been composed of a diverse serotype that cross-reacts with a majority of the field strains. However, the virus has a variable genetic profile that allows for the selection of field isolates with progressively greater resistance to host immunity. These vaccines can protect against clinical disease but do not provide sterile immunity.

When respiratory disease is endemic in closely congregated cats, kittens will likely be exposed and become ill early in life before successful immunization can be achieved. Colostric immunity to feline respiratory viruses is thought to last for not longer than 6 weeks, depending on the queen's titer and the virus (see [Table 100-4](#)). Early vaccination may protect kittens in congregated environments in which respiratory disease is endemic. IN FHV-1 and FCV vaccines can break through MDA earlier because of the reduced level of serum antibodies on mucosal surfaces. Early vaccination, before weaning, between 4 and 6 weeks of age with IN or parenteral vaccines, may be beneficial in controlling endemic respiratory disease in problem catteries, but they may also contribute to a carrier state and mild to moderate disease. When outbreaks occur at an earlier age, small doses of IN vaccine to 2- to 4-week-old kittens have been recommended to help stop or reduce disease in severe outbreaks.

Some breeders have vaccinated queens during pregnancy to increase protection against neonatal respiratory outbreaks; however, the value of this practice has been questioned. Nevertheless, in one study, vaccination during gestation was more beneficial than those given before conception in protecting against outbreaks of respiratory disease in kittens.²⁵⁵ Kittens born to queens vaccinated during gestation had reduced morbidity and mortality rates from respiratory infections, without any adverse effects on reproductive performance. When vaccinating pregnant queens is necessary, they should be vaccinated with inactivated vaccines just before conception with the shortest time interval possible.

Parenteral inactivated respiratory virus vaccines are safe for debilitated cats, in kittens younger than 4 weeks that have been deprived of colostrum, and in pregnant queens, although protection is generally weaker than that provided by MLV products. With these exceptions, MLV vaccines should always be used to protect cats in case of an outbreak. IN vaccine may be preferred in certain cases, especially pet cats. Inactivated virus vaccines that contain adjuvants have a greater risk of producing allergic or neoplastic complications so that the frequency of their use as boosters should be reduced (see Postvaccinal Complications, earlier). Because chronic ulcerative gingivostomatitis may be a hypersensitivity reaction to persistent FCV carriage, repeated booster vaccination against respiratory viruses is not recommended in affected cats.

In studies conducted over several years by one of the authors (RDS), none of the products used against respiratory infection, regardless of number of vaccinations, type of vaccine, or route of delivery, prevented FRDC in a significant percentage (e.g., 30%) of cats. Also noted was that in high-stress, high-density shelters, the killed products were preferred because fewer cats were showing mild or moderate signs of disease. Also shown in a certain number of these shelters was that the cats were so suppressed that the MLV IN products caused disease that was severe enough to lead to euthanasia of a high percentage of the cats. In contrast, in low-stress, low-density cat shelters that can isolate incoming cats, the IN vaccines were better than the MLV parenteral, and the killed products were the least effective. Ongoing studies will hopefully provide more information on the benefit, as well as the disadvantages, of these products in different environments. Results of these studies also suggest that vaccines against *Chlamydia* and *B. bronchiseptica* provided no advantage and occasionally seemed to increase the severity of respiratory disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

Several new serotypes of FCV initially isolated from cats in California were found that caused severe disease. These isolates have been confirmed in cats from the Midwest and East Coast and do not seem to be controlled by the current vaccines (see [Chapter 16](#)).

100.8.5.2 Noncore vaccines

100.8.5.2.1 Feline leukemia

(See also Prevention, [Chapter 13](#).) Protection against persistent infection with FeLV is dependent on humoral and cell-mediated mechanisms. Vaccinated kittens that develop measurable neutralizing antibodies to FeLV gp70 protein are protected from infection following challenge with virulent virus that readily infects unvaccinated kittens. Testing serum of cats for antibodies to gp70 protein might be used to determine which animals need to be vaccinated. However, antibody testing for FeLV is not routinely used and not readily available.

100.8.5.2.2 Prevaccination testing

Only clinically healthy and FeLV-negative cats should be vaccinated. Low-risk groups for infection include cats from single-cat households, FeLV-negative catteries, and isolated environments ([Table 100-23](#)). Whether these individuals should be tested is usually based on the practitioner's decision or advice given to the client and the client's reaction to the cost involved. Although some expense and inconvenience is inherent in prevaccination testing of all cats, it is not always comparable to the cost to the client of the complete vaccination series. In this regard, it can be recommended that all cats of all ages be tested for FeLV viremia before vaccination. If testing and eliminating all persistently viremic cats were possible, eradicating FeLV would be possible. The ELISA results can usually be used as the criteria for response to vaccine. Vaccines do not benefit ELISA-tested viremic cats and therefore are not recommended. Because transient and especially persistently viremic cats are the only source of virus to infect susceptible cats, viremic cats should be isolated from other cats, especially those younger than 6 months of age. When the cat is established as persistently infected, every effort should be made to spay or neuter the cat if the owners plan to keep the cat rather than eliminate it from the household or cattery. Vaccination of every cat will fail to reduce the prevalence of FeLV infection or disease significantly because vaccination cannot prevent infections before 3 months of age, the time of greatest susceptibility to FeLV infections that lead to persistent viremia. Vaccines cannot provide immunity before 3 months because the earliest that the first vaccination can be given is 8 to 10 weeks, depending on the product, and no significant immunity occurs until 1 to 2 weeks after the second dose; thus 3 months or more would be required for protection if the most effective vaccines are used and probably longer with use of less effective products.

Persistent viremic cats should not be bred because infection in utero and at birth will ensure all or most of the kittens would be persistently viremic.

Vaccination should be recommended for all at-risk kittens during their initial vaccination series. Vaccination should be started in young (younger than 12 weeks) cats that are at the greatest risk for developing infection if they are exposed. Cats at high risk of infection include those in endemic multiple-cat environments, outdoor roaming or stray cats, or those in groups with unknown status.

Although cats in that age group are 85% susceptible to infection following exposure, the risk percentage drops to 15% after 6 months of age. Cats older than 1 year of age have substantial natural immunity.

1113

1114

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 100-23 Recommendations for Testing for Feline Leukemia Virus and Feline Immunodeficiency Virus^a

FeLV Viremia

1. General:
 - a. FeLV status of *all* cats of *all* ages is desirable
 - b. Positive cats should not be vaccinated
 - c. Testing allows disease prevention and elimination
2. Timing:
 - a. When cat is first acquired and before introduction
 - b. If cat has never been tested before and is first presented
 - c. Maternal antibody in young kittens does not interfere^b
 - d. Before *any* FeLV vaccination
3. Repeating:
 - a. If serology results are positive or equivocal
 - b. To confirm positive blood, saliva, or tear test results
 - c. After two positive ELISA tests, perform indirect FA
 - d. Discordant results: repeat ELISA and indirect FA
 - e. Annual retest of high-risk cats, which includes those going outdoors; in open households; in closed households with test-positive cats

FIV Antibody

1. When:
 - a. Test all cats older than 6 months of age
 - b. Positive cats should not be vaccinated
 - c. All vaccinated cats should be identified with microchip or tattoo
2. Timing:
 - a. When cat is first acquired and before introduction
 - b. When newly adopted
 - c. Any previously untested cats
 - d. After known exposure (2-3 mos for seroconversion)

Infectious Diseases of the Dog and Cat, 3rd Edition

e. With unexplained fevers or recurrent infections	
3. Repeating:	
a.	ELISA is screen; indirect FA or immunoblot is more discriminating for positive results
b.	Passively acquired maternal antibody may cause false- positive results in kittens; retest after 6 mos of age
c.	Periodic retesting of at-risk cats (fighting, strays, unexplained wounds, routinely outdoors, mating to unknown male, known positive cat in household) recommended
<i>FeLV</i> , Feline leukemia virus; <i>FIV</i> , feline immunodeficiency virus; <i>ELISA</i> , enzyme-linked immunosorbent assay; <i>FA</i> , fluorescent antibody.	
a	For further information, consult American Association of Feline Practitioners/Academy of Feline Medicine, <i>Recommendations for Feline Retrovirus Testing</i> (6808 Academy Parkway East NE, Suite B-1, Albuquerque, NM 87109). Elston T, Rodano I, Flemming D, et al. 1998. Report of the American Association of Feline Practitioners and Academy of Feline Medicine Advisory Panel on feline vaccines, <i>J Am Vet Med Assoc</i> 212:227-241.
b	Less than 10 to 12 weeks of age, false-negative results from maternal antibody suppression of viremia might occur, although this is controversial.

If cats receive their initial vaccination 8 to 10 weeks of age or older, a prevaccination blood sample can be obtained at the time. This procedure saves the client an additional visit. If testing is not performed before vaccination, clients would become more concerned when their already-vaccinated cat later has a positive test result. Although some cats can be latently infected at the time of vaccination but remain undetected by FeLV testing until a later date, these cats may benefit from vaccination. The decision of whether and when to vaccinate cats with the currently available products rests with the practitioner. If the test result is negative, the vaccination series can be continued. If the result is positive, the series must be discontinued, and a second ELISA should be performed 4 to 8 weeks later. If the second test result is negative, the cat may be presumed to have recovered from natural infection, and the need for vaccination is minimal. If the second result is positive, an indirect FA test might be done; however, two positive ELISAs 2 months or more apart strongly suggests persistent viremia. An indirect FA test can determine whether the bone marrow is infected because most indirect FA–positive cats have a poor prognosis and remain persistently viremic. Persistently viremic cats are the major source of viral infection for contact susceptible cats (see [Chapter 13](#)). For general guidelines concerning FeLV and FIV testing, see [Table 100-23](#).

100.8.5.2.3

Challenge studies

Of the licensed FeLV vaccines, most contain noninfectious partially purified whole virus; one product is a genetically engineered subunit type; a final product is a canarypox virus–vectored recombinant vaccine. Varying types and quantities of adjuvant are present in some, but not all, vaccines ([Table 100-24](#)). Challenge studies of the vaccines, completed by their respective manufacturers using SPF cats, represent ideal laboratory conditions that may not be met in the field. Challenge studies vary tremendously with regard to age of vaccinates, route of challenge, type and dose of challenge strain, and the number of vaccinates and controls used. Manufacturers’ licensing studies (see [Table 100-24](#)) may represent the best-case scenario for measured protection. Direct challenge models generally show higher degrees of protection than occur with natural-exposure challenge models, which may explain some of the discrepancies in various vaccine studies conducted between manufacturers and independent researchers.

Infectious Diseases of the Dog and Cat, 3rd Edition

Natural exposure studies involve placing vaccinated and unvaccinated immunocompetent cats directly in an environment with FeLV-positive cats. For general guidelines on FeLV and comparative features of these products, see [Table 100-24](#) and [Appendix 3](#). For general guidelines concerning FeLV and FIV testing, see [Table 100-23](#).

100.8.5.2.4

Number of vaccine doses

As with other noninfectious products, antigen mass and repetitive vaccinations offer the best assurance of protective response. A reasonable recommendation is that all cats at risk be vaccinated with two doses as kittens. Based on manufacturer recommendations, cats receiving only one dose of FeLV vaccine in the initial series and not revaccinated within a 4- to 6-week period should have the vaccination series started over. Although studies on DOI are not available, subsequent annual revaccination with a single dose is recommended when need for ongoing protection is justified. Because of risk of sarcoma development and early age of susceptibility, continual revaccination has been questioned beyond the first year booster as stated previously. FeLV boosters are optional in older cats. Annual revaccination can be given to cats at very high risk of exposure. On the other hand, solitary cats should not receive vaccination beyond the primary series, if at all.

- a Although the vaccines are listed here for comparative purposes, the conditions of testing for licensing and experimental studies have varied between products, making absolute comparisons difficult. For additional information on available vaccines and manufacturers, see [Appendix 3](#).
- b *Leucogen*® (Virbac Ltd) in countries outside the United States.
- c UCD-1 is Kawakami-Theilen strain.
- d Preventable fraction has not been calculated for all of these studies, making exact comparison of percentages difficult.
- e Numbers in this row refer to references cited at the end of this chapter or on the CD.
- f Data is on monovalent product only; however, a combination product which includes adjuvant had a local reaction rate of up to 17.3% and a systemic rate of up to 6% (<http://www.emea.eu.int/vetdocs/vets/Epar/Eurifel/repFeLV.htm>. Last accessed 02/27/05).
- g Examining for latency is a more critical assessment of whether a cat is infected. Unfortunately, the time for examining for latency viremia after challenge varies among the studies, making exact comparison of percentages difficult.

100.8.5.2.5 Vaccination of high-risk cats

Cats that are in contact with viremic cats are known as high-risk cats. Multiple-cat households, catteries, and research facilities allow for close contact and therefore greater risk that FeLV infection will be spread when a viremic cat is present. Outdoor and roaming or feral cats have a high chance for contacting other infected cats. This virus is highly labile and is not highly contagious, thus small amounts of virus in the environment are not a major source of infection. Because efficacy of vaccines is never 100% under natural circumstances, clients should be advised to avoid placing FeLV-vaccinated cats less than 6 months of age in the same environment with viremic cats. Similarly, in established FeLV-free populations, vaccination *should not* be a substitute for routine FeLV testing and elimination or quarantine of viremic cats. Because of the short period of residence compared with the time and expense to induce protective immunity, vaccination of all cats entering humane shelters cannot be justified. Testing and removal of all incoming viremic cats will be of much greater benefit in shelters. Studies that have claimed a reduction in FeLV in infected populations in which vaccination is instituted have been misleading. The initial prevalence of infection cannot be accurately compared with subsequent incidence data because vaccination has been coupled with removal of infected cats. Ironically, the prevalence of FeLV in the general cat population has not changed over the last 30 years; it was approximately 3% ± 1% then and is now. However, one factor that has changed is that the number of cats with leukemia and lymphoma that are FeLV-positive is much lower today than it was 30 years ago. The prevalence of FeLV-persistent viremia in the feral cat population is the same as that seen in the domestic cat population.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.8.5.2.6 Vaccine safety

Adverse reactions to FeLV vaccines have been primarily of an allergic or a neoplastic nature. Vaccines do not cause immunosuppression in uninfected cats or any change in the course of illness of an already viremic cat, nor does vaccination appear to activate latent infections. Vaccines are noninfectious products and will *not* produce FeLV infection or cause cats to have positive FeLV diagnostic test results. No data exist on the prevalence of allergic reactions, but IM is more likely than SC administration is to produce anaphylaxis because of the more rapid absorption of antigen. The amount and composition of adjuvants vary among the products (see [Table 100-24](#) and prior discussion of Adjuvants). Precautions should be taken to limit the number of antigens given simultaneously to cats if such allergic reactions are noted. Limited safety studies have involved these vaccines in exotic cats. FeLV and rabies vaccines are associated with highest number of ISS. Reducing the number of boosters, through risk assessment, should decrease the risk of ISS in cats.

1116

1117

100.8.5.2.7 Chlamydomphila infections

Chlamydomphila vaccines are available as MLV or inactivated products for parenteral administration. Vaccines offer some degree of protection against clinical illness caused by *C. felis*, but immunity is not complete; exposed vaccinated cats develop milder clinical illness than do unvaccinated cats. MDA interference does not appear to be important with this vaccine, and no teratogenic effects are known. Kittens can be vaccinated as early as 3 weeks of age when neonatal conjunctivitis is a problem. Certain parenteral *Chlamydomphila* vaccines have been shown to produce protective immunity for 6 to 12 months. Attenuated chlamydomphilal vaccines have produced postvaccinal fever and malaise, and, as a result, some have had to be further attenuated. With combination products, vaccination for chlamydomphilosis, although probably not essential, can be accomplished without much additional expense or inconvenience to cat owners. The overall low prevalence of chlamydomphilal respiratory disease, or the potential for postvaccinal reactions, makes these products less essential or desirable on a routine basis. Nevertheless, inclusion of these products provides the potential for more complete protection. Should the disease be endemic, yearly boosters are recommended. A higher prevalence of feline chlamydomphilosis has been observed in the United Kingdom, justifying routine vaccination. Routine vaccination against all of the feline respiratory diseases is often necessary in cats that are stressed or congregated in catteries, research facilities, and multiple-cat households.

100.8.5.2.8 Feline bordetellosis

Feline respiratory disease can be complicated by bordetellosis. *B. bronchiseptica*, a commensal organism of the upper respiratory tract, has been isolated from cats with pneumonia and systemic manifestations. Disease is of most concern in catteries where significant numbers of clinically healthy cats and recovered cats carry the organism. Although experimental infections can produce mild disease, the importance of this problem in clinical settings is uncertain (see Feline Respiratory Disease, [Chapter 16](#)). A fimbrial antigen-based subunit vaccine (Nobivac® Bb Cat, Intervet, Boxmeer, The Netherlands) has been licensed only in The Netherlands. In the United States, a modified live IN vaccine (Protex®-Bb; Intervet, Millsboro, Del.), similar to vaccines used in dogs, is available (see [Appendix 3](#)).⁵⁹⁶ This vaccine causes a mild self-limiting respiratory infection in cats and microscopic inflammation throughout the respiratory tract.²⁰⁴ The vaccine should not be used in cats that are debilitated, immunosuppressed, or already showing clinical illness. The author (CEG) has also demonstrated spread of the organism from

Infectious Diseases of the Dog and Cat, 3rd Edition

vaccinated to contact cats. In the cycle of natural exposure, the prevalence of this infection is highly variable and is usually restricted to multiple-cat environments. If this vaccine is used, it should be reserved primarily for unaffected cats in an environment where an outbreak has been documented. Compared with control cats, signs of disease in vaccinated cats were reduced but not eliminated following vaccination. In some shelter studies, cats that received this vaccine had more severe disease than seen when only FCV and FHV vaccines were given.

100.8.5.2.9 Feline infectious peritonitis

(See also [Chapter 11](#).) Protection against FIP involves both humoral and cellular mechanisms. In the early stages, S-IgA is important in reducing the replication of surface coronavirus, which, in turn, reduces the chances that mutant FIP virus (FCoV) will originate. An IN product has been available for vaccination for approximately 15 years (Primucell® FIP, Pfizer, Exton, Pa.). The vaccine consists of a temperature-sensitive restricted replicating mutant that reportedly produces local secretory antibody and systemic CMI responses to FCoV. The IN vaccine is intended to produce local protection against viral replication, with subsequent mutation and invasion of the epithelial barrier, a prerequisite to the development of FIP. Previous use of parenteral vaccines caused sensitization of the humoral immune response and acceleration and precipitation of illness in vaccinates compared with controls (antibody-dependent enhancement). In certain studies, the IN vaccine was also reported to cause acceleration of disease.^{511a} Initial concern by the manufacturer was expressed that high aerosol or IN viral challenge doses allowed virulent virus to gain entry into the body despite IN vaccination.^{509,515} When such high-challenged doses were administered, animals developed antibody-dependent enhancement of disease. In contrast with lower oral-challenge doses, the vaccine was more protective. However, the amount of virus naturally infecting cats cannot be controlled, thus these studies may be misleading. In three controlled challenge studies reported by the manufacturer, preventable fractions ranged from 67% to 82%.¹⁸⁹ The perceived low prevalence of disease, prolonged incubation period, and required IN administration make the routine use of a vaccine for FIP questionable. However, the vaccine has been shown to be beneficial in controlled studies in which naïve animals (not infected with coronaviruses) are vaccinated before entering contaminated catteries.^{158,460} In these studies, vaccinated animals had a lower subsequent incidence of FIP than did unvaccinated animals; however, the overall incidence rate of FIP in these cats was low. In another study in which SPF cats were housed with cats from an endemic cattery, no difference in disease incidence was found between vaccinated and unvaccinated SPF cats.³⁴⁰ The vaccine is labeled for use in cats at 16 weeks of age or older, with a series of two inoculations being given 3 to 4 weeks apart. However, virtually all cats in endemic environments become infected immediately after weaning between 6 to 12 weeks of age. Cats having low or no antibody titer at the time of vaccination may benefit, while those already infected, which are a majority of cats over 9 weeks of age, that have a high FCoV antibody titer or infection may develop FIP despite vaccination.¹⁵⁸ Vaccination, when recommended in cats from environments in which FIP has been diagnosed, has not been shown to be beneficial. In one survey, owners of less than five breeding cats were more willing to vaccinate their cats as compared with larger professional cat breeders.⁴⁹ In addition to vaccination, other husbandry and control measures may be equally, if not more important, in reducing the prevalence of FIP-related illnesses in such catteries. This vaccine is not recommended by many feline vaccine experts, nor is it recommended by the American Association of Feline Practitioners (AAFP) in their most recent guidelines.¹⁴⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

100.8.5.2.10 Feline immunodeficiency virus infection

(See also [Chapter 14](#)). A commercial FIV vaccine has been licensed as an adjuvanted-inactivated whole-virus vaccine, containing subtypes A (Petaluma) and D (Shizuoka) strains, which induces a strong antibody response. In one challenge study, the type A (Dixon) strain that differed in genetic homology by 10% from the vaccine virus was used.¹³ After challenge with this strain, the preventable fraction in vaccinated cats was a maximum of 82%. In other studies, the protection rate was lower. However, field isolates vary among subtypes; thus the preventable fraction in the field may be even lower.

A major disadvantage of the vaccine is that, because the definitive test for infection relies on detecting serum antibodies, those induced by the whole-virus vaccine cannot be distinguished from those produced by natural infection. Thus current diagnostic tests will no longer be of value in detecting infected cats.³³² Cats that were vaccinated, but not clearly identified with tattoos or microchips, might be considered as being infected with virulent virus. Furthermore, because some vaccinated cats might still become infected, the true infection status of known vaccinated cats cannot be determined. If a cat does not get tested before vaccination and is already infected when it is vaccinated, a similar problem might arise.

1117

1118

For this reason, cats should have negative antibody test results immediately before receiving the vaccine. If kittens have positive results, their antibody may be from MDA, which is usually gone by 12 weeks.³⁴³ They should be retested at 12 to 16 weeks. A decline in antibody indicates MDA was present, but these kittens may already be infected from the queen; thus vaccination may be of no benefit.

Cats that have recently been bitten should not be vaccinated earlier than 60 days thereafter because this is the time period for seroconversion following natural infection. The AAFP has recommended that the currently available vaccine not be used until a suitable diagnostic test for infection can be developed.

Antibody titers are still the preferred means of diagnosis of FIV infection. PCR does not detect all viral subtypes and is not standardized, thereby leading to low test sensitivity and specificity.⁴⁵ Furthermore, PCR has not been evaluated for all strains of FIV, methods have not been standardized between laboratories, and the cost of a test, if developed, will be much higher than antibody measurements.

100.8.5.2.11 Feline giardiasis

A licensed vaccine (GiardiaVax™, Fort Dodge, Fort Dodge, Iowa) containing inactivated, adjuvanted *Giardia lamblia* tachyzoites has been shown to provide some protection when given to kittens in two doses at a 3-week interval.⁴¹⁷ Vaccinated animals had greater body weight gain, less diarrhea, and reduced prevalence and quantity of cyst shedding as compared with control unvaccinated kittens. The vaccine is licensed for use in cats that are 8 weeks of age or older. In 16 young adult cats infected with *Giardia*, vaccination at weeks 4, 6, and 10 PI was not effective in eliminating the organism from infected cats.⁵⁴⁰ The vaccine is similar to that marketed for use in dogs; however, the feline vaccine contains a different adjuvant. The vaccine causes significant injection-site reactions that are more severe than those seen with adjuvanted rabies. If ISS is a concern, use of this product would not be advised. Furthermore, little or no field data have been found to show that the product is needed; therefore it is not generally recommended.

Infectious Diseases of the Dog and Cat, 3rd Edition

100.8.5.2.12 Feline bartonellosis

Cats are known reservoirs for *Bartonella* spp. that cause cat-scratch disease and related illness in people. Experimentally, *Bartonella henselae* vaccines have been protective in some studies to rechallenge infections (see [Chapter 54](#)). Although homologous protection has been demonstrated, cats can still be infected, albeit at lower levels of bacteremia, with heterologous strains and closely related species. This finding makes the possibility of a universal vaccine for this disease unlikely. Prevention is best accomplished through control of the flea vector.

100.8.5.2.13 Feline toxoplasmosis

An experimental MLV *Toxoplasma gondii* vaccine was developed as an aid in the prevention of oocyst shedding by cats.⁸⁶ This vaccine consisted of tissue culture-propagated bradyzoites that have been purified. The vaccine was given orally with two doses at 3- to 4-week intervals, and it prevented oocyst shedding after challenge. This strain appears to be a phenotypically stable mutant, which does not produce oocysts (see [Chapter 80](#)). This vaccine is not available commercially.

100.9 NOSODES

Nosodes are homeopathic preparations of tissues from animals with the disease for which they are intended to prevent. They have also been recommended to be given immediately after exposure to an infectious agent. These alternative medical therapeutic preparations are claimed to protect animals as specific immunomodulators against a variety of infectious diseases. Their preparation consists of serial dilution with intervening agitation (succession, potentiation, vortexing) of tissues, discharges, or excretions from animals with corresponding diseases. Nosodes are administered orally. Clinical trials involving nosodes to prevent infectious disease^{112,495} have not been well controlled. In a controlled CPV challenge of puppies, nosodes were not protective.^{501a,604} Use of homeopathic nosodes to prevent serious infectious diseases is not advised.

PUPPIES						
DISEASE (CHAPTER)	SEVERITY	ORGANISM SURVIVAL IN ENVIRONMENT	EXPOSURE RISK	VACCINE ^a EFFICACY	OVERCOME MATERNAL IMMUNITY ^{b,c}	PRIMARY PUPPY VACCINATION ^b (Optional)
Core Vaccines						
Canine distemper (3)	Potentially fatal	Labile: sunlight, dessication; high temperature inactivates	High	MLV: strongest, quickest protection Recombinant: lower	MLV: 12 Recombinant: 12	MLV: (6–8), 9–11, 12–14 Recombinant: (15–18)
Hepatitis (adenovirus) infection (4)	Potentially fatal	Stable: highly resistant; mos to yrs	High	MLV: high Killed (inactivated): lower	12	(6–8), 9–11, 12–14
Canine parvovirus infection (8)	Potentially fatal	Stable: highly resistant; mos to yr	High	MLV: strongest Killed: lower	MLV: 12 Killed: 18	(6–8), 9–11, 12–14, (15–18, especially if killed)
Rabies (22)	Fatal, zoonosis	Labile: persists in reservoir hosts	High	High: established by product	12	≥12; depends on product
Noncore Vaccines						
Canine parainfluenza virus infection (6)	Low	Labile: sunlight, dessication; high temperature inactivates	High in dense population	IN: good, partial protection Parenteral: low	IN: 6; Parenteral: 12	IN: ≥12
Bordetellosis (6)	Low to moderate	Labile: persists in reservoir hosts	High with dense populations	IN: moderate Parenteral: low	IN: 2–3 Parenteral: 12	IN ^d & Parenteral: 9–11, 12–14
Canine coronavirus infection (8)	Mild	Stable: environment 2 mos	High in dense populations	Partial protection	12	(6–8), 9–11, 12–14
Leptospirosis (44)	Subclinical to fatal, zoonotic risk	Labile: wildlife and domestic reservoirs	Geographic and seasonal	Variable response, serovar specific	12	9–11, 12–14
Borreliosis (45)	Mild to moderate	Labile: tick reservoir	Geographic and seasonal	Effective if given prior to any tick exposure	Unknown	8–11, 12–14
Giardiasis (78)	Mild	Stable: high in unsanitary conditions	Variable	Reduce organism replication	Unknown	8–11, 12–14

1121

1122

Infectious Diseases of the Dog and Cat, 3rd Edition

ADULTS				
DISEASE (CHAPTER)	SUBSEQUENT BOOSTERS	PRIMARY ADULT VACCINATION ^a	ESTABLISHED LONG-TERM DURATION OF IMMUNITY WITH CHALLENGE ^e	COMMENTS/REACTIONS
Core Vaccines				
Canine distemper (3)	1yr; thereafter 1–3yrs depending on environmental exposure and vaccine type used	2 doses all products	MLV: ≥7yrs sterile immunity (Rockborn and Snyder Hill strains); ≥5yrs (Onderstepoort strain) Recombinant: ≥1yr	Variable DOI of MLV products is based on vaccine strain. MLV products provide strongest protection but there is potential of postvaccinal encephalitis or hypertrophic osteodystrophy. DOI of recombinant products has not been established beyond 1yr. Boosters could be extended to 3yrs if primary vaccination series uses MLV product. Recombinant vaccines should not be used in previously unvaccinated dogs exposed to high population density and/or highly contaminated environments. Distemper/measles combination vaccine is only recommended for IM use in pups <12 wks for first vaccine if the environment is highly contaminated and routine distemper immunization beginning at 6–8wks does not control vaccine breaks.
Hepatitis (adenovirus) infection (4)	1yr; thereafter 3yrs for MLV and 1yr if only killed (inactivated) used	MLV: 1 dose Killed: 2 doses	MLV: ≥7yrs sterile 1 dose immunity Killed: 1yr	CAV-2 vaccines have fewer adverse reactions compared to CAV-1, which can cause “blue eye” reaction. CAV-2 vaccines are preferred and are effective against infections causing tracheobronchitis and systemic infection by CAV-1. For these reasons, vaccines containing CAV-1 are not recommended.
Canine parvovirus infection (8)	1yr; thereafter 3yrs for MLV and 1yr for killed unless as initial series	MLV: 1 dose Killed: 2 doses	MLV: ≥7yrs sterile immunity Killed virus ≥mos	MDA blockade is strong. Potentiated products are most effective in overcoming this blockade. Cross protection between all strains CPV2, 2a, 2b, 2c exists. Killed vaccines do not break through MDA as well as MLV vaccines. Vaccinate to at least 16wks with killed products and do not use them for animals housed in high density and/or highly contaminated environments. Killed vaccine may protect >1yr as vaccinated animals have a likely risk of exposure to virulent virus or MLV virus in the environment which boosts their immunity.
Rabies (22)	1yr; thereafter 1–3yrs, see commentslocal	1 dose all products	1 or 3yrs	Adjuvanted vaccines have potential to cause allergic or neoplastic complications. State and local public health laws govern the frequency of administration.
Noncore Vaccines				

Infectious Diseases of the Dog and Cat, 3rd Edition

Canine parainfluenza virus infection (6)	1yr for animals in high-risk environments; 3yrs for others	IN: 1 dose Parenteral: 2 doses	IN and parenteral: up to 1yr; however, no long-term studies available	Recommended for dogs in shelters, kennels, shows, large colonies, or breeding establishments. Use IN vaccine at least 1–2wks prior to exposure for optimal protection. Natural resistance develops with increasing age.	1122
Bordetellosis (6)	1yr; thereafter IN at least 1wk prior to anticipated exposure	Killed injectable: 2 doses 2–4wks apart MLV IN: 1 dose	Natural infection: partial protection for 6–12 mos Longest vaccine challenge study is 10 mos; most are ≤1 mo.	MLV IN vaccine is recommended for dogs in shelters, kennels, shows, large colonies, or breeding establishments. Prevalence of postvaccinal illness is low and is characterized by rhinitis with persistent sneezing, cough, and nasal discharge. Should these signs persist, antimicrobial therapy is indicated. Avoid IN MLV in immunosuppressed animals.	1123
Canine coronavirus infection (8)	1yr, if indicated	MLV: 1 dose Killed: 2 doses	Unknown, no long-term studies. Protection is partial.	Purification of killed parenteral vaccine has reduced side effects of hypersensitivity but has also reduced potency. Alternating parenteral or IN vaccines, and using at least 3 doses in the initial series increases the primary immune response to challenge. Incidence is high in shelter, show, and breeding environments. Routine use is of questionable benefit. Disease is mild. Immunity is transient. Adverse reaction rates for vaccines are low, although adjuvants in killed products may increase reaction to leptospiral or high-titer CPV vaccines. MLV vaccine has no adjuvants and better breakthrough.	
Leptospirosis (44)	1yr, if indicated	Minimum of 2 doses, 2–4wks apart	1yr partial protection based on unpublished vaccine manufacturers' data. Protection against carrier state is variable.	Some products may cause anaphylaxis. Purification has been increased since combined with coronaviral products. Should not begin vaccination <9wks of age because of increased rate of fatal complications in younger animals. Older animals are more consistently protected. Vaccines should include products with most commonly observed serovars.	
Borreliosis (45)	1yr, if indicated; thereafter preferably prior to tick season	2 doses 3–4 wks apart	1yr based on vaccine licensing data; all companies have 1 yr licensing challenge data	Young (<24 wks) animals are more at risk. Where exposure rate is high, disease incidence is low. Side effects associated with vaccine are controversial. Subunit products are less reactive; however, whole-cell products may produce more consistent initial protection. Following at least 3 vaccines, especially subunit vaccines, immune response is more consistently protective.	
Giardiasis (78)	1yr, if indicated	2 doses 2–4wks apart	1yr based on vaccine licensing data; use in adults questionable	Animals vaccinated prior to exposure had reduced clinical signs of diarrhea and intestinal replication of organisms. Oocyst shedding was reduced. Disease is generally mild or subclinical, even in neonates.

KITTENS							
DISEASE (CHAPTER)	SEVERITY	ORGANISM SURVIVAL IN ENVIRONMENT	EXPOSURE RISK	VACCINE ^a EFFICACY	MATERNAL IMMUNITY WANE ^b	PRIMARY KITTEN VACCINATION ^b (OPTIONAL)	
Core Vaccines							1124
Panleukopenia (10)	Potentially fatal	Stable: highly resistant; mos to yrs	High ^c	MLV: strongest Killed (inactivated): lower	12 ^{c,d}	(6–8), 9–11, 12–14	1125
Herpesvirus-1 infection (16)	Potentially fatal in young kittens	Fragile: short survival time	High ^c	MLV: strongest	12 ^{c,d}	(6–8), 9–11, 12–14	
Calicivirus infection (16)	Potentially fatal	Stable: moderately resistant; survives about 2 wks	High ^c	Killed: lower MLV: strongest	12 ^{c,d}	(6–8), 9–11, 12–14	
Rabies (22)	Fatal, zoonosis	Labile: persists in reservoir hosts	High	High: established by product	NA	≥12 depends on product; canarypox-vectored vaccine can be administered at 8 wks	
Noncore Vaccines							
<i>Chlamydomydia felis</i> infection (30)	Mild to moderate ^d	Labile: environmentally very unstable ^d	High in contaminated environment	MLV: low to moderate Killed: low	Unknown	9–11, 12–14	
<i>Bordetella bronchiseptica</i> infection (16)	Low to moderate	Labile: persists in reservoir hosts	High in contaminated environment	IN: low ^c	IN: approximately 6wks	≥8, 1 dose (label)	1125
Feline infectious peritonitis (coronavirus infection) (11)	FECV infection: low	Stable: persists in environment about 2 mos	FECV: high FIPV: low	IN: low	Approximately 6wks	≥16, 2 doses 3–4wks apart	1126
Giardiasis (78)	Subclinical to severe ^d	Stable: high in unsanitary conditions	Variable	Reduces organism replication	Unknown	8–11, 12–14	
Feline leukemia (13)	Fatal	Labile: 24–48 hrs at moist warm temperatures	Moderate to high with long-term exposure to a positive cat	~14% to 100% depending on study	Approximately 12wks	9–11, 12–14	
Feline AIDS (14)	High	Labile	Moderate to high with one exposure	0% to 82%	12 ^e	9–11, 12–14	

Infectious Diseases of the Dog and Cat, 3rd Edition

ADULTS				
DISEASE (CHAPTER)	SUBSEQUENT BOOSTERS	PRIMARY VACCINATION ADULT ^a	ESTABLISHED LONG-TERM DURATION OF IMMUNITY WITH CHALLENGE ^f	COMMENTS/REACTIONS
Core Vaccines				
Panleukopenia (10)	1yr; thereafter 1–3yrs depending on environmental exposure and vaccine type used	MLV: 1 dose Killed (inactivated): 2 doses	7yrs sterile immunity ^d 30 mos ^g sterile immunity	Highly recommended for all cats. In most cats, protection derived following administration of booster vaccination 1yr after primary vaccination is sustained for at least 3yrs and probably longer. MLV vaccines should not be administered to pregnant queens or kittens <4wks old. IN is less effective than parenteral because fewer virus particles reach lymphoid tissue.
Herpesvirus-1 infection (16)	1yr; thereafter 1–3yrs depending on environmental exposure and vaccine type used	MLV: 1 dose Killed: 2 doses	7yrs ^d and 36 mos ^g with decrease in clinical signs	Highly recommended for all cats. MLV vaccines should not be administered to pregnant queens. IN is capable of inducing a local immune response in the face of high MDA titers. Can administer >2wks of age. All vaccines reduce clinical signs of disease; they do not prevent infection.
Calicivirus infection (16)	1yr; thereafter 1–3yrs depending on environmental exposure and vaccine type used	MLV: 1 dose Killed: 2 doses	7yrs ^d and 36 mos ^g with decrease in clinical signs	Highly recommended for all cats; MLV vaccines should not be administered to pregnant queens. IN is capable of inducing a local immune response in the face of high MDA titers. Can administer >2wks of age. All vaccines reduce clinical signs of disease; they do not prevent infection. They do not induce protection from all isolates FCV.
Rabies (22)	1yr; thereafter 1–3yrs, see comments	1 dose all products	1 or 3yrs	Highly recommended for all cats. Adjuvanted vaccines have the potential to cause allergic or neoplastic complications. One recombinant nonadjuvanted product available for 1-yr duration. State and local public health laws govern the frequency of administration.
Noncore Vaccines				

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>Bordetella bronchiseptica</i> infection (16)	1yr; thereafter IN at least 1wk prior to anticipated exposure	MLV: 1 dose	3wks following 1 dose at 4wks of age (as per label) with decrease in clinical signs	Not recommended for routine use. Can be used in cats in large groups (shelters, catteries, shows, breeding establishments) where organism has been documented. Prevalence of postvaccinal illness is low, characterized by rhinitis with persistent sneezing, cough, and nasal discharge. Should these signs persist, antimicrobial therapy is indicated.
<i>Chlamydomphila felis</i> infection (30)	1yr; thereafter annually if indicated	MLV: 1 dose Killed: 2 doses	13-mos data available from manufacturers with decrease in clinical signs	Avoid IN MLV in immunosuppressed animals. Not recommended for routine use. Consider for use in multiple-cat environments where <i>C. felis</i> infections associated with clinical disease have been documented. May cause transitory fever and lethargy. Antimicrobials are effective in controlling the clinical illness.
Feline infectious peritonitis (coronavirus infection) (11)	1yr; thereafter annually if indicated	MLV: 2 doses, 3–4wks apart	12-mos field exposure	Not recommended for routine use. At this time, there is insufficient evidence to support the conclusion that the vaccine induces clinically relevant protection.
Feline leukemia (13)	1yr; thereafter annually if indicated	2 doses, 2–4wks apart for all products	Killed-adjuvanted (some): 1yr Recombinant-vectored: 28 days	Recommended for cats that are not restricted to a closed, indoor, FeLV-negative environment; most important for cats <16wks old. Not recommended >16wks old with for minimal to no risk of exposure to
Feline AIDS (14)	1yr; thereafter annually if indicated	3 doses, 2–4wks apart	Not available	FeLV-infected cats. Not recommended. Vaccinated cats will become seropositive as determined by the currently available, commercial antibody-based diagnostic tests. This may complicate existing testing guidelines and disease control strategies.
Giardiasis (78)	1yr; thereafter annually if indicated	2 doses, 2–4wks apart	1yr based on vaccine licensing data; of questionable use in adults	Not recommended for routine use. Vaccination may be considered as a component of a comprehensive control program in multiple-cat environments in which infections associated with clinical disease have been documented.

MLV, Modified live virus; IN, intranasal; FECV, feline enteric coronavirus; FIP(V), feline infectious peritonitis (virus); AIDS, acquired immunodeficiency syndrome; MDA, maternally derived antibodies; FCV, feline calicivirus; FeLV, feline leukemia virus.

- a Potentiated canine parvovirus vaccines generally have a higher infectious dose titer and lower culture passage making them more protective than conventional products in breaking through maternally acquired immunity.
- b Sometimes recommended intraocularly, with certain brands, and in young kittens.

¹⁰⁴ APPENDIX 4 Compendium of Animal Rabies Prevention and Control, 2006*

National Association of State Public Health Veterinarians, Inc. (NASPHV)

Rabies is a fatal viral zoonosis and a serious public health problem (1). The recommendations in this compendium serve as a basis for animal rabies prevention and control programs throughout the United States and facilitate standardization of procedures among jurisdictions, thereby contributing to an effective national rabies control program. This document is reviewed annually and revised as necessary. These recommendations do not supersede state and local laws or requirements. Principles of rabies prevention and control are detailed in Part I; Part II contains recommendations for parenteral vaccination procedures; all animal rabies vaccines licensed by the United States Department of Agriculture (USDA) and marketed in the United States are listed in Part III.

^{104.1} PART 1: RABIES PREVENTION AND CONTROL

^{104.1.1} A. Principles of Rabies Prevention and Control

1. **Rabies Exposure.** Rabies is transmitted only when the virus is introduced into bite wounds, open cuts in skin, or onto mucous membranes from saliva or other potentially infectious material such as neural tissue (2). Questions about possible exposures should be directed to state or local public health authorities.
2. **Human Rabies Prevention.** Rabies in humans can be prevented either by eliminating exposures to rabid animals or by providing exposed persons with prompt local treatment of wounds combined with the administration of human rabies immune globulin and vaccine. The rationale for recommending preexposure and postexposure rabies prophylaxis and details of their administration can be found in the current recommendations of the Advisory Committee on Immunization Practices (ACIP) (2). These recommendations, along with information concerning the current local and regional epidemiology of animal rabies and the availability of human rabies biologics, are available from state health departments.
3. **Domestic Animals.** Local governments should initiate and maintain effective programs to ensure vaccination of all dogs, cats, and ferrets and to remove strays and unwanted animals. Such procedures in the United States have reduced laboratory-confirmed cases of rabies in dogs from 6,949 in 1947 to 94 in 2004 (3). Because more rabies cases are reported annually involving cats (281 in 2004) than dogs, vaccination of cats should be required. Animal shelters and animal control authorities should establish policies to ensure that adopted animals are vaccinated against rabies. The recommended vaccination procedures and the licensed animal vaccines are specified in Parts II and III of the compendium respectively.
4. **Rabies in Vaccinated Animals.** Rabies is rare in vaccinated animals (4). If such an event is suspected, it should be reported to state public health officials, the vaccine manufacturer, and USDA, Animal and Plant Health Inspection Service, Center for Veterinary Biologics (Internet: <http://www.aphis.usda.gov/vs/cvb/ic/adverseeventreport.htm>; telephone: 800-752-6255; or e-mail: CVB@usda.gov). The laboratory diagnosis should be confirmed and the virus characterized by a rabies reference laboratory. A thorough epidemiologic investigation should be conducted.
5. **Rabies in Wildlife.** The control of rabies among wildlife reservoirs is difficult (5). Vaccination of free-ranging wildlife or selective population reduction might be useful in some situations, but the

Infectious Diseases of the Dog and Cat, 3rd Edition

success of such procedures depends on the circumstances surrounding each rabies outbreak (see Part I. C. Control Methods in Wildlife). Because of the risk of rabies in wild animals (especially raccoons, skunks, coyotes, foxes, and bats), AVMA, NASPHV, and CSTE strongly recommend the enactment and enforcement of state laws prohibiting their importation, distribution, and relocation.

6. **Rabies Surveillance.** Laboratory-based rabies surveillance is an essential component of rabies prevention and control programs. Accurate and timely information is necessary to guide human postexposure prophylaxis decisions, determine the management of potentially exposed animals, aid in emerging pathogen discovery, describe the epidemiology of the disease, and assess the need for and effectiveness of oral vaccination programs for wildlife.
7. **Rabies Diagnosis.** Rabies testing should be performed by a qualified laboratory that has been designated by the local or state health department (6) in accordance with the established national standardized protocol for rabies testing (http://www.cdc.gov/ncidod/dvrd/rabies/Professional/publications/DFA_diagnosis/DFA_protocol-b.htm). Euthanasia (7) should be accomplished in such a way as to maintain the integrity of the brain so that the laboratory can recognize the anatomical parts. Except in the case of very small animals, such as bats, only the head or brain (including brain stem) should be submitted to the laboratory. Any animal or animal specimen being submitted for testing should preferably be stored and shipped under refrigeration rather than frozen to prevent a delay in testing and to facilitate laboratory processing. 1133
Chemical fixation of tissues should be avoided to prevent significant testing delays and because it may 1134
preclude reliable testing. Questions about testing of fixed tissues should be directed to the local rabies laboratory or public health department.

8. **Rabies Serology.** Some “rabies-free” jurisdictions may require evidence of vaccination and rabies antibodies for importation purposes. Rabies antibody titers are indicative of an animal's response to vaccine or infection. Titers do not directly correlate with protection because other immunologic factors also play a role in preventing rabies, and our abilities to measure and interpret those other factors are not well developed. Therefore, evidence of circulating rabies virus antibodies should not be used as a substitute for current vaccination in managing rabies exposures or determining the need for booster vaccinations in animals (8–10).

* From the National Association of State Public Health Veterinarians, Inc. (NASPHV). You can visit the NASPHV website at <http://www.nasphv.org/4436.html> or download the Compendium directly from www.nasphv.org/83416/83301.html.

104.1.2 B. Prevention and Control Methods in Domestic and Confined Animals

1. **Preexposure Vaccination and Management.** Parenteral animal rabies vaccines should be administered only by or under the direct supervision of a veterinarian. Rabies vaccinations may also be administered under the supervision of a veterinarian to animals held in animal control shelters prior to release. Any veterinarian signing a rabies certificate must ensure that the person administering vaccine is identified on the certificate and is appropriately trained in vaccine storage, handling, and administration and in the management of adverse events. This practice assures that a qualified and responsible person can be held accountable to ensure that the animal has been properly vaccinated.

Within 28 days after primary vaccination, a peak rabies antibody titer is reached and the animal can be considered immunized. An animal is currently vaccinated and is considered immunized if the primary

Infectious Diseases of the Dog and Cat, 3rd Edition

vaccination was administered at least 28 days previously and vaccinations have been administered in accordance with this compendium.

Regardless of the age of the animal at initial vaccination, a booster vaccination should be administered 1 year later (see Parts II and III for vaccines and procedures). No laboratory or epidemiologic data exist to support the annual or biennial administration of 3-year vaccines following the initial series. Because a rapid anamnestic response is expected, an animal is considered currently vaccinated immediately after a booster vaccination.

- a. **Dogs, Cats, and Ferrets.** All dogs, cats, and ferrets should be vaccinated against rabies and revaccinated in accordance with Part III of this compendium. If a previously vaccinated animal is overdue for a booster, it should be revaccinated. Immediately following the booster, the animal is considered currently vaccinated and should be placed on an annual or triennial schedule depending on the type of vaccine used.
- b. **Livestock.** Consideration should be given to vaccinating livestock that are particularly valuable or that might have frequent contact with humans (e.g., in petting zoos, fairs, and other public exhibitions) (11,12). Horses traveling interstate should be currently vaccinated against rabies.
- c. **Confined Animals.**
 - 1) **Wild.** No parenteral rabies vaccines are licensed for use in wild animals or hybrids (the offspring of wild animals crossbred to domestic animals). Wild animals or hybrids should not be kept as pets (13–16).
 - 2) **Maintained in Exhibits and in Zoological Parks.** Captive mammals that are not completely excluded from all contact with rabies vectors can become infected. Moreover, wild animals might be incubating rabies when initially captured; therefore, wild-caught animals susceptible to rabies should be quarantined for a minimum of 6 months before being exhibited. Employees who work with animals at such facilities should receive preexposure rabies vaccination. The use of pre- or postexposure rabies vaccinations for employees who work with animals at such facilities might reduce the need for euthanasia of captive animals. Carnivores and bats should be housed in a manner that precludes direct contact with the public.
2. **Stray Animals.** Stray dogs, cats, and ferrets should be removed from the community. Local health departments and animal control officials can enforce the removal of strays more effectively if owned animals have identification and are confined or kept on leash. Strays should be impounded for at least 3 business days to determine if human exposure has occurred and to give owners sufficient time to reclaim animals.
3. **Importation and Interstate Movement of Animals.**
 - a. **International.** CDC regulates the importation of dogs and cats into the United States. Importers of dogs must comply with rabies vaccination requirements (42 CFR, Part 71.51[c] (<http://www.cdc.gov/ncidod/dq/animal.htm>)) and complete CDC form 75.37 (<http://www.cdc.gov/ncidod/dq/pdf/cdc7537-05-24-04.pdf>). The appropriate health official of the state of destination should be notified within 72 hours of the arrival into his or her jurisdiction of any imported dog required to be placed in confinement under the CDC regulation.

Infectious Diseases of the Dog and Cat, 3rd Edition

Failure to comply with these confinement requirements should be promptly reported to the Division of Global Migration and Quarantine, CDC (telephone: 404-639-3441).

Federal regulations alone are insufficient to prevent the introduction of rabid animals into the country (17,18). All imported dogs and cats are subject to state and local laws governing rabies and should be currently vaccinated against rabies in accordance with this compendium. Failure to comply with state or local requirements should be referred to the appropriate state or local official.

- b. **Interstate.** Before interstate movement (including commonwealths and territories) dogs, cats, ferrets, and horses should be currently vaccinated against rabies in accordance with the compendium's recommendations (see Part I. B.1. Preexposure Vaccination and Management). Animals in transit should be accompanied by a currently valid NASPHV Form 51, Rabies Vaccination Certificate (<http://www.nasphv.org/83416/106001.html>). When an interstate health certificate or certificate of veterinary inspection is required, it should contain the same rabies vaccination information as Form 51.
- c. **Areas with Dog-to-Dog Rabies Transmission.** The movement of dogs from areas with dog-to-dog rabies transmission for the purpose of adoption or sale should be prohibited. Rabid dogs have been introduced into the continental United States from areas with dog-to-dog rabies transmission (17,18). This practice poses the risk of introducing canine-transmitted rabies to areas where it does not currently exist.

4. **Adjunct Procedures.** Methods or procedures which enhance rabies control include the following:

- a. **Identification.** Dogs, cats, and ferrets should be identified (e.g., metal or plastic tags or microchips) to allow for verification of rabies vaccination status.
- b. **Licensure.** Registration or licensure of all dogs, cats, and ferrets may be used to aid in rabies control. A fee is frequently charged for such licensure, and revenues collected are used to maintain rabies- or animal-control programs. Evidence of current vaccination is an essential prerequisite to licensure. 1134
1135
- c. **Canvassing.** House-to-house canvassing by animal control officials facilitates enforcement of vaccination and licensure requirements.
- d. **Citations.** Citations are legal summonses issued to owners for violations, including the failure to vaccinate or license their animals. The authority for officers to issue citations should be an integral part of each animal-control program.
- e. **Animal Control.** All communities should incorporate stray animal control, leash laws, and training of personnel in their programs.

5. **Postexposure Management.** Any animal potentially exposed to rabies virus (see Part I. A.1. Rabies Exposure) by a wild, carnivorous mammal or a bat that is not available for testing should be regarded as having been exposed to rabies.

- a. **Dogs, Cats, and Ferrets.** Unvaccinated dogs, cats, and ferrets exposed to a rabid animal should be euthanized immediately. If the owner is unwilling to have this done, the animal should be placed in strict isolation for 6 months. Rabies vaccine should be administered upon entry into

Infectious Diseases of the Dog and Cat, 3rd Edition

isolation or 1 month prior to release to comply with preexposure vaccination recommendations (see Part I.B.1.a.). There are currently no USDA licensed biologics for postexposure prophylaxis of previously unvaccinated domestic animals, and there is evidence that the use of vaccine alone will not reliably prevent the disease (19). Animals with expired vaccinations need to be evaluated on a case-by-case basis. Dogs, cats, and ferrets that are currently vaccinated should be revaccinated immediately, kept under the owner's control, and observed for 45 days. Any illness in an isolated or confined animal should be reported immediately to the local health department.

- b. **Livestock.** All species of livestock are susceptible to rabies; cattle and horses are among the most frequently infected. Livestock exposed to a rabid animal and currently vaccinated with a vaccine approved by USDA for that species should be revaccinated immediately and observed for 45 days. Unvaccinated livestock should be slaughtered immediately. If the owner is unwilling to have this done, the animal should be kept under close observation for 6 months. Any illness in an animal under observation should be reported immediately to the local health department.

The following are recommendations for owners of livestock exposed to rabid animals:

- 1) If the animal is slaughtered within 7 days of being bitten, its tissues may be eaten without risk of infection, provided that liberal portions of the exposed area are discarded. Federal guidelines for meat inspectors require that any animal known to have been exposed to rabies within 8 months be rejected for slaughter.
 - 2) Neither tissues nor milk from a rabid animal should be used for human or animal consumption (20). Pasteurization temperatures will inactivate rabies virus; therefore, drinking pasteurized milk or eating cooked meat does not constitute a rabies exposure.
 - 3) Having more than one rabid animal in a herd or having herbivore-to-herbivore transmission is uncommon; therefore, restricting the rest of the herd if a single animal has been exposed to or infected by rabies might not be necessary.
- c. **Other Animals.** Other mammals bitten by a rabid animal should be euthanized immediately. Animals maintained in USDA-licensed research facilities or accredited zoological parks should be evaluated on a case-by-case basis.

6. Management of Animals that Bite Humans.

- a. **Dogs, Cats, and Ferrets.** Rabies virus may be excreted in the saliva of infected dogs, cats, and ferrets during illness and/or for only a few days prior to illness or death (21–23). A healthy dog, cat, or ferret that bites a person should be confined and observed daily for 10 days (24); administration of rabies vaccine to the animal is not recommended during the observation period to avoid confusing signs of rabies with possible side effects of vaccine administration. Such animals should be evaluated by a veterinarian at the first sign of illness during confinement. Any illness in the animal should be reported immediately to the local health department. If signs suggestive of rabies develop, the animal should be euthanized and the head shipped for testing as described in Part I.A.7. Any stray or unwanted dog, cat, or ferret that bites a person may be euthanized immediately and the head submitted for rabies examination.
- b. **Other Biting Animals.** Other biting animals which might have exposed a person to rabies should be reported immediately to the local health department. Management of animals other

Infectious Diseases of the Dog and Cat, 3rd Edition

than dogs, cats, and ferrets depends on the species, the circumstances of the bite, the epidemiology of rabies in the area, the biting animal's history, current health status, and potential for exposure to rabies. Prior vaccination of these animals may not preclude the necessity for euthanasia and testing.

7. Outbreak Prevention and Control. The emergence of new rabies virus variants or the introduction of non indigenous viruses poses a significant risk to humans, domestic animals and wildlife (25–31). A rapid and comprehensive response should include all or some of the following measures:

- a. Characterize the virus at a national or regional reference laboratory.
- b. Identify and control the source of the introduction.
- c. Enhance laboratory-based surveillance in wild and domestic animals.
- d. Increase animal rabies vaccination rates.
- e. Restrict the movement of animals.
- f. Evaluate the need for vector population reduction.
- g. Coordinate a multi-agency response.
- h. Provide public and professional outreach and education.

8. Disaster Response. Animals may be displaced during and after manmade or natural disasters and require emergency sheltering (<http://www.bt.cdc.gov/disasters/hurricanes/katrina/petshelters.asp>). Animal rabies vaccination and exposure histories are often not available for displaced animals and disaster response creates situations where animal caretakers may lack appropriate training and previous vaccination. For these situations it is critical to implement and coordinate rabies prevention and control measures to reduce the risk of rabies transmission and the need for human post exposure prophylaxis.

- a. Coordinate relief efforts of individuals and organizations with the local emergency operations center prior to deployment.
- b. Examine each animal at a triage site for signs of rabies.
- c. Isolate animals exhibiting signs of rabies pending evaluation by a veterinarian.
- d. Ensure that all animals have a unique identifier.
- e. Administer a rabies vaccination to all dogs, cats and ferrets unless reliable proof of vaccination exists.
- f. Adopt minimum standards for animal caretakers that include personal protective equipment, previous rabies vaccination, and appropriate training in animal handling (see Part 1.C.).
- g. Maintain documentation of animal disposition and location e.g. returned to owner, died or euthanized, adopted, relocated to another shelter, address of new location.
- h. Provide facilities to confine and observe animals involved in exposures (see Part 1.A.1.).

1135

1136

Infectious Diseases of the Dog and Cat, 3rd Edition

- i. Report human exposures to appropriate public health authorities (see Part I.B.6).

104.1.3 C. Prevention and Control Methods Related to Wildlife

The public should be warned not to handle or feed wild mammals. Wild mammals and hybrids that bite or otherwise expose persons, pets, or livestock should be considered for euthanasia and rabies examination. A person bitten by any wild mammal should immediately report the incident to a physician who can evaluate the need for postexposure prophylaxis (2). State-regulated wildlife rehabilitators may play a role in a comprehensive rabies control program. Minimum standards for persons who rehabilitate wild mammals should include rabies vaccination, appropriate training, and continuing education. Translocation of infected wildlife has contributed to the spread of rabies (26–30); therefore, the translocation of known terrestrial rabies reservoir species should be prohibited.

1 **Carnivores.** The use of licensed oral vaccines for the mass vaccination of free-ranging wildlife should be considered in selected situations, with the approval of the state agency responsible for animal rabies control (5). The distribution of oral rabies vaccine should be based on scientific assessments of the target species and followed by timely and appropriate analysis of surveillance data; such results should be provided to all stakeholders. In addition, parenteral vaccination (trap-vaccinate-release) of wildlife rabies reservoirs may be integrated into coordinated oral rabies vaccination programs to enhance their effectiveness. Continuous and persistent programs for trapping or poisoning wildlife are not effective in reducing wildlife rabies reservoirs on a statewide basis. However, limited population control in high-contact areas (e.g., picnic grounds, camps, suburban areas) may be indicated for the removal of selected high-risk species of wildlife (5). State agriculture, public health, and wildlife agencies should be consulted for planning, coordination, and evaluation of vaccination or population-reduction programs.

2 **Bats.** Indigenous rabid bats have been reported from every state except Hawaii and have caused rabies in more than 40 humans in the United States (32–37). Bats should be excluded from houses, public buildings, and adjacent structures to prevent direct association with humans (38,39). Such structures should then be made bat-proof by sealing entrances used by bats. Controlling rabies in bats through programs designed to reduce bat populations is neither feasible nor desirable.

104.2 PART II: RECOMMENDATIONS FOR PARENTERAL RABIES VACCINATION PROCEDURES

- A. **Vaccine Administration.** All animal rabies vaccines should be restricted to use by, or under the direct supervision of a veterinarian (40) except as recommended in Part I.B.1. All vaccines must be administered in accordance with the specifications of the product label or package insert.
- B. **Vaccine Selection.** Part III lists all vaccines licensed by USDA and marketed in the United States at the time of publication. New vaccine approvals or changes in label specifications made subsequent to publication should be considered as part of this list. Any of the listed vaccines can be used for revaccination, even if the product is not the same brand previously administered. Vaccines used in state and local rabies control programs should have a 3-year duration of immunity. This constitutes the most effective method of increasing the proportion of immunized dogs and cats in any population (41). No laboratory or epidemiologic data exist to support the annual or biennial administration of 3-year vaccines following the initial series.

Infectious Diseases of the Dog and Cat, 3rd Edition

- C. **Adverse Events.** Currently, no epidemiologic association exists between a particular licensed vaccine product and adverse events, including vaccine failure (42,43). Adverse events should be reported to the vaccine manufacturer and to USDA, Animal and Plant Health Inspection Service, Center for Veterinary Biologics (Internet: <http://www.aphis.usda.gov/vs/cvb/ic/adverseeventreport.htm>; telephone: 800-752-6255; or e-mail: CVB@usda.gov).
- D. **Wildlife and Hybrid Animal Vaccination.** The safety and efficacy of parenteral rabies vaccination of wildlife and hybrids have not been established, and no rabies vaccines are licensed for these animals. Parenteral vaccination (trap-vaccinate-release) of wildlife rabies reservoirs may be integrated into coordinated oral rabies vaccination programs as described in Part I. C.1. to enhance their effectiveness. Zoos or research institutions may establish vaccination programs, which attempt to protect valuable animals, but these should not replace appropriate public health activities that protect humans (9).
- E. **Accidental Human Exposure to Vaccine.** Human exposure to parenteral animal rabies vaccines listed in Part III does not constitute a risk for rabies infection. However, human exposure to vaccinia-vectored oral rabies vaccines should be reported to state health officials (44).
- F. **Rabies Certificate.** All agencies and veterinarians should use NASPHV Form 51, Rabies Vaccination Certificate, or equivalent which can be obtained from vaccine manufacturers or from NASPHV (<http://www.nasphv.org>) or CDC (<http://www.cdc.gov/ncidod/dvrd/rabies/professional/professi.htm>). The form must be completed in full and signed by the administering or supervising veterinarian. Computer-generated forms containing the same information are also acceptable.

Infectious Diseases of the Dog and Cat, 3rd Edition

Part B: Laboratory Tests and Interpretation

AGENT (CHAPTER)	INTERNATIONAL	USA	DETECTION: TEST TYPE	SAMPLE (AMOUNT OR HANDLING)	COMMENTS
VIRAL, RICKETTSIAL, CHLAMYDIAL, AND MYCOPLASMAL INFECTIONS (1)					
Canine Distemper Virus (3)					
Antemortem	iD4, iSw1	Many	Ag: FA	Blood or buffy coat smear, conjunctival scraping, CSF, transtracheal wash (cytologic smears are air dried and refrigerated, alcohol- or acetone-fixed)	Positive result confirms infection with proper technique; false-negative in chronic (>1wk) CNS infections; false-positives due to poor lab technique
	iA2, iGer3, iSw1, iSwi3	AL2, CO1, LA1	Genome: PCR	Serum, whole blood, CSF, urine (refrigerated)	Positive result confirms infection if clinical signs are present. False-positive results can occur within several wks following MLV vaccination
	iA2, iD2, iGer3, Sw1	Many	Ab: VN (SN)	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) titer IgG or high IgM confirms active infection; >1:100 single VN (SN) titer indicates relative immune protection against disease
	iA2, iD2, iGer3, Sw1	Many, CA1 NY1, WA1	Ab: FA	As above	As above
			Ab: VN	CSF (1–3 ml) (refrigerated)	Positive titer confirms CNS infection if serum contamination is excluded or if CSF titer is high relative to serum titer and titer to another infectious agent; some inconsistencies have been noted. SN titers take such high antibody levels to be detected such that CSF levels may not be measurable
		WA1, TN2, AL2, CA1, IDX	Ab: FA	As above	As above

1148

Infectious Diseases of the Dog and Cat, 3rd Edition

Postmortem or tissue biopsy	iD1, iD4, iSw1	Many	Ag: FA	Lung, bladder, cerebellum, or conjunctival smear (refrigerated)	Positive result confirms infection	1149
		Many	Virus: VI	As above	As above	
		Many	Lesion: histology	Lung, bladder, brain, liver, stomach (formalin-fixed)	Inclusion body detection with compatible histologic changes indicates infection; some false-positive and false-negative results	
	iA2, iSwi3	AL2, MO1, AZ3, TX2, CA1, TX1, LA1 WA1, NY1, MN1, MI1	Genome: PCR Ag: IHC	Tissues (refrigerated) or in paraffin blocks As above	Positive result confirms infection Specific antigen staining confirms virus in tissues	
Infectious Canine Hepatitis (4)						
Antemortem	iSw1	Many	Virus: VI	Oropharyngeal swabs, urine, feces (refrigerated)	Positive result confirms infection	
	iA2	CO1, AZ3	Genome: PCR	EDTA blood, urine, liver (refrigerated)	As above	
	iSw1	AL2, TX2, NY1, GA2, KS1	Ab: VN (SN)	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) titer IgG or high IgM confirms active infection; high single VN titer indicates relative immune protection against disease	
Postmortem	iD2		Ab: CF Ab: HA-I	As above As above	As above As above	
	iGer3	Many	Ab: FA	As above	As above	
	iD1	Many	Inclusions: cytol	Liver-fresh impression smear (fresh or refrigerated)	Presence of intranuclear inclusions supportive of diagnosis	
	iD1		Ag: IHC	Liver	Positive result confirms infection	
		Many	Ag: FA	Spleen, liver, brain (refrigerated)	Positive result confirms infection	
	iD1, iSw1	Many	Lesions: histol	Liver, gallbladder, kidney, lung, stomach, brain (formalin-fixed)	Compatible histologic changes and intranuclear inclusions indicate infection	
			MN1	IHC	Positive result indicates presence of disease	
Canine Herpesvirus Infection (5)						

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem	iA1, iSw1	Many	Virus: VI	Nasal swab, vaginal swab (refrigerated)	Positive result confirms infection	1149
	ilt3 iA1, iA2, iD2, iGer3, iSwi1, iSw1	Many KS1, AL2, NY1, IA1, TX2, KY2, ANT	Ag: FA Ab: VN	As above Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	As above Paired samples: rising (4-fold) titer confirms active infection; single titer interpretation only determines prior exposure	
Postmortem	iD2 iSwi1, iSw1	Many	Ab: IPT Virus: VI	As above Neonates: lung, liver, kidney, CNS (refrigerated)	As above Positive result confirms infection	1150
Canine Parainfluenza Infection (6)						
	iA2, iGer3	TX2, CO1, MO1, AZ3, TX1 IN1, IN2, LA1	Genome: PCR Ag: FA	Puppy/fetus, tissue (fresh or fixed) Brain, lymph node, liver, adrenal, kidney, spleen, lung (refrigerated)	As above As above	
		Many	Virus: VI	Transtracheal washing, oropharyngeal swab, CSF (refrigerated)	Positive result confirms infection	
		IN1, IN2, LA1	Ag: FA	Respiratory washing or tissue section (acetone fixed smears)	As above	
		NY1, IA1	Ab: VN	Serum or CSF (2–3 ml) (refrigerated)	Paired serum samples: rising (4-fold) titer confirms active infection; CSF-must show higher relative titer with antibody indexing	
	iSw1	OH2, IA1, CO1, IL1, GA1, GA2	Ab: HA-I Ab: FA	As above As above	As above As above	
Canine Calicivirus Infection (6)						
		Many	Virus: VI	Oropharyngeal swab, fecal swab, trachea, lung, kidney, intestine (refrigerated)	Positive result confirms infection	
Canine Parvovirus Infection (8)						

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem	iA2, iGer3	Many	Ab: HA-I	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Positive titers (level varies with lab) indicate protection; paired samples: rising (4-fold) titer confirms active infection; IgG titer usually increased by the time clinical signs are observed. As a single specimen, high serum IgM titer or fecal Ag examination is more diagnostic of active infection. HA-I and VN titers are considered protective above defined levels	
		Many	Ab: VN	As above	As above	
		Many	Ab: FA	As above	As above	
		Many	Ab: ELISA	As above	As above	
	iD2	Many	Ag: HA	Feces or intestinal mucosa (refrigerated)	Positive result confirms infection; clinical disease associated with shedding of large quantities of virus; some shedders are subclinical; false-negative result after 5–7 days clinical illness	
	iA2, iGer4, iSA1, iSw1, iSwi3	Many	Virus: EM	As above	As above	1150
		Many	Ag: FA	As above	As above	
	iA2, iD1, iD4, iIlt3, iGer3, iSwi1, iSw1 iA2	Many	Ag: ELISA	As above	As above	1151
		CO1, ANT, MO1, AZ3, NY3, MI1, ON3	Genome: PCR	As above	As above	
Postmortem		Many	Ag: FA	Small intestine, heart (neonatal) (refrigerated)	Positive result confirms infection	
		Many	Virus: VI	As above	As above	
	iD1, iGer4	WA1	Lesions: histol	Intestines (formalin-fixed)	As above	
		MN1	IHC	Intestines, heart (fresh or frozen)	As above	
Canine Coronavirus Infection (8)						

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem		NY1, KS1	Ab: VN	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Single high titer indicates exposure only; serum titer does not reflect degree of protection against infection. Paired samples: rising (4-fold) titer confirms infection	
	iD2		Ab: IPT	As above	As above	
	iA2	Many	Ab: FA	As above	As above	
	iD2	AZ3	Ag: ELISA	Feces (refrigerated)	Positive result confirms infection	
	iSwi3	NY1	Virus: VI	As above	As above	
	iGer4	IA1, OH2, WA1, IN1, IN2, LA1	Virus: EM	As above	As above	
	iA2	MO1, NY3, MI1, ON3	Genome: PCR	As above	As above	
Postmortem		Many	Ag: FA	Intestine (refrigerated)	As above	
	iD2	Many	Ag: ELISA	As above	As above	
		Many	Virus: VI	As above	As above	
		Many	Lesions: histol	Intestine (formalin-fixed)	Positive result confirms infection	
Canine and Feline Rotavirus Infection (8, 12)						
Antemortem	iSwi3		Virus: VI	Feces (fresh) (refrigerate)	Positive result confirms infection; some shedders may be subclinical carriers	
	iA2, iGer4	IA1, OH2, IN1, IN2, LA1	Virus: EM	As above	As above	
	iGer3, iSw1	IA1, PA3, SD1, IL2, IL3, KY1, LA1	Ag: ELISA	As above	As above	
Postmortem		Many	Ag: LA	As above	As above	
		OH2, TX2, IN1, IN2	Ag: FA	Intestine (refrigerated)	Positive result confirms infection	
		LA1	Virus: EM	Intestine (glutaraldehyde-fixed)	As above	
Canine Papillomatosis (9)						
		Many	Lesion: histol	Oral tissue (formalin-fixed, glutaraldehyde-fixed)	Positive result suggests infection	
	iGer4	Many	Virus: EM	As above	Positive indicates viral-induced tumor	1151
Feline Panleukopenia (10)						1152

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem	iGB1, iGB3	Many	Ab: FA, VN	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) titer confirms active infection. HA-I and VN titers are considered protective above defined levels
	iD2	CO1	Ab: ELISA	As above	As above
	iGer3	KS1, NY1, IL1, TX2, IDX	Ab: HA-I	As above	As above
	iGB1, iGB3, iGer4, iSwi3	IA1, CO1, IL1, IN1, IN2, TN1, WA1	Virus: VI	Feces (fresh) (refrigerated)	Positive result confirms infection; some shedders (usually lower levels) are subclinical carriers
	iD1, iGer3, ilt3, iSwi1, iSw1	Many	Ag: ELISA	As above	As above
	iGer3	GA1, GA2, OH2, LA1	Virus: EM	As above	As above
	iA2	CO1, MI1	Genome: PCR	As above	As above
	iD1	WA1	Lesions: histol	Intestine, mesenteric lymph nodes, lung, pharyngeal swab (fresh or refrigerated)	Positive result confirms infection
	iGer4	Many	Virus: VI	As above (fresh or refrigerated)	As above
	iA2	MO1, AZ3, NY3, ON3	Genome: PCR	As above (fresh or refrigerated)	As above
Postmortem	iGer3	LA1	Virus: EM	As above (glutaraldehyde fixation) (fresh or frozen)	As above
		MN1	IHC		As above
	Feline Infectious Peritonitis (11)				

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem	iA2, iIt3	Many	Ab: FA	Serum, fluid effusion (1–2 ml) (refrigerated)	Positive serum titer at lowest level of reactivity suggests exposure to FCoV; interpretation of higher titer values or high cut-off value must be based upon level of	1152
					titer with knowledge of exposure of population of cats in environment. Titters vary between labs such that sequential titers should always be done at the same laboratory. The FA titers have the most specificity	1153
		NY1, LA1	Ab: kinELISA	As above	Positive serum titer suggests exposure to FCoV; higher titer levels and knowledge of exposure population can help with diagnosis as with antibody testing by FA	
	iGer3, iSw1	Many	Ab: ELISA	As above	Positive serum titer at lowest level of reactivity suggests exposure to FCoV; interpretation of higher titer values or high cut-off value must be based upon level of titer with knowledge of exposure of population of cats in environment. Less specific than with FA methods	

Infectious Diseases of the Dog and Cat, 3rd Edition

Postmortem	iD3	Many	Ab: PE	As above	High absolute level of globulin and increase compared to albumin is highly suggestive of FIP
		ANT	Ab:7b (gene): ELISA Serum (0.5 ml) (refrigerated)		Positive titers range from 1:40 to 1:640 and indicate exposure to virus; positive cats should be isolated and retested in 4wks to determine if titer is declining, stable, or rising; vaccination will not interfere with results. Specificity of this titer and its ability to distinguish enteric coronaviral from FIP viral infections is controversial
		Many	Ag: FA	Liver, small intestine, kidney (refrigerated)	Positive result confirms infection with virus in extra-intestinal tissues making this test very specific for FIP
	iD1	Many	Lesions: histol	Kidney, liver, small intestine (formalin-fixed)	Compatible histologic changes indicate infection. Can do IHC to detect intralésional virus making this test very specific for FIP
		WA1, MN1	Ag: IHC	Effusion fluid, lymphoid tissue, tissue sample, plasma, CSF (fresh, refrigerated, fixed, or embedded)	Positive result confirms lesions associated with this virus
Feline Leukemia Virus Infection (13)					
	iA2, iGer3 iSA1, iSw1	CO2, AL2, MO1, ANT, CO1, NY3, MI1, IDX, ON3	Genome: PCR	Effusion fluid, lymphoid tissue, tissue sample, plasma, CSF (fresh, refrigerated, fixed, or embedded)	Positive result can be seen with enteric coronavirus infection via viral translocation from the gut. Therefore a positive result is nonspecific for FIP

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem		Many	Ag: FA	Blood film or buffy coat or bone marrow smear (air dried)	Positive result confirms infection and high virus titers that make this test result positive are usually seen in persistently viremic cats. Because of lower test sensitivity, this test is more specific for established bone marrow infections than ELISA methods	
	iD2, iGer3, iGB1, iGB3, iIt3	Many	Ag: ELISA	Serum or anticoagulated whole blood (1–2 ml) (fresh or refrigerated)	Positive result confirms infection; ELISA on blood or serum is more sensitive than direct FA; with saliva, false negative results have been reported	1153
			Ag: Kits (Appendix 6)	Saliva (fresh or refrigerated)	As above	1154
	iSw1		Ag: Rapid immunomigration	Blood or serum (fresh or refrigerated)	Positive result confirms infection as with ELISA method	
	iGB1, iGB3		Ag: VI	Blood (EDTA) (fresh or refrigerated)	Positive result confirms infection	
Postmortem or antemortem		Many	Ag: FA	Blood (heparinized) or tissue, marrow (fresh or refrigerated)	Positive result confirms infection	
		ANT, MO1, NY3, GA3, MI1, ON3	Viral genome: PCR	Lymphoid tissue or bone marrow, anticoagulated blood (refrigerated)	As above	
Feline Immunodeficiency Virus Infection (14)						
Antemortem or postmortem	iD2, iGer3, iGB1, iGB3, iIt3	Many	Ab: ELISA	Serum, anticoagulated whole blood (1–2 ml) (refrigerated)	Positive result confirms exposure and probable infection with virus	
		NY1	Ab: kinELISA	As above	As above	
	iSw1		Ab:	As above	As above	
		TN1, LA1, IDX	Ab: IgG IFA	As above	As above	
		NY1, IDX, NY3, ANT, IDX	Ab: immunoblot	As above	Used for confirmation of nonspecific reactions to the other test methods	
	iGB1, iGB3, iGer3	CO1, TN2, NY3, ON3	Virus: PCR	Lymphoid tissue, anticoagulated whole blood, bone marrow (refrigerated)	Positive result confirms infection	
Rhinotracheitis Virus Infection (16)						

Infectious Diseases of the Dog and Cat, 3rd Edition

	KS1	Ab: ELISA	Serum, anticoagulated whole blood (1–2 ml) (refrigerated)	Positive result confirms exposure and probable infection with virus; may be subclinical carriers
	TN1, TN2, IA1, KS1, WA1, NY3, LA1	Ab: FA	As above	Paired samples: rising (4-fold) titer confirms active infection
iD2, iGer3, iSw1	Many	Ab: VN	As above	Paired samples: rising (4-fold) titer confirms active infection
iGB1, iGB3, iGer4	Many	Virus: VI	Tissue or exudates (refrigerated)	Positive result indicates infection
iGB1, iGB3	Many	Virus: VI	Respiratory washing or tissues (refrigerated)	As above
iGer4	IL1, GA1, GA2	Virus: EM	Lung, trachea, conjunctival smears, feces, CSF, whole blood, body fluids (glutaraldehyde fixation)	As above
iGer3, iSwi1, iSwi3	AL5, CO1, MO1, LA1, IDX	Viral genome: PCR	As above (refrigerated, not fixed)	As above
	Many	Ag: FA	Smears of lung, liver, kidney, trachea (acetone fixed smears)	As above
	MN1	Ag: IHC	Lung, liver, kidney, trachea (fresh or frozen tissue)	As above
Feline Calicivirus Infection (16)				
Antemortem	IA1, KS1, TN1, TN2, NY3	Ab: FA	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) titer confirms active infection. A single high VN titer indicates protection
	iGB1, iGB3, iGer3, Sw1	Ab: VN	As above	As above
	iGB1, iGB3, Sw1	Virus: VI	Oropharyngeal swabs, intestinal and fecal swabs (refrigerated)	Positive result indicates infection
	TN2, ANT	Ag: FA	As above	As above
	iGer4	Virus: EM	As above	As above
Postmortem	iGB1, iGB3	Virus: VI	Trachea, lung, kidney, intestine (refrigerated)	As above
	CO1, CA1, NY3, MI1, ON3	Viral genome: PCR	As above	As above
Feline Foamy (Syncytium-Forming) Virus Infection (17)				
	NY1	SN: Titer	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) titer IgG or high IgM confirms active infection; >1:100 single VN titer indicates relative immune protection against disease
Feline Cowpox Infection (19)				

1154

1155

Infectious Diseases of the Dog and Cat, 3rd Edition

	Antemortem	iSw1	Many	Virus: EM	Scabs or lesions (dry, sterile vial), fluid (refrigerated)	Positive result confirms infection with Poxvirus	
		iGB1, iGB3 iGB1, iGB3		Virus: VI Ab: VN	As above Serum (2–3 ml) (refrigerated)	As above Positive titer confirms exposure but not necessarily active infection	
	Feline Papillomavirus Infections (20)						
	Antemortem		Many	Lesions: histol	Skin biopsies (formalin-fixed)	A histologic diagnosis suggestive	
			CA2, LA1	FA or IHC	Skin biopsies (fixed or embedded)	Positive staining indicates lesions due to papillomavirus infection	
	Rabies (22)						
		iAus1, iA1, iB1, iD2, iFr2, iGer1, iGer2, ilt1, ilt2, iSp1, iSw1	AL2, KS1, NY3, IDX, ON3	Ab: RFFIT	Serum (refrigerated)	Sufficient titer implies postvaccination immunization *MICROCHIP NUMBER AND VAX HISTORY REQUIRED AT TIME OF SUBMISSION	1155
			KS1	Ab: FAVN	Serum (refrigerated)	Sufficient titer implies postvaccination immunization *MICROCHIP NUMBER AND VAX HISTORY REQUIRED AT TIME OF SUBMISSION	
		iSA1	Many	Ab: VN	CSF (2–3 ml) (refrigerated)	High titer means CNS is infected (vaccine or virulent virus); takes 1–2wks to develop a titer and must compare to serum value	
	Postmortem	iA1, iB1, iD2, iFi1, iFr2, iGer1, iGer2, ilt1, ilt2, iSA1, iSp1, iSw1	Many	Ag: FA	Brain (refrigerated)	Positive result confirms infection; more sensitive than Negri body detection	1156
		Research iFi1, iSA1	Many	Ag: IHC Lesions: histol	As above Brain (formalin-fixed)	As above Negri bodies not present in all cases; false-positive and false-negative results can occur, IHC makes testing more specific and sensitive	
	Pseudorabies (23)						

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem	iD2	Many	Ab: VN	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Positive result indicates exposure; paired samples; rising (4-fold) titer confirms active infection
Postmortem	iD2, iSw1		Ab: ELISA	As above	As above
		LA1	Ab: LA	As above	As above
		Many	Ag: FA	Brain, tonsils, lung, cervical lymph nodes, salivary glands, spleen (refrigerated)	Positive result indicates infection
	iD2	Many	Virus: VI	As above	As above
		Many	Lesions: histol	Brain (formalin-fixed)	Compatible histologic changes and intranuclear inclusions suggest infection
Tick-Borne Encephalitis (26)					
Antemortem or postmortem	iA2, iGer3		Genome: PCR	CSF, brain tissue (acute cases only)	Positive result confirms infection
Ehrlichiosis, Anaplasmosis, and Neorickettsiosis (28)					
	iGer3	Many	Cells: cytol	Blood films, bone marrow smears (alcohol-fixed or refrigerated)	Positive result confirms infection; many false-negatives due to low numbers of organisms
		Many	Ab: PE	Serum (2–3 ml) (refrigerated)	Nonspecific polyclonal hyperglobulinemia (occasional monoclonal) seen with <i>Ehrlichia canis</i> infection and other persistent intracellular infections
	iAus1, iD3, iGer3, iIt3, iSwi2, iSwi3	ANT, AL2, MO1, TN2, TX2, GA3, TN1, TX1, FL3, PA1, MI1, LA1, NC1, IDX	Ab: FA <i>E. canis</i>	As above	Positive titer confirms active infection with <i>E. canis</i> ; however, animal must be infected for at least 30 days to have positive titer. Cross-reactivity with <i>E. chaffeensis</i> exists. See Chapter 28 and Table 28-3
		NY3, GA3, ON3	Ab: ELISA <i>E. canis</i>	As above	Positive titer indicates exposure or infection, must correlate with clinical signs. Cross-reactivity within genus members is possible. See Chapter 28 and Table 28-3

1156

Infectious Diseases of the Dog and Cat, 3rd Edition

	iGer3	LA1, IDX	Ab: <i>Anaplasma platys</i>	As above	As above	1157	
		MI1, LA1, IDX	Ab: <i>Neorickettsia risticii</i>	As above	As above		
	iD3, iGer3, ilt3, iSw1	LA1, IDX	Ab: <i>Anaplasma phagocytophilum</i>	As above	As above		
	iGB5, iGer3, iSwi3	NY1, AZ3, NY3, ANT, MI1, LA1, NC1, IDX	PCR: <i>E. canis</i>	Blood, EDTA anticoagulated (2–3 ml) (sterile, refrigerated)	Positive result indicates active infection with specific <i>Rickettsia</i>		
	iGB5, iGer3, iSwi3	ANT, LA1, NC1, TN2, NY1, CO1, IL1, MO1, FL3, ANT, LA1, IDX	PCR: <i>A. platys</i>	As above	As above		
			PCR: <i>N. risticii</i>	As above	As above		
	iGB5, iGer3, iSwi3	IL1, NY1, TN2, TX2, ANT, LA1, IDX	PCR: <i>A. phagocytophilum</i>	As above	As above		
		KS1, NC1	PCR: <i>E. chaffeensis</i>	As above	As above		
		KS1, NC1	PCR: <i>Ehrlichia ewingi</i>	As above	As above		
Rocky Mountain Spotted Fever (29)							
Postmortem or Antemortem	ilt3	AL2, NC1, TN2, TX2, ANT, TX1, FL3, NY3, GA3, PA1, MI1, LA1	Ab: FA-IgG	Serum paired samples (refrigerated)	Paired samples: rising (4-fold) IgG titer confirms active infection; species-specific testing required	1157	
	ilt3	AL2, NC1, TN2, TX2, ANT, TX1, FL3, GA3, PA1, MI1, LA1	Ab: FA-IgM	Serum: single sample taken 10–14 days apart (1–2 ml) (refrigerated)	Single positive IgM titer indicates active infection; a second titer may be needed to clarify some low titers		
		Many	Ab: LA	Serum: single sample (1–2 ml) (refrigerated)	Single positive latex titer indicates active infection since measures IgM		
		MO1, MI1, NC1, ANT	Genome: PCR	Anticoagulated whole blood, tissue	Positive result confirms active infection		
Q Fever (29)							
Postmortem or Antemortem		TX2	Ab: FA	Serum (2–3 ml) (refrigerated)	Acute: high phase II antibodies	1157	
	iGer3, iSA1	IA1, TX2, TX1, WI1	Ab: CF	As above	Chronic: high phase I lipopolysaccharide antibodies		
		NY1 WA1, CA2	Genome: PCR	Tissues (fresh or frozen)	Positive result confirms infection		
			Ag: IHC	As above	As above	1158	
Chlamydial Infection (30)							1158

Infectious Diseases of the Dog and Cat, 3rd Edition

iD3, iGer3, iSA1	NY1, IA1, WI1	Ab: CF	Serum (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) titer confirms active infection, single positive titer indicates exposure
	TX2, PA3, SD3, TN1, TN2, TX1, LA1	Ab: FA	As above	As above
iSwi2	MO1, OR1, TN2, ANT	Ab: ELISA	As above	As above
iGB1, iGB3, iSA1	NY1, FL3, OH2, TX2, MN1 IA1, WA1, MN1, NY3, IDX	<i>Chlamydia</i> : cult Ag: ELISA	Nasal and ocular swabs, lung (refrigerated) As above	Positive result confirms infection Positive result confirms infection; large numbers of organisms more indicative of active infection
iD3	CA2, AL2, TN1, GA1, GA2, LA1, TN2, KY2, OH2	Ag: FA	Conjunctival or tissue smear (refrigerated or air-dried in sterile container)	Positive result confirms infection; large numbers of organisms more indicative of active infection
	NE1, CA2	Ag: IHC	Tissue (formalin-fixed)	Positive result confirms infection
iGer3	NE1, NY1, MO1, IN1, IN2, CO1, KS1, TX2, AZ3, NY3, WY1, LA1, IDX, ON3	Genome: PCR	Blood or tissue sample (fresh, formalin-fixed or refrigerated)	As above
Hemotropic Mycoplasmosis (Hemobartonellosis) (31)				
iD1, iGer3	Many	Organism: cytol	Blood films (unstained and unfixed)	Positive result confirms infection; stained artifacts must be viewed cautiously
	AL2, CO1, IL1, KS1, MO1, NE1, TX2, CO3, MI1, PA1, NY3, IDX	Ag: FA	As above	Positive result confirms infection without risk of false-positives due to stain artifact
iGB1, iGB3, iGer3	CO1, CO3, ON3	Genome: PCR	Blood, EDTA anticoagulated, (refrigerated)	Positive result confirms active infection and determines which strain is involved
Mycoplasma Infection (32)				
iD3, iSA1, iSw1	Many	Mycoplasma: cult	Nasal swab, trachea (refrigerated)	Positive result confirms infection; many infections are subclinical since part of resident microflora
	NY3, TX1, ON3	Genome: PCR	1 ml serum or sterile swab (refrigerated)	Positive result confirms infection
BACTERIAL INFECTIONS (33)				
Gram-Negative Bacterial Infections (37)				

1158

1159

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem		Many	Verotoxin (Shiga-like toxins): for enterohemorrhagic strains	Feces: fresh fecal material (refrigerated)	Positive result with specific antisera neutralization of toxin confirms pathogenic strain	
		SD1	LT toxin: enterotoxigenic strains	As above	As above	
	iD3, iSA1	NY1, TX2, TX1, WY1, NY3 KY2, FL3, SD1, MN1	Bacteria (O157: A7): cult, PCR Pili Ag: FA	Feces, foods, tissues Fecal smears (refrigerated)	Positive result confirms pathogenic strain Positive result with fluorescence	
			PCR: Pillus Ag and toxin ID	Feces, tissues (refrigerated)	Positive result confirms infection with pathogenic strain	
		KS1 NY1, IL1, KS1, NE1, PA3, IN1, IN2	Pili Ag: ELISA Culture and Genotyping: DNA Probe	As above As above	As above As above	
Postmortem		Many	Lesions: histol for attaching an effacing strain	Intestinal sections (fresh (refrigerated) or formalin fixed)	Bacterial attachment with associated pathologic changes characteristic for a presumptive diagnosis	
Salmonellosis (39)						
	iD3, iSA1, iSwi3	Many	Bacteria: cult	Feces or fecal swab (3g) (fresh or refrigerated)	Positive result confirms active infection; may be subclinical carrier	
	iD3, iSA1, iSwi3	Many	Bacteria: cult	Blood (1–2 ml), internal tissues (collect sterilely, transport blood in blood culture broth media)	Positive result confirms clinically significant bacteremic or systemic infection	
	iD3, iSA1, iSwi3	Many	Bacteria: cult	Intestinal lymph nodes, spleen, many internal organs other than intestine (refrigerated)	Positive result confirms active systemic infection	
	iD1	Many	Bacteria: cult	Entire animal (fresh or refrigerated)	As above	
		IN1, IN2, MO1, KS1, TX2, IL1, CO1, FL3, GA1, NY3, TX1, LA1, MN1	Genome: PCR IHC	Intestine, colon, lymph node, lung, spleen (fresh or frozen) As above	Positive result confirms infection As above	1159
Campylobacteriosis/Helicobacteriosis (39)						
	iSA1, iSwi3	Many	Bacteria: cult	Gastric biopsy material in sterile screw cap with saline or feces (2–3g, fresh, in sterile airtight container; add thioglycolate medium) (see sample needed)	Positive result confirms infection; may be subclinical carrier	1160
		Many	Lesions: histol	Intestine, colon, lymph node, lung, spleen (formalin fixed)	Compatible histologic changes indicate infection	
		IL1, TX1, NY3	Genome: PCR	1 ml EDTA whole blood or feces (refrigerated)	Positive result indicates infection	
Clostridium perfringens Infection (39)						

Infectious Diseases of the Dog and Cat, 3rd Edition

Brucellosis (40) Antemortem or postmortem		OR1, AZ2, NY3, ON3	Toxin: RPLA toxin A assay	Feces or loops of intestine (2–3 ml) (refrigerated)	Positive result confirms organism is producing toxins associated with clinical illnesses	1160
	iSA1	IN1, IN2, TX2, IA1, CO1, NY1, TX1 IL1, PA3, WY1, WI1, MN1, AZ2	Genome: PCR Toxin Typing: PCR	Isolated organism (culture material) Feces or intestine (refrigerated)	Positive result confirms species of organisms Positive result confirms organism is producing toxins associated with clinical illnesses	
		NY1, CO1 SD1, NE1 IDX	Toxin: LA Toxin Typing: cult Toxin Typing: ELISA	As above As above As above	As above As above As above	
	iAus1, iD3, iGer3, iLt3, iSA1, iSwi2	Many	Ab: SAT	Serum: single sample (2–3 ml) (refrigerated until sent)	Screening test for infection, false positive with other bacterial infection. Follow a positive result with serologic testing	
	iSwi2	Many	Ab: TAT	As above	Titer of >1:50 suspicious; >1:100 positive; >1:200 usually bacteremic; some false-negative and false-positive results; do AGID or culture (if positive) for confirmation	
		TX2, GA1, LA1, IDX	Ab: FA	As above	Has been used for screening to substitute for agglutination testing (see previously). Positive result may be confirmed by AGID and culture	
		KS1, NY1, GA2, ANT, IDX	Ab: AGID	As above	May detect rare seronegatives, more specific test; use to check SAT and TAT positives	
		IA1, ND1	Ab: ELISA	As above	More sensitive and less specific than agglutination tests	
	iSA1, iSwi2	TN1, LA1	Bacteria: cult	Anticoagulated blood (5–10 ml) (heparinized, refrigerated)	Positive result confirms bacteremia; negative is uncertain	
	iD3, iSA1, iSwi2	TN1, LA1	Bacteria: cult	Tissue, fetus, testicles, placenta, semen, genital swabs (refrigerated)	Positive result confirms infection; negative is uncertain	
Anaerobic Infections (41)		NY3, ON3	Genome: PCR	Tissue, fetus, testicles, placenta, semen, genital swabs (refrigerated)	Positive result confirms infection	1161

Infectious Diseases of the Dog and Cat, 3rd Edition

		Many	Bacteria: cult	Lesion exudates (refrigerated in airtight or anaerobic transport system)	Positive result confirms infection but usually are contaminants of wounds from penetrating tissue injuries
Botulism (42)					
	iD3, iSA1		Toxin analysis	Feces, blood, serum, intestinal contents (5 ml) (refrigerated)	Test performed with and without specific antisera for confirmation of toxin type involved
Leptospirosis (44)					
Antemortem	iAus1, iD3, iGer3, iSA1, iSwi2	Many	Ab: MA	Serum: paired samples taken 2–3wks apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) titer confirms active infection; single positive titer $\geq 1:400$ confirms past exposure in nonvaccinate; lower or equivalent titers associated with vaccination; titer $= 1:800$ by itself, or changing 4-fold titers over 2–3wks, suggests recent or active infection
		ANT	Ab: LA	Serum (refrigerated)	Titer $\geq 1:250$ suggests recent or current infection; negative result does not rule out disease, vaccination can cause positive titers
	iSA1	Many	Spirochetes	Urine (1–2 ml) (refrigerated)	Positive result suggests infection; nonpathogenic spirochetes and artifacts make unreliable
	iSA1	Many	Spirochetes: cult	1 ml serum (refrigerated)	Positive result confirms infection
		Many	Ag: FA	Tissue or body fluids (In transport media)	As above
		Many	Spirochetes: histol	Tissue: kidney, fetal fluid, placenta, or urine (refrigerated)	As above
	iGer3, iSA1	NE1, KS1, MO1, TX2, IN1, IN2, NY3, TX1, ON3	Genome: PCR	Tissue (kidney), urine (refrigerated)	Positive result suggests infection; nonpathogenic spirochetes and artifacts make unreliable
		NE1, WA1, WI1, MN1	Ag: IHC	Tissue (formalin fixed)	Positive result confirms infection
Lyme Borreliosis (45)					

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem	iD1, ilt3, iSw1, iSwi2	Many	Ab: FA	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) IgG titer confirms active infection with <i>Borrelia</i> spp.	
	iGer3	Many	Ab: ELISA-IgG	As above	As above	1161
	iGer3	NY1, TN2, CT1, MI1, NY3, IDX, ON3	Ab: Immunoblot IgG	As above	Helps distinguish other spirochetal infections and vaccine responses from tissue exposure or infection	1162
	iGer3		Ab: ELISA-IgM	As above	Single high IgM titer confirms recent or active infection with <i>Borrelia</i> spp., although IgM from other spirochetal infections such as <i>Leptospira</i> may cause some cross-reactivity	
	iGer3	NY1	Ab: immunoblot IgM	As above	Specific reactivity can help determine whether natural infection, vaccine exposure, or cross-reactive antibodies exist	
	iGB5, iGer3, iSwi3	NY1, MO1, PA3, MI1, NY3, MN1	Genome: PCR	Blood, anticoagulated, tissue, joint fluid (2–3 ml) (refrigerated)	Positive result confirms infection	
Postmortem		Many	Ag: IHC, FA	Tissue (formalin fixed)	Positive result confirms infection	
Feline Lyme Borreliosis (45)						
Antemortem		LA1	Ab: FA	Serum taken 10–14 days apart (0.5 ml) (refrigerated)	Paired samples: rising (4-fold) IgG titer suggests active infection with <i>Borrelia</i> spp	
	iGer3		Ab: immunoblot	Serum (0.5 ml) (refrigerated)	Positive result helps distinguish true seroreactivity to <i>B. burgdorferi</i> from that with other spirochetes	
	iGB5, iGer3, iSwi3		Genome: PCR	Blood, anticoagulated, or body fluid (0.5 ml), or tissue (refrigerated)	Positive result confirms infection	
		ANT	Ab: ELISA (IgG)	1 ml serum (refrigerated)	titer $\geq 1:64$ suggest exposure or active infection; borderline results should be retested in 3–4wks, vaccination can cause positive titer	
Postmortem		Many	Ag: IHC, FA	Tissue (formalin-fixed, embedded)	Positive result confirms infection	
Plague (47)						

Infectious Diseases of the Dog and Cat, 3rd Edition

Postmortem or antemortem		WY1, NM1	Ab: passive HA	Serum (2–3 ml) (refrigerated)	Positive result confirms exposure; rising (4-fold) titer confirms active infection	1162	
		Many	Ag: FA	Blood, sputum, fluid, or tissue smears, exudates (2–3 ml) (shipped with biohazard precautions, refrigerated)	Positive result confirms infection		
		Many	Bacteria: cult	Exudates (swabs, sputum, fluid) tissue, blood (shipped with biohazard precautions, refrigerated)	As above		
		WY1	Genome: PCR	Tissues or body fluids (refrigerated)	As above		
	Tularemia (48)						
Antemortem		IA1, KY1, WY1, NM1	Ab: MA	Serum: paired specimens taken 2–3wks apart (2–3 ml) (refrigerated)	Positive result confirms exposure; rising (4-fold) titer confirms active infection	1163	
Nocardiosis (49)		LA1	Bacteria: cult	Swab or exudate (on ice) or tissue (exudate on ice)	Positive result confirms infection	1163	
		WY1	Genome: PCR	As above	As above		
	Antemortem	iSw1	Many	Bacteria: cult	Peritoneal, pleural, and pericardial fluid (refrigerated)		Positive result confirms infection
	Mycobacteriosis (50)						
		iD3, iSA1, iSw1	Many	Bacteria: cult	Tissue specimen or exudates (fresh or frozen)		Positive result confirms infection
		iD3	Many	Lesions: histol	Tissue (formalin fixed)	Finding acid-fast bacteria must be combined with bacterial culture for determining organism involved	
Feline Bartonellosis (54)							
Antemortem	Many	Many	Bacteria: cult	Blood, EDTA, anticoagulated (aseptically collected)	Positive result confirms infection		
	iGB5, iSwi3	IN1, IN2, AL2, NY3, ANT, LA1, ON3 NC1, TX2, CA3, TX1, LA1, IDX	Genome: PCR	As above	As above		
			Ab: FA	Serum, free of hemolysis (refrigerated)	Positive result indicates present or past exposure, useful for epidemiologic monitoring. Some bacteremic animals can be seronegative		
Canine Bartonellosis (54)							

Infectious Diseases of the Dog and Cat, 3rd Edition

	NC1	Ab: FA	Blood or serum (refrigerated)	Positive result indicates exposure	
	Many	Bacteria: cult	Blood, EDTA, anticoagulated or material from culture plate (aseptically collected)	Positive result confirms infection	
iGB5	AL2, ANT, LA1, NC1, CO3	Genome PCR	As above	As above	
FUNGAL INFECTIONS (56)					
Fungal Identification and Susceptibility Testing (56)					
iSA1, iSwi3	Many	Fungus: cult	Tissue, exudate, or body fluid (refrigerated)	Confirms infection	
	NY1, IL1, KS1	Susceptibility: antifungal susceptibility testing	Organism from animal is isolated on fungal medium	Determines susceptibility to drugs, which may not always correlate with in vivo efficacy	
	ANT	Drug: antifungal drug concentrations	Serum, body fluids, or tissues (refrigerated)	Determines achieved concentrations of antifungal drug	1163
Dermatophytosis (58)					
iD1, iD3, iSA1, iSw1, iSwi3	Many	Fungus: cult	Lesion (scabs or plucked hairs) (sterile, dry tubes)	Positive result confirms infection; some cats may be subclinical carriers	1164
Blastomycosis (59) or Histoplasmosis (60)					
Antemortem or postmortem	Many	Ab: CF	Serum: single sample (2–3 ml) (refrigerated)	Positive result confirms exposure but not necessarily active infection	
	Many	Ab: AGID	As above	As above	
	Many	Fungus: cult	Tissues or fluid aspirates (1–2 ml) (sterile container)	Positive result confirms infection	
	Many	Fungus: cytol	As above	As above	
	Many	Lesions: histol	Tissue biopsy (formalin fixed)	As above	
	IN3	Ag: ELISA	2 ml serum, separated from clot; urine, plasma, CSF, bronchial fluid, sterile body fluids (ambient temp or refrigerated)	Positive result confirms disease, some cross reaction with other fungal antigens	
Cryptococcosis (61)					

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem or postmortem		ANT, TN2, LA1	Ag: ELISA	Serum or CSF: single sample (1–2 ml) (sterile, container refrigerated)	Positive result confirms active infection. Level can be used to monitor treatment
		TX2, MO1, CO1, KS1, GA1, TN1, PA1, GA3, FL3, LA1, IDX	Ag: LA	As above	As above
	iSw1	Many	Fungus: cult	Tissue or fluid aspirate (sterile container, refrigerated)	Positive result confirms infection
	iSw1	Many	Fungus: cytol Ag: FA	Tissue or fluid aspirate on smear Tissue (sterile container, refrigerated)	As above As above
Coccidioidomycosis (62)					
Antemortem or postmortem		Many	Ab: ELISA	Serum: single or paired samples (2–3 ml) (refrigerated)	See Table 62-1 for interpretation
		Many TX2, CA1 CA1	Ab: AGID	As above	As above
			Ab: CF Ab: FA	As above As above	As above As above
		Many	Fungus: cult	Tissue or fluid aspirate (1–2 ml) (refrigerated)	Positive result confirms infection
Sporotrichosis (63)		Many	Fungus: cytol	Tissue (refrigerated)	As above
		Many	Fungus: cytol	Exudate from lymphatics (1–2 ml) (refrigerated)	Positive result confirms infection
		IN1, IN2, LA1	Fungus: cult	As above	As above
Aspergillosis (64)					
		PA1	Ab: ELISA	Serum: single sample (2–3 ml) (refrigerated)	Positive result confirms exposure but not necessarily active infection
		Many	Ab: AGID	As above	As above
		Many	Ab: CF	As above	As above
	iSw1, iGer3	Many	Fungus: cult	Tissue or exudates (refrigerated)	Positive result confirms infection; can be a contaminant. Histopathologic lesions in association with fungus help with confirmation
		IN3	Ag: ELISA	2 ml serum, separated from clot (refrigerated)	Positive result confirms disease
Candidiasis (65)					
	iSw1	Many	Fungus: cult	Blood or tissue (refrigerated)	Positive result of deeper tissues or body fluids confirms disseminated infection in association with microscopic lesions
Pythium, Lagenidium, and Zygomycete Infections (67)					

1164

1165

Infectious Diseases of the Dog and Cat, 3rd Edition

Pneumocystosis (68)	LA2	ELISA or WB	Serum (fresh or refrigerated)	Positive result indicates exposure or infection
	LA2	Culture	Tissue (fresh or refrigerated [<36 hr])	Positive result confirms infection
	LA2	IHC	Tissue (paraffin blocks)	As above
	LA2	Genome: PCR	Cultured organisms (In media at ambient temp.)	As above
	Many	Protozoa: cytol	Sputum, lung aspirates (refrigerated)	Positive result suggest infection; difficult-to-find and numerous artifacts make visualization difficult
	Many	Ag: FA	As above	Positive result confirms infection
Protothecosis (see Diagnosis, Chapter 69)				
PROTOZOAL INFECTIONS (70)				
Trypanosomiasis (72)				
Leishmaniasis (73)	TX2	Ab: FA	Serum (refrigerated)	Positive result makes infection likely in animal with compatible signs; infection usually persists
	Many	Protozoa: cytol	Blood film (thick and thin)	Positive result confirms infection
	iGer3, ilt3, iSwi3	NC1, CO3, TX2, TX1, MI1	Ab: FA	Serum or dried blood spots (on filter paper)
	iN2 iGer3	Many	Ab: ELISA (Dog-Cat) Protozoa: cytol	Serum (refrigerated) Lymph node aspirate (fixed in methanol, stained with Giemsa)
				Positive result makes infection likely in animal with compatible signs; infection usually persists
				As above
				Amastigote I smear confirms infection
Hepatozoonosis (74)	NY1, NY3, ON3	Ag: ELISA	Serum (refrigerated)	Positive titer seen with moderate or heavy infections
	iGB5, iGer3	NC1	Genome: PCR	EDTA blood, tissue (refrigerated)
	NY1	Western Blot	Serum (refrigerated)	As above
	Many	Protozoa: cytol	Blood film (air dried smear)	Positive result confirms infection
	Many	Protozoa: histol	Tissues; muscle biopsy (refrigerated or formalin fixed)	As above
Microsporidiosis (Encephalitozoonosis) (see Diagnosis, Chapter 5)				
Cytauxzoonosis (76)				
	Many	Protozoa: cytol	Blood films, bone marrow (air dried smear)	Positive result confirms infection; may be uncommon in peripheral blood films
Babesiosis (77)				

Infectious Diseases of the Dog and Cat, 3rd Edition

	iSA1, iGer3	Many	Protozoa: cytol	Blood film (air dried smear)	Positive result confirms infection; may be uncommon in peripheral blood films	
	iGB5, iGer3	AL2, NC1, NY3, ON3	Genome: PCR	EDTA-whole blood and ticks	Positive result confirms infection; also may be used to determine infecting species	
	iGer3, ilt3, iSwi3	TN2, IL1, IA1, NC1, TX2, TX1, NY3, FL3, PA1, MI1, ANT, LA1, IDX, ON3	Ab: FA	Serum: single sample (2–3 ml) (refrigerated)	Positive titer > 1:40 indicates active or very recent infection. Some variation in titers exists among laboratories	
		IA1	Ab: CF	As above	As above	
Enteric Protozoal Infections (78)						
	Many	Many	Protozoa: flotation, sedimentation	Feces (refrigerated)	Positive result indicates infection; may be subclinical carrier	
		Many	Protozoa: fecal smears, wet mounts	As above	As above	
	Many	ANT, CO1, NY1, SD1, TN2, NY3, MT1, MT2, WY1, UT1, LA1, IDX, ON3	<i>Giardia</i> Ag: ELISA	Feces (refrigerated)	Positive result confirms infection	
	Many	Many	<i>Giardia</i> Ag: FA	As above	As above	
		NC1, NY3, ON3	Genome: PCR <i>Tritrichomonas foetus</i>	Feces (2–3 ml) (refrigerated)	Positive result confirms infection when fecal exam has detected suspicious organism	1166
Toxoplasmosis (80)						1167

Infectious Diseases of the Dog and Cat, 3rd Edition

	Many	Ab: HA-I	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) IgG titer confirms active infection; single positive titer is nonspecific
iGer3, ilt3	Many	Ab: IFA-IgG Ab: CF	As above As above	As above As above
	Many	Ab: ELISA-IgG	As above	As above
	NY1	Ab: kinELISA	As above	As above
	Many	Ab: ELISA-IgM	Serum: single sample (2–3 ml) (refrigerated)	A single high IgM or agglutination (LA) titer indicates active or recent infection; evaluation of IgG and IgM simultaneously is more informative
iGer3, ilt3	TN2, TX2, FL3, MI1, LA1, IDX	Ab: FA-IgM	As above	As above
iSw1	IA1, KS1, GA1, CA2, MN1, WI1, WY1, LA1	Ab: LA	As above	As above
iGer3, iSw1	Many	Oocysts: flotation	Feces (cat only) (refrigerated)	Oocyst identification is positive, although inoculation into intermediate host is often needed to confirm exact species
	Many	Histol	Tissue biopsy (lung, brain, lymphoid, liver, kidney) (formalin fixed)	Positive for infection; if detected, clinical significance must be determined
iSw1	IA1, OH2, PA3, WA1, CA2, ND1, MN1	IHC	As above	As above
	MO1, ANT	Genome: PCR	Tissue or body fluids (refrigerated)	Positive result indicates infection; may be subclinical carrier

Neosporosis (80)

Infectious Diseases of the Dog and Cat, 3rd Edition

	iD3, iLt3, iGer3, iSw1	TN1, TN2, OH2, OR1, PA3, SD1, TX2, WI1, MI1	Ab: IFA	Serum: paired samples taken 10–14 days apart (2–3 ml) (refrigerated)	Paired samples: rising (4-fold) IgG titer confirms active infection; single high positive titer, as defined by the respective laboratory, indicates previous exposure	
	iSw1	CA2, MO1, CO, IL1, OH2, TX2, WI1, ND1, NY3, UT1, ON3	Ab: ELISA	As above	As above	
	iSw1	OH2, GA1, GA2, TN1, WY1, LA1	Ag: FA	Tissue biopsy (brain, kidney, liver, muscle, skin) (formalin fixed or refrigerated)	Positive result confirms infection	
	iSw1	CA2, OH2, CO1, IA1, PA3, WA1, ND1, MN1	IHC	Tissue (formalin fixed)	As above	
	iSw1	IN1, IN2, UT1	PCR	Tissue	As above	1167
Coccidiosis (81)	Many	Many	Oocysts: flotation	Feces (refrigerated)	Oocyst identification is positive	1168
Cryptosporidiosis (82)	iD3	Many	Oocysts: float	Feces (refrigerated)	Oocyst identification is positive	
		ANT, AZ3, OH2, TN2, TX2, CT1, IL2, IL3, NC2, MN2, MN1	Ag: FA	Feces (2–3g) (in 10% formalin)	Positive result confirms infection	
	Many	NY1, IL2, IL3, NY3, IDX, ON3	Ag: ELISA	As above	As above	
		MI1	Genome: PCR	Feces or intestine (refrigerated)	As above	
Immunodeficiency Testing (95)		ANT, NY1, TX2, IL1, CA1, CO1, WA2, PA2, TN2, IN1, TX1, IDX	IgG: radial diffusion	Serum (3–5 ml) (refrigerated)	Low immunoglobulin concentration reflects humoral immunodeficiency	
		ANT, NY1, TX2, IL1, CA1, CO1, WA2, PA2, TX1, IDX	IgM: radial diffusion	As above	As above	
		ANT, NY1, TX2, IL1, CA1, CO1, WA2, PA2, TN2, TX1, IDX	IgA: radial diffusion	As above	As above	
	<i>Leukocyte adhesion deficiency (LAD)</i> iB2		PCR	EDTA sample (refrigerated)	Neutrophil adhesion defect in cell culture	

Infectious Diseases of the Dog and Cat, 3rd Edition

Ab, Antibody; *Ag*, antigen; *AGID*, agar gel immunodiffusion; *CF*, complement fixation; *CNS*, central nervous system; *CSF*, cerebrospinal fluid; *Cult*, culture; *Cytol*, cytology; *EDTA*, ethylenediaminetetraacetic acid; *ELISA*, enzyme-linked immunosorbent assay; *EM*, electron microscopy; *FA*, fluorescent antibody; *FAVN*, fluorescent antibody virus neutralization; *FCoV*, feline corona-virus; *FIP*, feline infectious peritonitis; *HA*, hemagglutination; *HA-I*, hemagglutination inhibition; *histol*, histopathology; *IHC*, immunohistochemistry; *IPT*, immunoprecipitin test; *kinELISA*, kinetic ELISA; *LA*, latex agglutination; *LT*, heat labile; *MA*, microscopic agglutination; *PCR*, polymerase chain reaction; *PE*, protein electrophoresis (serum); *RFFIT*, rapid fluorescent focus inhibition test; *RPLA*, reverse passive latex agglutination; *SAT*, slide agglutination test; *SN*, serum neutralization; *TAT*, tube agglutination test; *VI*, viral inhibition; *VN*, viral neutralization; *WB*, western blot.

Part B: Test Kits Commercially Available for Infectious Diseases

DISEASE (CHAPTER)	KIT NUMBER	NAME OF TEST AND ORGANISM	SPECIES	SPECIMEN TESTED	TYPE OF TEST
VIRAL INFECTIONS (SEE ALSO Chapter 1)					
Canine Distemper					
3	K2	ImmunoComb Canine Distemper (IgM and IgG Kits)	D	Serum, blood, CSF	Ab: ELISA
3	K21	TiterCHECK CDV/CPVD		Serum, plasma	Ab: ELISA
3	K7	Canine Distemper Virus	D	Serum	Ab: FA
3	K16	RapiGEN Distemper Ag TEST	D	Serum, plasma	Ag: Lateral flow assay
3	K14	FASTest DISTEMPER Strip	D	Body fluids	Ag: comp to RT-PCR
Canine and Feline Enteric Viral Infections					
8	K2	ImmunoComb Canine Parvovirus	D	Serum	Ab: ELISA
8, 10	K5	Rapid PARVO Dipstick	D, C, M	Feces	Ag: Latex One Step
8	K14	FASTest CPV Ab	D	feces	Ab: H-I
8,10	K14	FASTest PARVO Card	D, C, M	Feces	Ag: ELISA
	K14	FASTest PARVO Pen	D, C, M	Feces	Ag: ELISA
	K14	FASTest PARVO Strip	D, C, M	Feces	Ag: ELISA
8	K7	Canine Parvovirus	D	Feces	Ag: ELISA
8	K10	SNAP Parvo	D	Feces	Ag: ELISA
8, 10	K20	Svanodip	D, C	Feces	Ag: ELISA
10	K19	Parvovirus	C	Feces	Ag: ELISA
8	K21	Assure Parvovirus	D	Feces	Ag: ELISA
8, 10	K6	Canine/Feline Parvo One Step	D, C	Feces	Ag: ELISA
8	K21	Witness CPV	D	Feces	Ag: Rapid immunomigration- stat
8	K1	AGEN Parvo Ag Test	D	Feces	Ag: RIM (Rapid Immunomigration)
8	K2	ImmunoComb Canine Distemper & Parvovirus (IgM & IgG Kits)	D	Serum, blood	Ab: ELISA
10	K21	TiterCHECK CDV/CPVC		Serum, plasma	Ab: ELISA
8, 10	K14	FASTest Rota Strip	D, C	Feces	Ag: ELISA
8, 10	K15	Immunocard STAT! Rotavirus	H (D, C)a	Feces	Ag: ELISA
8, 10	K17	ProSpecT Rotavirus	H (D, C)	C) Feces	Ag: ELISA; available outside US only
8, 10	K15	MERITEC-RotavirusH	(D, C)	Feces	Ag: LA
8, 10	K23	Virogen Rotatest	H (D, C)	Feces	Ag: LA
8, 10	K17	Rotavirus (REF 30950401)	H (D, C)	Feces	Ag: Rapid latex agglutination
8, 10	K15	Immunocard STAT Rotavirus	H (D, C)	Feces	Ag: Immunochromatography
Feline Panleukopenia					
10	K7	Feline Panleukopenia C		Serum	Ag: ELISA

1170

1171

Infectious Diseases of the Dog and Cat, 3rd Edition

Feline Infectious Peritonitis					
11	K21	ViraChek CV	C	Serum, plasma	Ab: ELISA
11	K2	ImmunoComb Feline Coronavirus Antibody test (FIP)	C	Serum, blood	Ab: ELISA
11	K7	Feline Infectious Peritonitis	C	Serum	Ab: FA
11	K14	FASTest FIP	C	Blood, plasma, serum	Ab: Immunoassay
Feline Retroviral Infections					
13	K1	AGEN FeLV test	C	Serum, plasma, whole blood	Ab: Immunochromatography
13	K14	FASTest FeLV	C	Serum, plasma (anticoagulated whole blood for screening only)	Ag: ELISA
13	K21	ViraCheck FeLV	C	Serum, plasma, anticoagulated whole blood	Ag: ELISA
13	K10	SNAP FeLV	C	Serum, plasma, whole blood	Ag: ELISA
13	K21	Assure FeLV	C	Saliva, whole blood, anticoagulated plasma, serum	Ag: ELISA
13	K21	Witness FeLV	C	Serum, plasma, anticoagulated whole blood	Ag: Rapid immunomigration-stat
13	K5	FeLV Dipstick	C	Serum, plasma, whole blood	Ag: Immunochromatography
13, 14	K10	Snap FeLV/FIV	C	Serum, plasma, whole blood	Ag-Ab: ELISA
13, 14	K5	Combo FIV/FeLV Dipstick	C	Serum, plasma, whole blood	Ag-Ab: Immunochromatography
13, 14	K21	Witness FeLV/FIV	C	Serum, plasma, anticoagulated whole blood	Ag: Rapid immunomigration-stat
14	K5	FIV Dipstick	C	Serum, plasma, whole blood	Ab: Immunochromatography
14	K21	Witness FIV	C	Serum, plasma, anticoagulated whole blooe	Ag: Rapid immunomigration-stat
14	K14	FASTest FIV Labcard	C	Serum, plasma, whole blood	Ab: Immunochromatography
14	K1	AGEN FIV test	C	Serum, plasma, whole blood	Ab: Immunochromatography
14	K14	FASTest FIV	C	Serum, plasma, whole blood	Ab: Immunochromatography
14	K21	ViraChek FIV	C	Serum, plasma	Ab: ELISA
Feline Calicivirus Infection					
16	K7	Calicivirus	C	Serum	Ab: FA
RICKETTSIAL, CHLAMYDIAL AND MYCOPLASMAL INFECTIONS (SEE ALSO Chapter 1)					
28	K9	<i>Ehrlichia canis</i>	D	Serum	Ab: ELISA
28	K2	Immunocomb <i>Ehrlichia canis</i> (Immunocomb Ab test for Canine Ehrlichiosis)	D	Serum, blood	Ab: ELISA
28	K7	<i>Ehrlichia</i>	D	Serum	Ab: FA

1171

1172

Infectious Diseases of the Dog and Cat, 3rd Edition

28	K14	FasTest Canine <i>Ehrlichia canis</i>	D	Serum, plasma, whole blood	Ab: Immunoassay
29	K9	<i>Rickettsia rickettsii</i>	D	Serum	Ab: ELISA
29	K7	<i>Rickettsia rickettsii</i>	D	Serum	Ab: FA
29	K9	<i>Rickettsia conorii</i>	D	Serum	Ab: ELISA
29	K7	<i>Rickettsia conorii</i>	D	Serum	Ab: FA
29	K7	<i>Rickettsia akari</i>	C	Serum	Ab: FA
29	K7	<i>Rickettsia felis</i>	C	Serum	Ab: FA
29	K7	<i>Coxiella burnetii</i> (Q-fever)	D	Serum	Ab: FA
31	K2	ImmunoComb Feline Toxo & <i>Chlamydomphila</i>	C	Serum, blood	Ab: ELISA
31	K7	<i>Chlamydomphila</i> <i>psittaci</i>	C	Serum	Ab: FA
31	K4	<i>Chlamydia</i> CELISA	D, C	Feces	Ag: ELISA
31	K23	Clearview <i>Chlamydia</i>	H (D, C)	Secretions	Ag: ELISA
31	K15	Premier <i>Chlamydia</i>	H (D, C)	Secretions	Ag: ELISA
31	K15	Meriflour <i>Chlamydia</i>	H (D, C)	Secretions	Ag: ELISA
28, 45	K10	Canine Snap 3DX Test Heartworm, Lyme, <i>Ehrlichia canis</i>	D	Serum, plasma	Ab: Immunoassay for <i>E. canis</i> , Ab: ELISA for Lyme; Ag: heartworm
BACTERIAL INFECTIONS (SEE ALSO Chapter 33)					
39	K13	CLOtest		Tissue biopsy	Colorimetric
	K9	C-Reactive Protein	D	Serum	Protein: ELISA
40	K21	D-TEC-CB (<i>Brucella canis</i>)	D	Serum	Ab: RSAT
40	K7	Canine <i>Brucella</i>	D	Serum	Ab: FA
44	K7	<i>Leptospira</i> IFA	D	Serum	Ab: FA
44	K2	Immunocomb Antibody test for canine leptosporosis	D	Serum, blood	Ab: Enzyme immunoassay
45, 28	K10	Canine Snap 3DX Test Heartworm, Lyme, <i>Ehrlichia canis</i>	D	Serum, plasma	Ag for heartworm, Ab for <i>E. canis</i> (immunoassay), Ab: ELISA for Lyme
45	K7	<i>Borrelia burgdorferi</i>	D	Serum	Ab: FA
45	K14	FASTestLyme	D	Serum, plasma, blood	Ab: Immunoassay
45	K11	Quali Code Canine Lyme Disease	H (D)	Serum	Ab: Immunoblot
FUNGAL INFECTIONS (SEE ALSO Chapter 56)					
58	K3	Diagnostics In-Tray DM	D	Hair	Organism: color test
58	K16	RapiGEN Ready-DTM Test	D, C	Hair	Organism: color test
58	K21	Fungassay	D, C	Hair	Organism: color test
61	K15	Premier Cryptococcal Antigen	H (D, C)	Serum, CSF	Ag: ELISA
61	K23	Crypto-LA	H (D, C)	Body fluids	Ag: LA
61	K23	"Calas"-Cryptococcal Latex	H (D, C)	Serum, CSF	Ag: LA
61	K12	Latex-Cryptococcus	H (D, C)	Body fluids	Ag: LA
61	K17	<i>Cryptococcus</i> Antigen	H (D, C)	Serum, CSF	Ag: LA
62	K15	Coccidioides Latex	H (D, C)	Serum	Ag: LA
66	K12	<i>Candida ID Antigen</i>	H (D, C)	Serum	Ag: AGID
68	K4	Pneumo Cel IFA	H (D, C)	Respiratory secretions	Ag: FA

78	K8	Enterotest	H (D, C)	Duodenal Fluid	Nylon string in capsule
78	K4	<i>Giardia</i> CELISA	D, C	Feces	Ag: ELISA
78	K18	<i>Giardia lamblia</i> Immunoassay	D, C	Feces	Ag: ELISA
78	K10	SNAP <i>Giardia</i>	D	Feces	Ag: ELISA
78	K15	Premier <i>Giardia</i>	D, C	Feces	Ag: ELISA
78	K14	FASTest <i>Giardia</i>	D, C	Feces	Ag: ELISA
78	K22	<i>Giardia</i>	H (D, C)	Feces	Cyst detection: MAB-ELISA
78	K17	ProSpecT/ <i>Giardia</i> rapid assay	H (D, C)	Feces	Ag: ELISA
78	K17	ProSpecT/ <i>Giardia</i> and <i>Cryptosporidium</i>	H (D, C)	Feces	Ag: ELISA
78, 82	K15	Meriflour Crypto & <i>Giardia</i>	H (D, C)	Feces	Ag: ELISA
82	K23	<i>Cryptosporidium</i> Test	H (D, C)	Feces	Ag (oocysts): ELISA
80	K2	Immunocomb <i>Toxoplasma</i> and <i>Chlamydia</i>	C	Serum, blood	Ab: ELISA
80	K4	Toxo CEL IFA	H (D)	Serum	Ag: FA
80	K23	TPM-Toxotest	H (C)	Serum	Ab: HA-I
80	K7	<i>Neospora caninum</i>	D	Serum	Ab: FA
82	K15	Premier <i>Cryptosporidium</i>	H (D, C)	Feces	Ag: ELISA
82	K18	<i>Cryptosporidium</i> Immunoassay Kit	D	Feces	Ag: ELISA
82	K22	<i>Cryptosporidium</i> Test	H (D, C)	Feces	Ag: ELISA
82	K4	Crypto Celisa	H (D, C)	Feces	Ag: ELISA
82	K17	ProSpecT <i>Giardia</i> Rapid	H (D, C)	Feces	Ag: ELISA
82	K4	CryptoCEL IFA	(D, C)	Feces	Ag: ELISA
82	K17	Xpect Crypto	H (D, C)	Feces	Ag: Rapid immunochromatography
82, 78	K4	Crypto/ <i>Giardia</i> Cel	D, C	Feces	Ag: FA

D, Dog; C, cat; M, mink; H, human; CSF, cerebrospinal fluid; Ab, antibody; Ag, antigen; ELISA, enzyme-linked immunosorbent assay; CDV, canine distemper virus; CPV, canine parvovirus; FA, fluorescent antibody; FIP, feline infectious peritonitis; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; RSAT, rapid slide agglutination test; PCR, polymerase chain reaction; LA, latex agglutination; AGID, ager-gel immunodiffusion; HA-I, hemagglutination-inhibition.

a Kit is marketed as a human diagnostic test but have been used for small animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

107 APPENDIX 7 Disease Rule-Outs for Medical Problems

Craig E. Greene

Christie Mayo

INTEGUMENTAL PROBLEMS		
Ulcers or Fistulas		
Canine parvovirus-2 infection (8)	Mycobacterial infections (50)	Eumycotic mycetoma (67)
Feline poxvirus infection (19)	Dermatophilosis (51)	Lagenidiosis (67)
Pseudorabies (23)	Abscesses and pyogranulomas (52)	Phaeohyphomycosis (67)
Anaerobic infections (41)	Blastomycosis (59)	Pythiosis (67)
Plague (47)	Histoplasmosis (60)	Bacterial infections of skin (85)
Actinomycosis (49)	Cryptococcosis (61)	
Feline leprosy (50)	Coccidioidomycosis (62)	
Nodules		
Canine viral papillomatosis (9)	Histoplasmosis (60)	Pythiosis (67)
Poxvirus infections (19)	Cryptococcosis (61)	Zygomycosis (67)
Melioidosis (46)	Coccidioidomycosis (62)	Protothecosis (69)
Feline leprosy (50)	Sporotrichosis (63)	Caryosporosis (81)
Mycobacterial infections (50)	Eumycotic mycetoma (67)	Sarcocystosis (81)
Dermatophytosis (58)	Lagenidiosis (67)	Bacterial infections of skin (85)
Blastomycosis (59)	Hyalohyphomycosis (67)	
Pruritus		
Rabies (22)	<i>Mallassezia</i> infections (58)	Otitis externa (85)
Pseudorabies (23)	Candidiasis (65)	
Dermatophytosis (58)	Bacterial infections of skin (85)	
Pustules or Vesicles		
Distemper (3)	Feline adenovirus infection (15)	<i>Chryseomonas</i> infection (46)
Canine herpesvirus infection (5)	Anthrax (35)	Dermatophytosis (58)
Feline immunodeficiency virus infection (14)	Staphylococcal infection (36)	Bacterial infections of skin (85)
Edema		
Infectious canine hepatitis (4)	Typhus (29)	Miscellaneous fungal infections (67)
Feline calicivirus infection (16)	Q Fever (29)	Zygomycosis (67)
Arthropod-borne viral infections (26)	Anthrax (35)	African trypanosomiasis (72)
Canine granulocytotropic ehrlichiosis (28)	Endotoxemia (38)	Babesiosis (77)
Ehrlichiosis (28)	Botulism (42)	Bacteremia and endocarditis (87)
Rocky Mountain spotted fever (29)	Canine aspergillosis-penicilliosis (64)	Inflammatory bowel disease (89)
Abscesses		
Mycoplasmal infections (32)	Staphylococcal infections (36)	Plague (47)
L-form infections (32)	Salmonellosis (39)	Nocardiosis (49)
<i>Rhodococcus equi</i> infections (35)	Anaerobic infections (41)	
Streptococcal infections (35)	Melioidosis (46)	

1174

Infectious Diseases of the Dog and Cat, 3rd Edition

1175

MUSCULOSKELETAL PROBLEMS		
Muscle Inflammation		
Canine monocytotropic ehrlichiosis (28)	Feline abscesses (52)	Toxoplasmosis (80)
<i>Rhodococcus equi</i> infection (35)	Candidiasis (65)	Bacterial endocarditis (87)
Anaerobic infections (41, 86)	Trypanosomiasis (72)	
Dermatophilosis (51)	Hepatozoonosis (74)	
Joint Inflammation Infectious or Immune-Mediated		
Feline leukemia virus infection (13)	L-form infections (32)	Bartonellosis (54)
Feline calicivirus infection (16)	Mycoplasmal infections (32)	Coccidioidomycosis (62)
Feline foamy virus infection (17)	Streptococcal infections (35)	Aspergillosis, disseminated (64)
Mumps (25)	Enterococcal infections (35)	Leishmaniasis (73)
Canine ehrlichiosis (28)	Endotoxemia (38)	Bacterial skin infections (85)
Feline ehrlichiosis (28)	Lyme borreliosis (45)	Bacteremia (87)
Rocky Mountain spotted fever (29)	Actinomycosis (49)	Complement (C3) deficiency (95)
Chlamydial infections (30)	Feline abscesses (52)	Immunodeficiencies in Weimaraners (95)
Diskospondylitis		
Streptococcal infections (35)	Mycobacterial infections (50)	Hyalohyphomycosis (67)
Staphylococcal Infections (36)	Abscesses and pyogranulomas (52)	Bacteremia (87)
Canine brucellosis (40)	Aspergillosis, disseminated (64)	Pyelonephritis (91)
Bone Inflammation Osteomyelitis		
L-form infections (32)	Anaerobic infections (41)	Phaeohyphomycosis (67)
<i>Rhodococcus equi</i> infections (35)	Nocardiosis (49)	Bacteremia (87)
Streptococcal infections (35)	Actinomycosis (49)	Cyclic hematopoiesis (95)
<i>Proteus mirabilis</i> infection (37)	Abscesses and pyogranulomas (52)	Immunodeficiencies in Weimaraners (95)
<i>Pseudomonas aeruginosa</i> infections (37)	Blastomycosis (59)	Hereditary neutropenia in border collies (95)
Salmonellosis (39)	Candidiasis (65)	
Hypertrophic Pulmonary Osteopathy		
Anaerobic infections, pulmonary abscess (41)	Mycobacterial infection, pulmonary granulomas (50)	

CARDIOVASCULAR PROBLEMS		
Heart Muscle Cardiomyopathy, Myocarditis		
Distemper (3)	Rocky Mountain spotted fever (29)	Borreliosis (45)
Canine parvovirus-1 infections (8)	Q fever (29)	Bartonellosis (54)
Canine parvovirus-2 infections (8)	Streptococcal infections (35)	American trypanosomiasis (72)
Pseudorabies (23)	Campylobacteriosis (39)	Neosporosis (80)
Arthropod-borne viral infections (26)	Yersiniosis (39)	
Endocarditis		
Streptococcal infections (35)	<i>Escherichia coli</i> infections (37)	Feline bartonellosis (54)
Enterococcal infections (35)	Canine bartonellosis (54)	Bacteremia (87)
<i>Erysipelothrix</i> infections (35)		
Pericarditis		
Feline calicivirus infection (16)	Staphylococcal infections (36)	Canine disseminated aspergillosis (64)
Streptococcal infections (35)		

1175

Infectious Diseases of the Dog and Cat, 3rd Edition

1176

RESPIRATORY PROBLEMS		
Upper Respiratory Tract Rhinitis, Sinusitis		
Canine herpesvirus infection (5)	<i>Pseudomonas aeruginosa</i> infections (37)	Canine aspergillosis-penicilliosis (64)
Canine infectious tracheobronchitis (6)	Leptospirosis (44)	Ciliary dyskinesia (95)
Feline leukemia virus infection (13)	Abscesses and pyogranulomas (52)	Bacterial rhinitis/bronchopneumonia of Irish wolfhounds (85)
Feline rhinotracheitis (16)	Bartonellosis (54)	
Tracheobronchitis		
Distemper (3)	Feline immunodeficiency virus infection (14)	Chlamydial infections (30)
Infectious canine hepatitis (4)	Influenza (25)	Mycoplasmal infections (32)
Canine herpesvirus infection (5)		Staphylococcal infections (36)
Bordetellosis, canine (6)		<i>Basidiobolus</i> infection (67)
Canine parainfluenza virus infection (6)		
Lower Respiratory Tract Alveolar-Interstitial Pneumonia		
Distemper (3)	Feline calicivirus infection (16)	Mycobacterial infections (50)
Infectious canine hepatitis (4)	Mycoplasmal infections (32)	Acanthamebiasis (79)
Canine infectious tracheobronchitis (6)	Streptococcal infections (35)	Toxoplasmosis (80)
Canine parainfluenza virus infection (6)	Endotoxemia (38)	Pneumocystosis (83)
Feline enteric viral infections (12)	Plague (47)	Bacterial respiratory infections (88)
Bordetellosis (16)	Nocardiosis (49)	Aspiration pneumonia (88)
Interstitial Pneumonia		
Infectious canine hepatitis (4)	Canine monocytotropic ehrlichiosis (28)	Leishmaniasis (73)
Canine herpesviral infection (5)	Feline monocytotropic ehrlichiosis (28)	Aspiration pneumonia (88)
Canine infectious tracheobronchitis (6)	Rocky Mountain spotted fever (29)	
Feline calicivirus infection (16)	Mycoplasmal infections (32)	
Salmon poisoning disease (27)		
Interstitial-Nodular Pneumonia		
Glanders (46)	Blastomycosis (59)	Coccidioidomycosis (62)
Melioidosis (46)	Histoplasmosis (60)	Acanthamebiasis (79)
Mycobacterial infections (50)	Cryptococcosis (61)	
Pleural Effusion		
Feline infectious peritonitis (11)	Nocardiosis (49)	Candidiasis (65)
Feline leukemia virus infection (13)	Mycobacterial infections (50)	American trypanosomiasis (72)
Equine morbillivirus infection (18)	Feline abscesses (52)	Toxoplasmosis (80)
Anaerobic infections (41)	Blastomycosis (59)	Bacterial respiratory infections (88)
Actinomycosis (49)	Coccidioidomycosis (62)	

Infectious Diseases of the Dog and Cat, 3rd Edition

GASTROINTESTINAL PROBLEMS		
Oral Inflammation (Stomatitis)		
Canine herpesvirus infection (5)	Feline calicivirus infection (16)	Feline bartonellosis (54) (controversial)
Canine parvoviral-2 infection (8)	Feline rhinotracheitis (16)	Candidiasis (65)
Feline parvoviral infections (10)	Anaerobic infections (41)	Immunodeficiencies in Weimaraners (95)
Feline immunodeficiency virus infection (14)	Plague (47)	
Dental Enamel Hypoplasia		
Canine distemper (3)	Feline panleukopenia (10)	
Hepatomegaly/Hepatic Inflammation and/or Infiltration		
Infectious canine hepatitis (4)	Anaerobic infections (41)	Babesiosis (77)
Canine herpesvirus infection (5)	Borreliosis (45)	Toxoplasmosis (80)
Feline leukemia virus infection (13)	Melioidosis (46)	Neosporosis (80)
Feline calicivirus (16)	Tularemia (48)	Inflammatory bowel disease (89)
Canine granulocytotropic anaplasmosis (28)	Nocardiosis (49)	Cholecystitis/extrahepatic bile duct occlusion (90)
<i>Rhodococcus equi</i> infections (35)	Mycobacterial infections (50)	Hepatobiliary infections (90)
Intestinal helicobacteriosis (39)	Histoplasmosis (60)	Nonsuppurative cholangitis (90)
Tyzer's disease (39)	American trypanosomiasis (72)	Pyogenic abscess (90)
Vomiting		
Infectious canine hepatitis (4)	Campylobacteriosis (39)	Bacteremia (87)
Canine herpesvirus infection, neonate (5)	<i>Clostridium difficile</i> -associated diarrhea (39)	Tonsillitis and pharyngitis (88)
Coronavirus infection (8)	Gastric helicobacteriosis (39)	<i>Anaerobiospirillum</i> ileocolitis (89)
Canine parvovirus-1 infection (8)	Salmonellosis (39)	Chronic colitis (89)
Canine parvovirus-2 infection (8)	Anaerobic infections (41)	Hemorrhagic gastroenteritis (89)
Feline parvoviral infections (10)	Leptospirosis (44)	Intraabdominal infections (89)
Feline coronavirus infection (11)	Borreliosis (45)	Bile peritonitis (90)
Feline enteric viral infections (12)	Plague (47)	Nonsuppurative cholangitis (90)
Feline leukemia virus infection (13)	Mycobacterial infections (50)	Emphysematous cholecystitis (90)
Pseudorabies (23)	Canine aspergillosis-penicilliosis, disseminated (64)	Cholecystitis/extrahepatic bile duct occlusion (90)
Salmon poisoning disease (27)	Pythiosis (67)	Hepatic abscess (90)
Canine monocytotropic ehrlichiosis (28)	Zygomycosis (67)	Mastitis (91)
Canine granulocytotropic anaplasmosis (28)	Pneumocystosis (68)	Pyelonephritis (91)
Feline monocytotropic ehrlichiosis (28)	Babesiosis (77)	Pyometra (91)
Rocky Mountain spotted fever (29)	Amebiasis (78)	Immunodeficiencies in Shar-Peis (95)
Enterococcal infections (35)	Toxoplasmosis (80)	Immunodeficiencies in Weimaraners (95)
Listeriosis (35)	Enteric coccidiosis (81)	
Endotoxemia (38)	Intrahepatic biliary coccidiosis (81)	
Diarrhea		
Distemper (3)	Chlamydial infections (30)	American trypanosomiasis (72)
Infectious canine hepatitis (4)	Enterococcal infections (35)	Leishmaniasis (73)
Nonrespiratory parainfluenza viral infection (7)	Listeriosis (35)	Hepatozoonosis (74)
Canine parvovirus-1 infection (8)	<i>Escherichia coli</i> infection (37)	Amebiasis (78)
Canine parvovirus-2 infection (8)	Endotoxemia (38)	Balantidiasis (78)
Coronavirus infection (8)	Campylobacteriosis (39)	Giardiasis (78)
Rotavirus infection (8)	<i>Clostridium perfringens</i> infection (39)	Trichomoniasis (78)
Feline panleukopenia (10)	<i>Clostridium difficile</i> -associated diarrhea (39)	Toxoplasmosis (80)

1176

1177

Infectious Diseases of the Dog and Cat, 3rd Edition

Feline parvoviral infections (10)	Gastric helicobacteriosis (39)	Enteric coccidiosis (81)	1177	
Feline coronavirus infection (11)	Salmonellosis (39)	Cryptosporidiosis (82)		
Feline enteric viral infections (12)	Yersiniosis (39)	Bacteremia (87)		
Feline leukemia virus infection (13)	Anaerobic infections (41)	<i>Anaerobiospirillum</i> /ileocolitis (89)		
Feline immunodeficiency virus infection (14)	Leptospirosis (44)	Inflammatory bowel disease (89)		
Poxvirus infections (19)	Plague (47)	Intraabdominal bacterial infections (89)		
Pseudorabies (23)	Nocardiosis (49)	Chronic colitis (89)		
Human enterovirus infections (24)	Mycobacterial infections (50)	Nonsuppurative cholangitis (90)		
Elokomín fluke fever (27)	Histoplasmosis (60)	Pyogenic abscess (90)		
Salmon poisoning disease (27)	Pythiosis (67)	Hereditary neutropenia in border collies (95)		
Canine granulocytotropic anaplasmosis (28)	Pneumocystosis (68)	Immunodeficiencies in Shar-Peis (95)		
Feline monocytotropic ehrlichiosis (28)	Protothecosis (69)	Immunodeficiencies in Weimaraners (95)	1178	
Abdominal Pain				
Infectious canine hepatitis (4)	Endotoxemia (38)	Chronic colitis (89)	1178	
Canine herpesvirus infection (5)	Salmonellosis (39)	Bile peritonitis (90)		
Feline panleukopenia (10)	Tyzzler's disease (39)	Cholecystitis/extrahepatic bile duct occlusion (90)		
Feline infectious peritonitis (11)	Yersiniosis (39)	Emphysematous cholecystitis (90)		
Rocky Mountain spotted fever (29)	Leptospirosis (44)	Pyogenic abscess (90)		
<i>Rhodococcus equi</i> infection (35)	Intraabdominal infections (89)			
Abdominal Effusion				
Infectious canine hepatitis (4)	Actinomycosis (49)	Infectious pericardial effusion (87)		
Feline infectious peritonitis (11)	Bartonellosis (54)	Inflammatory bowel disease (89)		
Feline leukemia virus infection (13)	Histoplasmosis (60)	Intraabdominal infections (89)		
Streptococcal infections (35)	<i>Basidiobolus</i> infection (67)	Pyogenic abscess (90)		
Anaerobic infections (41)	American trypanosomiasis (72)			
Nocardiosis (49)	Toxoplasmosis (80)			
Abdominal Mass				
Feline infectious peritonitis (11)	Blastomycosis (59)	Pythiosis (67)		
Feline leukemia virus infection (13)	Histoplasmosis (60)	Zygomycosis (67)		
Actinomycosis (49)	Coccidioidomycosis (62)	Toxoplasmosis (80)		
Nocardiosis (49)	Eumycotic mycetoma (67)	Intraabdominal infections (89)		
Mycobacterial infections (50)	Miscellaneous fungal infections (67)	Hepatobiliary infections (90)		
URINARY PROBLEMS				
Renal Failure				
Arthropod-borne viral infections (26)	Protothecosis (69)	Hepatobiliary infections (90)		
Rocky Mountain spotted fever (29)	Microsporidiosis (75)	Pyelonephritis (91)		
<i>Escherichia coli</i> infection (37)	Babesiosis (77)	Pyometra (91)		
Leptospirosis (44)	Bacteremia (87)	Complement C3 deficiency (95)		
Surgical and traumatic wound infections (55)	Infective endocarditis (87)			
Cryptococcosis (61)	Sepsis (87)			

Infectious Diseases of the Dog and Cat, 3rd Edition

GENITAL PROBLEMS		
Scrotal Enlargement or Drainage		
Feline infectious peritonitis (11)	Rocky Mountain spotted fever (29)	Rhodotorulosis (65)
Feline infectious peritonitis (11)	Canine brucellosis (40)	African trypanosomiasis (72)
Canine ehrlichiosis (28)	Blastomycosis (59)	Genitourinary infections (91)
Reproductive Failure, Infertility, Abortion		
Distemper (3)	Arthropod-borne viral infections (26)	Salmonellosis (39)
Canine herpesvirus infection (5)	Q-fever (29)	Canine brucellosis (40)
Canine parvovirus-1 infection (8)	Chlamydial infections (30)	Feline bartonellosis (54)
Feline panleukopenia (10)	Streptococcal infections (35)	Toxoplasmosis (80)
Feline leukemia virus infection (13)	Campylobacteriosis (39)	Neosporosis (80)
Birth of Ill (Fading) Neonates		
Canine parvovirus-1 infection (8)	Feline leukemia virus infection (13)	Toxoplasmosis (80)
Feline panleukopenia (10)		

1178

Infectious Diseases of the Dog and Cat, 3rd Edition

1179

HEMOLYMPHATIC PROBLEMS		
Lymphadenomegaly		
Distemper (3)	Borreliosis (45)	Trichosporonosis (66)
Infectious canine hepatitis (4)	Glanders (46)	Lagenidiosis (67)
Canine viral papillomatosis (9)	Melioidosis (46)	Miscellaneous fungal infections (67)
Feline parvoviral infections (10)	Plague (47)	Phaeohyphomycosis (67)
Feline infectious peritonitis (11)	Tularemia (48)	Pythiosis (67)
Feline leukemia virus infection (13)	Actinomycosis (49)	Zygomycosis (67)
Feline immunodeficiency virus infection (14)	Nocardiosis (49)	Protothecosis (69)
Feline foamy virus infection (17)	Mycobacterial infections (50)	African trypanosomiasis (72)
Mumps (25)	Dermatophilosis (51)	American trypanosomiasis (72)
Salmon poisoning disease (27)	Abscesses and pyogranulomas (52)	Leishmaniasis (73)
Canine granulocytotropic anaplasmosis (28)	Feline abscesses (52)	Feline hepatozoonosis (74)
Canine monocytotropic ehrlichiosis (28)	Bite wound infections (53)	<i>Hepatozoon americanum</i> infection (74)
Feline monocytotropic ehrlichiosis (28)	Feline bartonellosis (54)	Encephalitozoonosis (75)
Q-fever (29)	Blastomycosis (59)	Cytauxzoonosis (76)
Rocky Mountain spotted fever (29)	Histoplasmosis (60)	Babesiosis (77)
Chlamydial infections (30)	Cryptococcosis (61)	Toxoplasmosis (80)
L-form infections (32)	Coccidioidomycosis (62)	Bacteremia and endocarditis (87)
<i>Rhodococcus equi</i> infections (35)	Sporotrichosis (63)	Cyclic hematopoiesis (95)
Streptococcal infections (35)	Canine aspergillosis-penicilliosis (64)	Immunodeficiencies in Weimaraners (95)
Salmonellosis (39)	Canine disseminated aspergillosis (64)	Rhinitis/bronchopneumonia in Irish Wolfhounds (95)
Canine brucellosis (40)	Candidiasis (65)	
Splenomegaly		
Feline leukemia virus infection (13)	Canine brucellosis (40)	African trypanosomiasis (72)
Feline immunodeficiency virus infection (14)	Borreliosis (45)	American trypanosomiasis (72)
Canine granulocytotropic anaplasmosis (28)	Melioidosis (46)	Leishmaniasis (73)
Canine monocytotropic ehrlichiosis (28)	Plague (47)	Cytauxzoonosis (76)
Feline monocytotropic ehrlichiosis (28)	Tularemia (48)	Babesiosis (77)
Q-fever (29)	Nocardiosis (49)	Bacteremia (87)
Hemotropic mycoplasmosis (hemobartonellosis) (31)	Mycobacterial infections (50)	Infective endocarditis (87)
Endotoxemia (38)	Histoplasmosis (60)	Hepatobiliary infections (90)
Immunodeficiency: See Table 95-4		
Anemia		
Regenerative		
Hemotropic mycoplasmosis (hemobartonellosis) (31)	<i>Hepatozoon canis</i> infection (74)	Babesiosis (77)
Bartonellosis (54)		
Nonregenerative		
Feline infectious peritonitis (11)	Nocardiosis (49)	<i>Hepatozoon canis</i> infection (74)
Feline leukemia virus infection (13)	Mycobacterial infections (50)	Cytauxzoonosis (76)
Feline immunodeficiency virus infection (14)	Abscesses and pyogranulomas (52)	Toxoplasmosis (80)
Canine monocytotropic ehrlichiosis (28)	Histoplasmosis (60)	Pulmonary abscess (88)

Infectious Diseases of the Dog and Cat, 3rd Edition

Feline monocytotropic ehrlichiosis (28)	Coccidioidomycosis (62)	Hepatobiliary infections (90)	1179
Endotoxemia (38)	Leishmaniasis (73)	Nonsuppurative cholangitis (90)	
Salmonellosis (39)	<i>Hepatozoon americanum</i> infection (74)		
Actinomycosis (49)	Feline hepatozoonosis (74)

108 APPENDIX 8 Antimicrobial Drug Formulary

Craig E. Greene

Katrin Hartmann

Janet Calpin

108.1 PROFESSIONAL FLEXIBLE LABELING

This practice of customized dosing of veterinary drugs has been adopted by the Food and Drug Administration in the United States. The concept of individualized dosing of an animal based on the animal and disease being treated is new to veterinary drugs where fixed-dosage regimens have been customary. Dosages given on antimicrobial labels in the past have often been based on licensing data obtained by using the antimicrobial on the most susceptible infection for the organ system under consideration. Thus, dosage information was the lowest level and was ineffective for managing infections involving resistant organisms or other body systems. Future veterinary labels will provide the veterinarian with pharmacokinetic and pharmacodynamic information concerning each drug and its microbiologic susceptibility data. Dosage ranges and specific dosage indications will also be provided.

The information in this formulary is intended to support the concept of flexible labeling. Information is provided on each drug to enable veterinarians to adjust dosages on the bases of clinical and toxicologic data. Recommendations for dosing with each drug are variable depending on the type and location of infection. The reader is referred to other dosage tables in their respective disease chapters for specific dosage regimens. An attempt has been made to include the majority of drugs available internationally to treat animal infections. Many of these drugs are approved for human use, but limited studies have been performed on dogs and cats. References to newer information are cited on the basis of information in the respective chapters on antiviral drugs ([Chapter 2](#)), antibacterial drugs ([Chapter 34](#)), antifungal drugs ([Chapter 57](#)), and antiprotozoal drugs ([Chapter 71](#)). References appear with the chapter number followed by the specific citation number.

1191

108.2 ACEMANNAN

1192

108.2.1 CLASS.

Complex carbohydrate (polymannose) extracted from *Aloe vera*.

108.2.2 ACTION.

Immunostimulant and antiviral. Stimulates mononuclear phagocytes and T cells; interferes with viral glycosylation. In murine tissue culture, it induces macrophages to produce tumor necrosis factor- α and interleukin-1.

108.2.3 MORE INFORMATION.

See Antivirals, [Chapter 2, Table 2-3](#), and Immunotherapy, [Chapter 100](#); References: [Ch 2](#), ref. 36; 72; 133; 51; 178; 69a; 70a; 98a; 144a.

108.2.4 PHARMACOKINETICS.

Uncertain.

108.2.5 SPECTRUM.

Interferon inducer; has antitumor activity. Direct antiviral effect as it inhibits growth of HIV, Newcastle disease virus, and influenza virus in vivo.

108.2.6 INDICATIONS.

Treatment of clinically affected, symptomatic FeLV-positive or FIV-positive cats ([Ch 2](#), ref. 178). Intralesional injection into vaccine-induced fibrosarcomas. Prospective controlled studies on efficacy not available. Has been used in combination with surgery and radiation therapy for fibrosarcomas in dogs and cats ([Ch 2](#), ref. 72). It may also accelerate wound healing.

108.2.7 APPROVED USES.

Veterinary-adjunctive treatment for fibrosarcoma, nonspecific immunostimulant.

108.2.8 CONTRAINDICATIONS.

Previous hypersensitivity reaction to the drug.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.2.9 ADVERSE REACTIONS.

IV causes tachypnea, tachycardia, salivation, weakness, collapse, pale mucosae. Avoid by using slow IV drip infusion rather than bolus infusion. Very high (80 mg/kg) IP doses in dogs cause transient abdominal discomfort, vomiting, and diarrhea (Ch 2, ref. 36). Histologic findings of mononuclear phagocyte infiltrates in liver, spleen, and peritoneal surfaces (atypical microgranulomatous peritonitis) when treated IP. When treated IV, mononuclear phagocytes accumulate in lungs (Ch 2, ref. 36). SC injection rarely causes hypersensitivity reactions. Increased WBC counts during treatments. Intralesional injections may cause discomfort and bleeding from injection sites. Necrosis can occur at the injection site (Ch 2, ref. 36). Sedation or anesthesia is recommended. Tumors will become enlarged and painful before regression, if any, is noted.

108.2.10 INTERACTIONS.

Unknown.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Lyophilized powder for injection	10-mg vial	<i>AcemannanImmunostimulant</i> , Carrisyn (Carrington)

108.2.11 HANDLING.

Reconstitute to 1 mg/ml with 10 ml of 0.9% NaCl (supplied). Higher concentrations are insoluble and become gelatinous. Discard unused solution within 4 hr of reconstitution.

108.2.12 ADMINISTRATION.

Intralesional and/or IP weekly injection given concurrently. Continue injections until necrosis and/or edema evident in mass (usually 4th-7th week). Then use surgery to remove mass by wide excision. May also consider radiotherapy using cobalt 60 teletherapy, immediately after surgery (Ch 2, ref. 72).

Dosage				
INDICATIONS (<i>Dogs & Cats</i>)	DOSE	ROUTE	INTERVAL	DURATION
Immunostimulant	2 mg/kg	IP, SC	Weekly	6 week
Fibrosarcoma				
Preoperative ^a	1 mg/kg	IP	Weekly	4 week (weeks 1-4)
	2 mg	Intralesional	Weekly	4 week (weeks 1-4)
Surgical removal, week 5	1 mg	IP	Weekly	2 week (weeks 5, 6)
Postoperative	1 mg/kg	IP	Monthly	6 mo-1yr (thereafter)

^a The intralesional dose can be used in treatment of papillomatosis.

108.2.13 ADDITIONAL DOSAGES.

None.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.2.14 DISPENSING INFORMATION.

IP: animal may have abdominal tenderness; observe for allergic reactions. Intralesional: may cause bleeding or necrosis of lesion with some exudation for days afterward.

1192

108.3 ACTIVATED PROTEIN C (SEE DROTRECOGIN ALFA ACTIVATED)

1193

108.4 ACYCLOVIR

108.4.1 CLASS.

Nucleoside (guanosine) analog.

108.4.2 ACTION.

Antiviral; interferes with DNA replication in herpesviruses types 1, 2, and some others. Converted in cell to triphosphate derivative, only in cells with virus since uses viral thymidine kinase making it very selective. Accumulates and activates only in herpesvirus-infected cells, therefore has low toxicity, and high therapeutic index. Viral DNA polymerase is 10 times more sensitive to drug than host enzyme. Affects only replicating and not latent virus. Best therapeutic index (efficacy/toxicity) of available antiviral drugs. Unfortunately, in vitro activity of acyclovir against FHV-1 is 1000-fold less than against human herpes simplex virus (Ch 2, ref. 21; 129). Thymidine kinase activity is lower in FHV-1 than HSV (Ch 2, ref. 28). Activity of deoxycytidine kinase can influence sensitivity to acyclovir (Ch 2, ref. 170). Many animal herpesviruses such as FHV-1 and pseudorabies virus lack this latter enzyme.

108.4.3 MORE INFORMATION.

See Acyclovir, Chapter 2. See elsewhere GANCICLOVIR (*Cytovene*, Syntex); Famciclovir (*Famvir*, SmithKline Beecham); Valacyclovir (*Valtrex*, Glaxo Wellcome). See Table 2-2; references: Ch 2, ref. 61; Ch 2, ref. 141; 172. (Ch 2, ref. 117; 112.)

108.4.4 PHARMACOKINETICS.

IV gives good bioavailability; with PO use, bioavailability is only 15%-30% of levels of those after the same parenteral dosage (Ch 2, ref. 117). Penetrates into most body tissues, including CNS. CSF concentrations are 50% of plasma. Minimal metabolism and from 45% to 85% excreted unchanged in urine (Ch 2, ref. 117). Excretion is delayed in renal failure. Valacyclovir, a prodrug, has higher bioavailability (see Chapter 2).

108.4.5 SPECTRUM.

Herpesvirus infections. Some resistance has developed with extensive use.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.4.6 INDICATIONS.

In humans, for systemic, CNS, respiratory, or genital herpesvirus infections. Suppresses respiratory tract infections and mucosal eruptions. Does not prevent subclinical viral shedding. Should not be used in mild or self-limiting disease.

108.4.7 CONTRAINDICATIONS.

Reduce dosage in renal failure. Use with caution in pregnant animals because it crosses placenta. High doses are fetotoxic.

108.4.8 ADVERSE REACTIONS.

Nephrotoxic if given rapidly IV, transient renal tubular obstruction by crystals. CNS signs after IV infusion. IV can cause phlebitis and local irritation. Oral use may cause vomiting and diarrhea. Must evaluate initial hemogram prior to treatment and periodically thereafter during drug administration. Leukopenia and mild nonregenerative anemia can occur. Accidental oral ingestion by dogs occurs (see Acyclovir, [Chapter 2](#)).

108.4.9 INTERACTIONS.

If coadministered with zidovudine, may cause mental drowsiness and depression.

AVAILABILITYTYPE		SIZES	PREPARATIONS (COMPANY)
Human	Topical (ophthalmic ointment)	5% polyethylene glycol ointment	Zovirax (Glaxo Wellcome)
	Oral	200-mg capsule, 400- and 800-mg tablets, 200-mg/5 ml suspension	Zovirax
	IV solution	500-mg vial	Zovirax

108.4.10 INTERNATIONAL PREPARATIONS.

Acicloftal, Aciyiran, Acyvir, Avyclor, Cusiviral, Cycloviran, Geavir, Herpotern, Maynar, Neviran, Vipral, Virmen, Zovir, Zyclir.

108.4.11 HANDLING.

In people, IV preparation is made by dissolving powder in 10-20 ml of sterile preservative-free water. Add to calculated volume of IV solution to be given over 1 hr. Discard unused solution after 12 hr. Do not add to biologic or colloidal fluids. For cats, prepared IV solution should be further diluted in NaCl to avoid irritation.

108.4.12 ADMINISTRATION.

For cats SC route is preferred. With this route the drug has been diluted to a concentration of 1 mg/ml with 0.9% NaCl and given SC ([Ch 2](#), ref. 60). Oral and IV have more side effects in cats. IV use preferred to treat systemic infections in people. Must infuse slowly to avoid crystal precipitation in renal tubules. Rates lower than 5 mg/kg/hr have low toxicity. Give any dose over at least 1-hr time period. Monitor renal function and urine sediment for needle-shaped crystals.

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>Dosage</i>				
INDICATIONS ^a	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Pups: Systemic herpesvirus	15 mg/kg	SC, IV	8	5–7
Cats: Systemic herpesvirus	10 mg/kg	SC	8	7–21
Systemic herpesvirus	10–25 mg	PO, SC	12	7–21
Ocular herpesvirus	Ointment	Topically	4	prn
<p>a Should be combined with human interferon-a or feline interferon-w. Similar dosages could be tried in pups with herpesvirus infection.</p>				

108.4.13 ADDITIONAL DOSAGES.

None.

108.4.14 DISPENSING INFORMATION.

Animal may become depressed or drowsy or have vomiting and diarrhea. Notify veterinarian if persists.

1193

108.5 ALBENDAZOLE

1194

108.5.1 CLASS.

Benzimidazole carbamate.

108.5.2 ACTION.

Antinematodal, antiprotozoal by inhibiting parasite intestinal cell microtubular function.

108.5.3 MORE INFORMATION.

See FENBENDAZOLE, MEBENDAZOLE (elsewhere). See Antiprotozoals, [Chapter 71](#), and Giardiasis, [Chapter 78](#); [Table 78-3](#); references: [Ch 71](#), ref. 7; 86; 89; 60.

108.5.4 PHARMACOKINETICS.

Poorly absorbed (<1%) from GI tract and passes through. Any absorbed drug is rapidly metabolized into sulfoxide and sulfone derivatives with antihelminthic activity. Metabolites are predominantly excreted in urine.

108.5.5 SPECTRUM.

Various nematodes and cestodes. **Protozoa:** *Encephalitozoon*; *Pneumocystis*; *Giardia*. **Fungus:** *Cryptococcus* (in vitro). **More effective:** 50 times more active than metronidazole and 10-40 times more active than quinacrine against *Giardia*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.5.6 INDICATIONS.

Microsporidiosis (encephalitozoonosis), pneumocystosis. Closely related fenbendazole (50 mg/kg PO once every 24 hr for 3 days) is also effective against giardiasis in dogs ([Ch 71](#), ref. 7).

108.5.7 CONTRAINDICATIONS.

Hepatic dysfunction, cholestasis, pregnancy, or lactation. Do not need to alter dosage in renal failure.

108.5.8 ADVERSE REACTIONS.

Vomiting, diarrhea, liver enzyme activity increases, cholestatic hepatitis. Weight loss, myelotoxicity, and blood dyscrasias at 30-60 mg/kg daily for 26 weeks. Pancytopenia has been reported at therapeutic dosages (25 mg/kg) for 4 and 10 days in a cat and a dog, respectively ([Ch 71](#), ref. 89; 60). Leukopenias may be associated with sepsis. They can be reversed with supportive antibiotic and fluid therapy. Embryotoxic and teratogenic in lab animals. Low systemic toxicity with short-term usage because poorly absorbed.

108.5.9 INTERACTIONS.

Cimetidine increases its biliary excretion; dexamethasone increases its steady-state concentrations; albendazole potentially increases theophylline concentrations.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	200 mg, 400 mg	<i>Alben</i> (SmithKline Beecham) 400 mg
Veterinary	Oral liquid suspension (cattle)	113.6 mg/ml	<i>Valbazen</i> (Pfizer Animal Health)

108.5.10 INTERNATIONAL PREPARATIONS.

Albenza, Eskazole, Zeben, Zentel.

108.5.11 HANDLING.

Store at controlled room temperature; shake well before using.

108.5.12 ADMINISTRATION.

Give with fatty meals to increase (although variable) absorption. Poor absorption is a benefit in treating intestinal-restricted diseases such as giardiasis. For giardiasis, at least four doses must be given to be effective. For encephalitozoonosis in people, has been given concurrently with trimethoprim or pyrimethamine and sulfonamides. For longer (>30 days) therapy, should have blood count checked every 3-4 weeks to detect myelotoxicity.

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>Dosage</i>				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Humans				
Encephalitozoonosis	200–400 mg/person	PO	8–12	14–28
Dogs				
Leishmaniasis	10 mg/kg	PO	24	30
Leishmaniasis	5 mg/kg	PO	6	60
Giardiasis	25 mg/kg ^a	PO	12	2
Cats				
Giardiasis	25 mg/kg ^a	PO	12	5

^a Potentially myelotoxic at this dose (Ch 71, ref. 60).

108.5.13 ADDITIONAL DOSAGES.

Enteric protozoal infections, Table 78-3.

108.5.14 DISPENSING INFORMATION.

Contact veterinarian if vomiting, diarrhea, abdominal tenderness, yellow mucous membranes, and skin are observed.

1194

108.6 ALLOPURINOL

1195

108.6.1 CLASS.

Purine analog. Xanthine oxidase inhibitor.

108.6.2 ACTION.

Metabolized by *Leishmania* to produce an inactive analog of inosine. This molecule is incorporated into leishmanial RNA, causing faulty protein synthesis. Interferes with purine and subsequent RNA synthesis.

108.6.3 MORE INFORMATION.

References: Ch 71, ref. 10; 21; 35; 48; 51; 55; 56; 43; 17; 24; 11; Ch 73, ref. 213.

108.6.4 PHARMACOKINETICS.

Absorbed from GI tract after PO administration, converted to oxypurinol in liver. Distributed in tissues and extracellular fluid spaces but less in CSF. Renal excretion of metabolite predominates, with some in feces.

108.6.5 SPECTRUM.

Protozoa: *Leishmania*, *Trypanosoma cruzi*. **Others:** Treatment of gout or urate urolithiasis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.6.6 INDICATIONS.

Inexpensive, less toxic, PO therapy for leishmaniasis. Also considered for American trypanosomiasis, because nifurtimox is more toxic.

108.6.7 APPROVED USES.

For hyperuricemia and gout in people.

108.6.8 CONTRAINDICATIONS.

Reduce dosing, increase interval of administration, or avoid in cases involving renal failure or hepatic dysfunction. Safety in breeding or pregnant animals not established.

108.6.9 ADVERSE REACTIONS.

Vomiting, diarrhea, dermatologic eruption (pruritus and rash), myelosuppression, xanthine urolith formation (Ch 71, ref. 50). Monitor for hepatic or renal dysfunction as xanthine uroliths can occur, especially in dogs with liver dysfunction.

108.6.10 INTERACTIONS.

May continue adjunctive therapy with meglumine antimoniate or sodium stibogluconate in leishmaniasis. Increases myelotoxicity of cyclophosphamide. Urinary acidifiers increase risk of xanthine urolith formation. Increases toxicity of anticoagulant rodenticides and serum aminophylline concentrations. Dermatologic reactions are enhanced with coadministration of cytotoxic drugs and ampicillin.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	100 mg, 300 mg	Zyloprim (Glaxo Wellcome), generic (various)

108.6.11 INTERNATIONAL PREPARATIONS.

Alloprin, Allopur, Allopurin, Alloremed, Allural, Aloral, Aluline, Apurin, Caplenal, Capurate, Dabrosan, Foligan, Jenapurinol, Lysuron, Novopuro, Purinol, Zyloric.

108.6.12 HANDLING.

Store at room temperature (59–77°F) in airtight container protected from light. A 120-ml suspension of 20 mg/ml may be prepared by taking 24 100-mg tablets (Zyloprim) crushed and adding glycerin or distilled water to levigate, methylcellulose 40 ml, and a sufficient quantity of a 2 : 1 simple syrup to bring the volume to 120 ml. The mixture should be refrigerated and labeled “shake well”; is stable for 8 weeks in the dark.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.6.13 ADMINISTRATION.

Check blood cell counts and serum hepatic enzymes, urea, and creatinine every 2 weeks. Use in combination with meglumine antimoniate for the first 30 days to improve efficacy.

<i>Dosage</i>				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Leishmaniasis (Induction therapy with or without antimony)	15–30	PO	12	30 ^a
Maintenance	15	PO	12	240
Extended maintenance of remission	20	PO	24	7 sequential days each month (every 4th week) ^b
Leishmaniasis	20	PO	24	15 mo ^c

a May treat for an extended period (=120 days) as needed to control infection. Switch to maintenance after remission achieved.

b For further information see [Ch 71](#), ref. 24.

c Cat was infected with FIV and had pancytopenia, but therapy for Leishmania kept it from clinical illness with leishmaniasis ([Ch 73](#), ref. 160b).

108.6.14 ADDITIONAL DOSAGES.

Antimicrobial therapy for canine leishmaniasis, [Table 73-4](#).

108.6.15 DISPENSING INFORMATION.

Give 1-2 hr after feeding.

1195

108.7 AMANTADINE

1196

108.7.1 CLASS.

Adamantanamine.

108.7.2 ACTION.

Antiviral against RNA viruses. Blocks viral penetration into host cells.

108.7.3 MORE INFORMATION.

See Rimantidine and [Chapter 2](#), Antivirals; [Table 2-2](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.7.4 PHARMACOKINETICS.

Well absorbed from GI tract when given PO, not metabolized, excreted unchanged in urine, also in milk.

108.7.5 SPECTRUM.

At achievable concentrations, only affects influenza A viruses. Resistance can develop.

108.7.6 INDICATIONS.

Early (within 48 hr of onset of signs) or prophylactic use in influenza. Reduces severity of pulmonary lesions and clinical illness. Also augments dopaminergic activity, used to treat human parkinsonism.

108.7.7 CONTRAINDICATIONS.

Reduce dose in renal failure; avoid in pregnancy, lactation, seizure-prone animals, gastric ulceration.

108.7.8 ADVERSE REACTIONS.

Allergic reactions, ataxia, CNS manifestations with overdosage.

108.7.9 INTERACTIONS.

Synergistic with anticholinergics.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules	100 mg	<i>Symadine</i> (Solvay), <i>Symmetrel</i> (DuPont Pharma), generic (various)
	Syrup, raspberry flavor	50 mg/5 ml	<i>Symmetrel</i>

108.7.10 HANDLING.

Store in airtight container.

108.7.11 ADMINISTRATION.

Treat as early in illness as possible.

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dosage and toxicity	4.4–8.8 ^a	PO	24	5–7
uncertain ^a	2.2–4.4 ^a	PO	12	5–7

^a Do not exceed 150 mg total/day. Extrapolated from human pediatric dose.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.7.12 ADDITIONAL DOSAGES.

None.

108.7.13 DISPENSING INFORMATION.

Can be taken with or without food. Store capsules at room temperature, away from moisture and direct sunlight. Store syrup at room temperature.

108.8 AMICARBALIDE ISETHIONATE

108.8.1 CLASS.

Aromatic diamidine.

108.8.2 ACTION.

Antiprotozoal; interferes with nucleic acid metabolism.

108.8.3 MORE INFORMATION.

See IMIDOCARB, DIMINAZENE, PHENAMIDINE, PENTAMIDINE; [Chapter 71](#).

108.8.4 PHARMACOKINETICS.

Similar to imidocarb.

108.8.5 SPECTRUM.

Babesia, *Ehrlichia*.

108.8.6 INDICATIONS.

Babesiosis, ehrlichiosis. Licensed to treat bovine anaplasmosis but has been used in dogs. Not available in U.S.

108.8.7 CONTRAINDICATIONS, ADVERSE REACTIONS, INTERACTIONS.

See IMIDOCARB.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Parenteral solution	Unknown	<i>Diampron</i> (Rhône-Poulenc Rorer)

Infectious Diseases of the Dog and Cat, 3rd Edition

108.8.8 HANDLING.

See IMIDOCARB.

108.8.9 ADMINISTRATION.

May repeat injection after 1 week because of relapses that may occur.

<i>Dosage</i>				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Babesiosis	20	IM	24	1

108.8.10 ADDITIONAL DOSAGES:

Ehrlichiosis, [Table 28-4](#).

108.8.11 DISPENSING INFORMATION:

Watch for signs of weakness and neurologic dysfunction, and report them immediately to your veterinarian.

See also IMIDOCARB and DIMINAZENE.

1196

108.9 AMIKACIN

1197

108.9.1 CLASS.

Aminoglycoside.

108.9.2 ACTION.

Antibacterial.

108.9.3 MORE INFORMATION.

See GENTAMICIN, and Aminoglycosides, [Chapter 34](#); [Tables 34-5](#) and [34-6](#).

108.9.4 PHARMACOKINETICS.

Not well absorbed PO; must give parenterally for systemic use. Distribution restricted to extracellular fluid because of low lipid solubility. Enhanced with inflammation. Reaches therapeutic concentrations in peritoneal, pleural, and synovial fluids, bile, and respiratory secretions. Concentrates in kidney tissues and excreted unchanged in urine. See also GENTAMICIN.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.9.5 SPECTRUM.

Gram positive: *Staphylococcus*. **Gram negative:** *Acinetobacter*, *Citrobacter*, *Enterobacter*, *Escherichia*, *Klebsiella*, *Proteus*, *Serratia*, *Salmonella*, *Yersinia*. **Others:** *Nocardia*, *Mycobacterium tuberculosis*. **More effective:** *Pseudomonas*: more effective than gentamicin. **Ineffective:** Obligate anaerobes.

108.9.6 INDICATIONS.

For infections caused by gentamicin- resistant, gram-negative bacilli. Often shows broader antibacterial spectrum than gentamicin.

108.9.7 APPROVED USES.

For *Mycobacterium avium-intracellulare*- complex infections in combination with other effective agents.

108.9.8 CONTRAINDICATIONS.

Renal failure.

108.9.9 ADVERSE REACTIONS.

Nephrotoxic in dogs and cats; the latter are more sensitive. See also GENTAMICIN; thought to be less nephrotoxic than gentamicin. Ototoxic, causing deafness, especially in cats.

108.9.10 INTERACTIONS.

See GENTAMICIN.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Parenteral solution	250 mg/ml	<i>Amikin</i> (Apothecon), generic (various)
	Pediatric injectable solution	50 mg/ml	As above
Veterinary	Parenteral solution	50 mg/ml, 250 mg/ml	<i>Amiglyde-V</i> (Fort Dodge)

108.9.11 INTERNATIONAL PREPARATIONS.

Amicasil, *Amikan*, *Amikine*, *Amiklin*, *Amukin*, *Biklin*, *Chemacin*, *Kanbine*, *Lukadin*, *Pierami*.

108.9.12 HANDLING.

Compatible in 5% dextrose, 0.9% sodium chloride, and lactated Ringer's solutions. Stable for 24 hr. Should not premix or add to any other drug solutions. Solutions may change from colorless to pale yellow but no loss in potency occurs.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.9.13 ADMINISTRATION.

For IV give over a 30-min period in solutions. Maximum treatment duration usually 7-10 days. Important to monitor renal, vestibular, and auditory function. The greater the interval between doses, the less is its nephrotoxicity.

<i>Dosage</i>				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Urinary infections	2.3	IM, SC	12	7-10
Soft tissue infections	7.5	IV, IM, SC	12	7-10
	5	IV, IM, SC	8	7
Orthopedic infections	10	IV, IM, SC	8	7
Bacteremia, sepsis	7	IV	8	7
Cats				
Soft tissue infections	15-10	IV, IM, SC	24	7-10
Soft tissue infections	5-10	IM, SC	12	7
Bacteremia	10-12	IV, IM, SC	8-12	7

108.9.14 ADDITIONAL DOSAGES.

None.

108.9.15 DISPENSING INFORMATION.

Must be given SC; therefore, not advised for home administration. Monitoring for renal toxicity is also needed.

1197

108.10 AMOXICILLIN

1198

108.10.1 CLASS.

Aminopenicillin.

108.10.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.10.3 MORE INFORMATION.

See AMPICILLIN; [Chapter 34](#), Aminopenicillins; [Table 34-1](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.10.4 PHARMACOKINETICS.

See also AMPICILLIN. Better absorbed from GI tract than ampicillin and less affected by feeding. Rapidly absorbed after IM or SC. Injection site on body does not markedly affect this uptake from SC tissues. Longer serum half-life than ampicillin permits BID dosing. Mainly distributed in extracellular fluid compartment. Enters most tissues and body fluids except brain and CSF. With PO administration, liquid forms slightly better absorbed than tablets (bioavailability of suspension 77%; drops 68%; tablets 64%) (Ch 34, ref. 208). Most drug excreted unchanged in urine. When dogs were given endotoxin, clearance of the drug decreased significantly (Ch 34, ref. 237). Therefore dosage may be reduced when endotoxemia is suspected.

108.10.5 SPECTRUM.

Same as ampicillin. **Gram positive:** *Streptococcus*, non- β -lactamase *Staphylococcus*. **Gram negative:** *Escherichia*, *Proteus*, *Pasteurella*. See also AMPICILLIN. Anaerobes: some efficacy but less than penicillin G. **Other:** borreliosis, leptospirosis. **Ineffective:** β -lactamase-producing bacteria.

108.10.6 INDICATIONS.

Infections of nasopharynx, middle ear, urinary tracts, skin and soft tissue, upper and lower respiratory tracts, prophylaxis during dentistry, genitourinary infections.

108.10.7 CONTRAINDICATIONS.

Previous hypersensitivity to penicillins.

108.10.8 ADVERSE REACTIONS.

Dogs: diarrhea and vomiting; facial swelling, dermal rash; less diarrhea than with ampicillin; proximal renal tubular dysfunction (glucosuria, proteinuria, aminoaciduria, isosthenuria, hyposthenuria, with electrolyte loss and metabolic acidosis in one dog [Ch 34, ref. 18]). **Cats:** vomiting, diarrhea, depression, anorexia, facial swelling, ocular irritation, polydipsia and polyuria, salivation, personality change (Ch 34, ref. 209).

108.10.9 INTERACTIONS.

False-positive glucosuria result with Clinitest (Ames Laboratories, Elkhart, IN). See also AMPICILLIN.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral	tablets 125 mg	<i>Amoxil</i> (SmithKline Beecham), generic (various)
	Oral capsules	250 mg, 500 mg	<i>Polymox</i> (Apothecon), <i>Wymoxl</i> (Wyeth-Ayerst)
	Powder for oral suspension (trihydrate)	125 mg/5 ml, 250 mg/5 ml, 500 mg/5 ml	<i>Amoxil</i> , <i>Polymox</i> , <i>Wymox</i>
Veterinary	Oral tablets	50 mg, 100 mg, 150 mg, 200 mg, 400 mg	<i>Amoxi-Tabs</i> (Pfizer Animal Health)
		50 mg, 100 mg, 200 mg, 400 mg	<i>Robamox-V</i> Tablets (Fort Dodge)
	Powder for oral suspension	50 mg/ml	<i>Amoxi-Tabs</i> , <i>Robamox-V</i> , <i>Qualamox</i> (Merial)
	Powder for parenteral suspension	3gm (dilutes to 100 mg/ml or 250 mg/ml)	<i>Amoxi-Inject</i> (Pfizer Animal Health)
	Oral paste	20 mg/ml	<i>Vetrimoxin</i> (Sanofi)

108.10.10 INTERNATIONAL PREPARATIONS.

Amoxilan, *Amoxina*, *Cilamox*, *Flemoxin*, *Helvamos*, *Polymox*, *Supramox*, *Trimox*, *Wymox*.

108.10.11 HANDLING.

Store all tablets, capsules, and powders in airtight containers away from moisture at room temperature. Reconstituted oral suspension is stable for 2 weeks at refrigerated or room temperatures. Once reconstituted, parenteral suspension is stable for 3 mo at room temperature, 12 mo refrigerated.

108.10.12 ADMINISTRATION.

Mix well before administering; food can reduce absorption. Continue treatment for 48 hr after all signs of infection are gone.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Urinary infections	0–20 mg/kg	PO	12	5–7
	10 mg/kg	IM, SC	24	5
Systemic, bacteremia, sepsis	22–30 mg/kg ^a	IV, IM, SC	8	7
Orthopedic infections	22–30 mg/kg	IV, IM, SC, PO	6–8	7–10
Cats				
Urinary and soft tissue infections	50 mg/cat	PO	24	5–7
	11–22 mg/kg	PO	24	5–7
Sepsis	10–20 mg/kg	IV, SC, PO	12	prn

^a Clearance of drug is reduced in dogs with endotoxemia (Ch 34, ref. 237) so that dosage increases may not be necessary much above those used to treat localized infections. In fact a reduction might be indicated.

1198

Infectious Diseases of the Dog and Cat, 3rd Edition

1199

108.10.12 ADDITIONAL DOSAGES.

Canine distemper, [Table 3-5](#); feline panleukopenia, [Table 10-2](#); streptococcal infections, [Table 35-4](#); enteric bacteria, [Table 39-2](#); leptospirosis, [Table 44-7](#); Lyme borreliosis, [Table 45-5](#); actinomycosis, [Table 49-2](#); dermatophilosis, [Table 51-1](#); feline abscesses, [Table 52-3](#); musculoskeletal infections, [Table 86-4](#); respiratory infections, [Table 88-8](#); oral infections, [Table 89-4](#); intraabdominal infections, [Table 89-21](#); urinary infections, [Table 91-10](#).

108.10.14 DISPENSING INFORMATION.

Shake solution well before using. Give to fasted animal and no feeding for 2 hr before or after dosing. Keep refrigerated. Discard unused drug after 2 weeks.

108.11 AMOXICILLIN-CLAVULANATE

108.11.1 CLASS.

Aminopenicillin and β -lactamase inhibitor in 4 : 1 ratio.

108.11.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis and bacterial β -lactamase.

108.11.3 MORE INFORMATION.

See [Chapter 34](#), Aminopenicillins; [Tables 34-1](#) and [34-2](#).

108.11.4 PHARMACOKINETICS.

Stable in the presence of gastric acid; absorption not influenced by food. Clavulanate does not affect the pharmacokinetics of amoxicillin. The only orally bioavailable-lactamase inhibitor and penicillin group combination. Widely distributed to most tissues *except* the CNS and CSF, where amoxicillin penetrates only with inflammation. Penetration of clavulanate into CNS is uncertain. High urinary levels of unchanged drug.

108.11.5 SPECTRUM.

Gram positive: *Staphylococcus*, some *Streptococcus*, *Erysipelothrix*, *Corynebacterium*. **Gram negative:** *Escherichia*, *Klebsiella*, *Proteus*, *Enterobacter*, *Pasteurella*, *Bordetella*. **Anaerobes:** *Clostridium*, *Peptococcus*, *Peptostreptococcus*, others. **More effective:** Clavulanate has minimal antibacterial activity itself but extends the spectrum of amoxicillin to include β -lactamase producers, improving activity against *Escherichia*, *Salmonella*, *Klebsiella*, *Proteus*, *Staphylococcus*, and *Bacteroides* and other anaerobes. **Ineffective:** *Pseudomonas*, *Enterobacter*. Oral administration of β -lactamase concurrent with ampicillin reduced the development of resistant fecal flora in dogs ([Ch 34](#), ref. 152a).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.11.6 INDICATIONS.

Otitis media, sinusitis, respiratory infections, urinary tract infections, anal sacculitis, gingivitis, pyoderma, soft tissue infections, osteomyelitis, bite wounds, *Proteus* urinary infections.

108.11.7 CONTRAINDICATIONS.

Some dosage reduction in severe renal failure. Avoid with previous allergic reaction to β -lactam.

108.11.8 ADVERSE REACTIONS.

Vomiting and diarrhea, depression, anorexia, dermal rash. Polyuria, polydipsia, lameness, personality change ([Ch 34](#), ref. 209).

108.11.9 INTERACTIONS.

False-positive glucosuria using Clinitest (Ames Laboratories). *See also* AMOXICILLIN.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Tablets	125 mg, 250 mg, 500 mg	<i>Augmentin, Clamoxyl, Synulox</i> (SmithKline Beecham)
	Oral suspension	125 mg/5 ml, 250 mg/5 ml	<i>Augmentin, Clamoxyl, Syrulox</i>
Veterinary	Tablets	62.5 mg, 125 mg, 250 mg, 375 mg total	<i>Clavamox</i> (Pfizer Animal Health)
	Oral solution	62.5 mg/ml	<i>Clavamox</i>

108.11.10 INTERNATIONAL PREPARATIONS.

Bimoxi, Ciblor, Clavepen, Clavucid, Clavulin, Duplamox.

108.11.11 HANDLING.

Oral suspension: powder should be stored in airtight container away from moisture at room temperature. Add water and shake to mix. Once reconstituted, must refrigerate; activity lasts 10 days. **Tablets:** supplied in sealed strips in moisture-proof foil wrapping to maintain stability. Store at room temperature away from moisture.

108.11.12 ADMINISTRATION.

Usual duration of treatment is extended for at least 21 days for deep pyoderma in dogs and 10-14 days in cats with resistant infections for up to a maximum of 30 days. Treat for at least 48 hr after signs have resolved.

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>Dosage</i>				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Urinary	12.5 mg/kg	PO	12	5–7
Skin, soft tissue infections	12.5 mg/kg	PO	12	5–7 ^a
Deep pyoderma	12.5 mg/kg	PO	12	14–120
Systemic, bacteremia	22 mg/kg	PO	8–12	7
Cats				
Urinary tract	62.5 mg/cat	PO	12	10–30
Skin, soft tissue infections	62.5 mg/cat	PO	12	5–7
	10–20 mg/kg	PO	12	5–7
Sepsis, pneumonia	10–20 mg/kg	PO	8	7–10

a May have to treat 21 days with resistant infections for a maximum of 30 days. Much higher dosages have been recommended for resistant skin infections. See [Table 85-3](#).

1199

108.11.12 ADDITIONAL DOSAGE.

1200

Tracheobronchitis, [Table 6-2](#); gram-negative infections, [Table 37-3](#); *Clostridium perfringens* diarrhea, [Table 39-10](#); anaerobic infections, [Table 41-12](#); canine pyoderma, tetanus, [Table 43-2](#); [Table 85-3](#); respiratory disease, [Table 88-8](#); oral infections, [Table 89-4](#); colitis, [Table 89-19](#); hepatobiliary infections, [Table 90-5](#).

108.11.14 DISPENSING INFORMATION.

Can be given with or without food; however, advisable to avoid use within 2 hr of mealtime. See AMOXICILLIN.

108.12 AMPHOTERICIN B

108.12.1 CLASS.

Polyene antifungal. Originally isolated from a soil sample containing *Streptomyces nodosus*.

108.12.2 ACTION.

Amphotericin B (AMB) binds to sterols in fungal cell membrane, opens pores allowing leakage of contents. Preference for ergosterol in fungi instead of cholesterol in mammalian cells. Active against *Leishmania* spp which also contain ergosterol.

108.12.3 MORE INFORMATION.

[Chapter 57](#). See [Tables 57-1](#). See [57-2](#) for comparative features of the four formulations. All four preparations have different properties and dosage regimens. References: [Ch 57](#), ref. 106; 1; 31; 32; 48; 52; 54; 57; 60; 61; 73; 78; 83; 97; 109; 114; 131; 145; [Ch 71](#), ref. 46; 67; 47; 61; [Ch 73](#), ref. 114; 150.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.12.4 PHARMACOKINETICS.

Conventional drug is insoluble in water so prepared as a colloidal dispersion with the bile salt deoxycholate (ABD; *Fungizone*). Available in lipid-complex formulations, which include cholesteryl sulfate (ABCD; *Amphocil*); *encapsulated unilamellar liposomes (L-AMB; AmBisome)* or *lipid complexed (ABLC; Abelcet)*. ABD is not absorbed from GI tract after PO administration; given parenterally, usually IV. Initial rise in blood concentration in 24 hr is followed by prolonged elimination period over 2-3 weeks. Strongly bound to cell membranes. Use of AMB in lipid-complex formulations may be less nephrotoxic because of selective uptake by the MPS and reduced uptake of the lipid preparations by mammalian cells. Lipid formulations are taken up by macrophages that carry it to the site of fungal-induced inflammation.

108.12.4.1 ABD.

Poor oral absorption. Painful IM, so usually given IV. Widely distributed and penetrates many tissues and inflammatory exudates but is highly protein bound. Poor penetration into bones, brain and CSF (even with inflammation), aqueous and vitreous humor, amniotic fluid, muscle, respiratory secretions, pancreas, and salivary gland, and uninflamed body cavities (pleura, peritoneum, joints, pericardium). Accumulates in liver, kidneys, and lungs. Metabolism is uncertain; small amount of biliary excretion; slow urinary excretion (up to 2 mo) occurs with a small portion (<10%) as active drug. In dogs, up to 20% dose is excreted in bile over time. Does not accumulate to greater extent in renal failure, but is nephrotoxic ([Ch 57](#), ref. 31; 142).

108.12.4.2 ABCD.

Stable in plasma, not dissociating to free AMB; leads to mononuclear phagocyte uptake and lower renal concentrations and toxicity. In animal studies, compared with ABD, ABCD had lower plasma levels, higher liver concentrations, greater volume of distribution, and longer half-life. Highest drug concentration achieved in organs of the MPS (liver, spleen) and in lung, with lower concentrations in kidney, stomach, and small intestine. Lower concentrations in bone marrow and heart muscle, and little in brain and CSF ([Ch 57](#), ref. 31; 142). With this preparation, concentrations are lower in kidneys, lungs, heart, brain, GI tract, and CSF than with deoxycholate. Most of the drug is concentrated in the liver with this formulation. Lower renal concentrations correlate with less nephrotoxicity of the liposomal-encapsulated derivative. Higher hepatic, splenic, and bone marrow concentrations resulting from increased mononuclear phagocyte concentrations were not associated with increased toxicity.

108.12.4.3 L-AMB.

Highest serum and CSF levels are achieved with this formulation, presumably because of its small particle size and lower uptake by the MPS. Greatest concentrations in liver and spleen compared with ABD with similar levels in lung and kidney ([Ch 57](#), ref. 4).

108.12.4.4 ABLC.

Because of large molecular size and rapid uptake by the MPS, serum concentrations are lower than with ABD. Greatest concentration in dogs has been found in liver, spleen, and lung. Kidney concentrations are slightly lower than with ABD.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.12.5 SPECTRUM.

Fungi: *Histoplasma*, *Cryptococcus*, *Coccidioides*, *Paracoccidioides*, *Blastomyces*, *Candida*, *Sporothrix*, *Mucor*, *Aspergillus*, *Rhizopus*, *Absidia*, *Basidiobolus*, *Entomophthora*. **Others:** *Leishmania* (Ch 71, ref. 46).
Ineffective: dermatophytes.

108.12.6 INDICATIONS.

Cryptococcosis, coccidioidomycosis, histoplasmosis, mucormycosis, sporotrichosis, aspergillosis, candidiasis, leishmaniasis. Primary drug for severe overwhelming systemic mycoses. Most effective antifungal for severe life-threatening infections of disseminated aspergillosis and other filamentous fungal infections. Lipid formulations can be given at higher doses to enhance efficacy at a significantly greater cost. They are indicated over ABD when it has been ineffective or has caused nephrotoxicity if pre-existing renal impairment is evident. In rodents, L-AMB was more effective than ABD in CNS penetration in treating fungal meningoencephalitis (Ch 57, ref. 41a) and potentially suppressing CNS infection in a dog with disseminated phaeohyphomycosis (Ch 57, ref. 79). ABD was superior to fluconazole, or a combination of both drugs, in treatment of experimental CNS histoplasmosis in mice (Ch 57, ref. 49). ABD is better excreted in the urine than lipid formulations and it should be used to treat fungal urinary tract infections. In people, lipid formulations of AMB have been shown to be better tolerated, with respect to nephrotoxicity, and more efficacious in treatment of patients with invasive fungal infections (Ch 57, ref. 141a). Indicated in cases of *Leishmaniasis* unresponsive to other forms of treatment or if a cure is desired.

108.12.7 CONTRAINDICATIONS.

Renal failure, hepatic failure. Lipid formulations are associated with less nephrotoxicity.

108.12.8 ADVERSE REACTIONS.

The use of AMB deoxycholate is complicated by acute infusion-related toxicity and constitutional and chronic renal toxicities. These limit the dose and duration of AMB in clinical practice. During infusion of ABD, animals can develop fever, vomiting, myalgia, muscle tremors, phlebitis, and occasional anaphylaxis. Lipid formulations have a greater tendency to cause these infusion-related reactions, which can be reduced by slowing the infusion rate. The anaphylactic reaction can be variable and only to certain of the formulations available (Ch 57, ref. 65). Lipid formulations, especially ABCD, may be associated with infusion-related reactions. The theoretical advantage of the three lipid formulations is their ability to concentrate in the MPS and to be transported to the sites of infection. Larger doses of lipid formulations drug can be given with lower renal toxicity (Ch 71, ref. 15). AMB preparations are not advised in pregnancy, although there is no known toxicity. Can cause hypokalemia, which may affect cardiac, skeletal muscle, or renal function. Weight loss with long-term treatment. Nonregenerative normochromic normocytic anemia occurs with long-term therapy, presumably caused by nephrotoxicity or interference with erythropoietin. AMB alters renal tubular cell injury, which may result in potassium loss in urine, decreased medullary tonicity, and decreased urinary acidification. AMB increases intracellular calcium in vascular smooth muscle cells, leading to arachidonic acid cascade and subsequent accumulation of vasoconstrictive eicosanoids. Increased renal vascular resistance develops without changes in blood pressure, thereby reducing renal blood flow. To combat toxicity, renal dopamine DA1 receptors may be stimulated. Dopamine infusion has been used to reduce toxicity but has a nonselective effect; however controlled studies in humans showed no statistical benefit in preventing nephrotoxicity (Ch 57, ref.

1200

1201

Infectious Diseases of the Dog and Cat, 3rd Edition

14a). Fenoldopam (SmithKline Beecham), a specific DA1 agonist for receptors in renal tubules, might be more selective (Ch 57, ref. 97). Loading of isotonic NaCl by parenteral infusion at the time of AMB administration has been the most beneficial factor in reducing the nephrotoxicity of these preparations. Reduced nephrotoxicity may relate to lipid binding of drug in plasma and its direct uptake into the MPS. Nephrotoxicity is the dose-limiting factor; may have to interrupt therapy, reduce dosage, or use alternative drugs. Gradually increase dose if drug reinstated.

108.12.9 INTERACTIONS.

AMB in any formulation increases nephrotoxicity of cyclosporine, aminoglycosides, vancomycin, inhalation anesthetics, and cisplatin. Sometimes used in conjunction with an azole antifungal. Synergistic effects occur with combined use of rifampin against *Histoplasma*, *Aspergillus*, *Candida*, and tetracycline or fluorocytosine against *Candida* and *Cryptococcus*. AMB may alter the fungal cell membrane, allowing these other drugs to disrupt fungal metabolism. Combination therapy with azole antifungals may induce fungal resistance to AMB, although it is often recommended in rapidly advancing systemic mycoses. In experimental studies with combination therapy either concomitant or in succession, FCZ was synergistic while ITZ was inhibitory (see also Azoles, Chapter 57) (Ch 57, ref. 129).

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)	
Human	ABD	Powder for injection (deoxycholate)	50 mg/vial	<i>Fungizone</i> (E.R. Squibb)
	ABCD	Powder for injection (colloidal dispersion)	50 mg/vial and 100 mg/vial	<i>Amphocil</i> , <i>Amphotec</i> (Sequus)
	L-AMB	Powder for injection (liposomal)	50 mg/vial	<i>AmBisome</i> (Fujisawa; Nexstar)
	ABLC	Solution for injection (lipid complex)	100 mg/20 ml vial (5 mg/ml)	<i>Abelcet</i> (Liposome Co.)

108.12.10 INTERNATIONAL PREPARATIONS.

Ampho-Moronal, *Funganiline*, *Fungilin*, *Fungizona*.

108.12.11 HANDLING.

ABD: Dilute powder with 10 ml sterile water (electrolyte or preservative free), shake until clear to give 5 mg/ml solution. Dilute further 1 : 50 with 5% dextrose to give final concentration of 10 mg/100 ml. Incompatible with many other fluids, but can use dilute heparin for flush. Precipitates will form if preservatives or saline are used. Stored powder is refrigerated in the dark in unopened vials. If accidentally left unrefrigerated; powder is stable for 2-4 weeks. Prepared 5-mg/ml solutions are stable for 24 hr in the dark at room temperature and for 1 week when refrigerated. When further diluted in 5% dextrose, solution is stable in PVC IV bags for 24 hr. Exposure to light during daily infusions (<8 hr duration) does not affect potency enough to warrant concern. **To reduce toxicity: heating of ABD** to form superaggregation has been noted to reduce toxicity (Ch 57, ref. 35; 104). The powdered drug as supplied is reconstituted with 10 ml of 5% dextrose. Then the ABD is pre-heated for 20 min at 70°C prior to administration. **Mixing of ABD with lipid** for the treatment of canine leishmaniasis (Ch 71, ref. 47) is done by aseptically adding 40 ml sterile H₂O and 10 ml of a commercial soya bean solution (*Intralipid*) to 50 mg AMB. After shaking the mixture (1 mg AMB/ml) is stable for 3 weeks (Ch 71, ref. 97). **ABCD:** As dry powder, stable at room temperature for at least 2 years. After reconstitution, vials can be stored refrigerated for 24 hr but not frozen. With further dilution to approximately 1 mg/ml in 5% dextrose, the stability is 24 hr refrigerated. **L-AMB:** Dry powder is stored under refrigeration. It is diluted with sterile water without preservatives to a 4-mg/ml solution. Shaking is necessary until the drug is completely dispersed. Reconstituted drug is stable up to 24 hr refrigerated, if not frozen. For

Infectious Diseases of the Dog and Cat, 3rd Edition

further dilution to 1-2 mg/ml or lower concentrations, the drug is flushed through a 5- μ m filter (provided) into 5% dextrose. Infusion into the patient should be within 6 hr of dilution. An in-line membrane filter may be used if the mean pore diameter is $>1\ \mu\text{m}$. **ABLC:** Shake vial to suspend yellow sediment, withdraw drug via 18-gauge needle into 20-ml syringes and infuse through the supplied 5- μ m filter needle into 5% dextrose for infusion to a concentration of 1-2 mg/ml. Refrigerate suspension until used. Stable in 5% dextrose solution for 48 hr refrigerated and 6 hr at room temperature. Aseptic technique must be practiced because no bacteriostatic preservatives are included. Do not dilute with saline solutions or other drugs. Infusion catheters carrying such fluids can be flushed with 5% dextrose first. In-line filters should not be used. It should not be frozen.

108.12.12 ADMINISTRATION.

ABD: Animals should be well hydrated before treatment, and pre-existing dehydration must be corrected by fluid therapy. Manufacturer of deoxycholate preparation recommends dose be given over 2-6 hr. When large-volume infusion is used, an IV catheter is placed and the dose (10 mg/100 ml) is given in 300-500 ml of 5% dextrose, depending on size of animal. Administration over this interval may reduce the likelihood of renal damage. However, clinical experience in dogs and cats has shown that more concentrated solutions, with the dose placed in a volume of 10 ml to 60 ml 5% dextrose, can be placed in a syringe and infused through a butterfly or indwelling catheter over a 5- to 10-min period. Ten milliliters of 5% dextrose flush should be infused immediately before and after administration of the drug. Although bolus infusions may have a higher risk of toxicity, this can be overcome by administering an equal or greater volume of lactated Ringer's or 0.9% NaCl (equal to that otherwise given with routine dilution of AMB) by IV or SC administration without the risks associated with extravasated drug. Supplemental fluid diuresis is highly recommended with each dose. 1201

For cats, indwelling catheters are preferable because of the difficulties of repeated venipuncture. Often test dose (1 mg) slowly IV to check for immediate systemic reactions. Co-administration of nonsteroidal anti-inflammatories, antihistamines, antiemetics, and/or small doses of IV glucocorticoids or heparin may reduce systemic reaction. Prevent thrombophlebitis by flushing catheters, using larger veins, rotating sites, adding heparin to the solution. The only way to ensure reaching the CNS is by intrathecal use of deoxycholate preparation, which can be irritating. 1202

Renal toxic effects are monitored at least once, if not twice weekly, by checking serum urea concentrations and by examination of the urine for specific gravity, protein, casts, and hematuria. Serum creatinine and electrolytes (including magnesium, which may decrease) determinations are optional but may be required if screening tests or health becomes altered. Urine changes detect toxicity earlier than blood biochemical alterations. Therapy should be temporarily discontinued if anorexia or vomiting occurs or if serum urea increases to $>30\ \text{mg/dl}$. Therapy with AMB or alternative drug is reinstituted after signs and laboratory findings of nephrotoxicity disappear. Maintenance therapy with weekly or monthly injections of AMB or daily oral imidazoles has been used to avoid relapses that develop once therapy is discontinued.

Hypokalemia, a problem in people receiving AMB, has been documented in dogs and cats. Any potassium supplements should be given PO, SC, or by alternative IV route, because these solutions will precipitate the colloid.

Fever, nausea, and vomiting that occur during or immediately after treatment may be less severe if a physiologic dose of hydrocortisone sodium succinate (0.5 mg/kg, IV), diphenhydramine (0.5 mg/kg, IV or PO), or aspirin (10 mg/kg, PO) is given before administration of AMB. Anti-inflammatory or immunosuppressive doses of glucocorticoids should be avoided because they may lead to fungal dissemination. Muscular fasciculations and rigors that develop in people during IV infusions have been controlled with dantrolene sodium (10-50 mg, IV) or meperidine.

Infectious Diseases of the Dog and Cat, 3rd Edition

Attempts to avoid nephrotoxicity with ABD have been made using mannitol (0.5-1 g/kg, IV), sodium bicarbonate (1-2 mmol/kg, IV), and dopamine (3-10 µg/kg/min, IV), but controlled studies have either not been done or have shown no benefit (Ch 57, ref. 14a). Beneficial effects have been obtained when sodium-containing fluids or furosemide (5 mg/kg route) or aminophylline was given to dogs just before administration of AMB. SC administration is less nephrotoxic (see later).

Heparin has been added to ABD to control phlebitis that develops after repeated infusions, but there is no conclusive evidence that its use decreases the reaction. In-line micropore filters used to remove particulate matter and bacteria from IV solutions are less than 0.45 µm and will also remove the drug. Filters of greater than 1 µm can be used but will not remove bacteria.

108.12.12¹ Alternative Routes.

Usual IV therapy requires repeated venous access, often necessitating catheter placement, especially in cats. ABD may be used topically, intra-articularly, or intrathecally or may be flushed in the bladder or renal pelvis if the infection site is accessible by these means. This will help achieve maximal concentrations with lower risk of systemic toxicity. **Intra-articularly**, 5 to 15 mg can be used to infuse one joint. For **bladder infusions**, AMB is mixed to a concentration of 30 to 50 mg in 50-100 ml sterile water and is infused once daily for 5-15 days. The bladder is distended, and the animal is permitted to void spontaneously. Alternatively, a constant-drip infusion of 50 mg/L has been used. For **intrathecal** use, 0.2-0.5 mg is diluted in 5 ml of 10% dextrose or CSF freshly removed from the animal under anesthesia. It is injected in the lumbar or cisternal space, and the head is lowered for a few minutes if signs of intracranial involvement are apparent. Unfortunately, this procedure must be repeated two to three times each week. **Aerosol** use achieves higher concentration in the respiratory tract than other tissues, thus reducing nephrotoxicity. Conventional AMB is less efficiently nebulized than lipid-based products. For AMB use 50 mg divided into three doses. Generally well tolerated; however, bronchospasm or vomiting has been observed in people. Aerosol AMB has been used long term (3 weeks-2.5 yrs) in people for prophylaxis or treatment of pulmonary fungal infections. **Ocular injection:** Systemic therapy should suffice for early chorioretinitis before vitreitis develops. Although established intraocular mycotic infections are difficult to cure, enophthalmitis in people has been effectively treated by injecting simultaneously intravitreally 5 µg, peribulbar space 125 µg, and episclerally 5 mg. Intravitreal injections were well tolerated in rabbits (5 µg), monkeys (10-20 µg). Liposomal AMB was well tolerated in doses that were at least 4-fold higher. The drug persists in clinically healthy eyes for at least 7-15 days and for shorter periods following vitrectomy and lens extraction. Single doses have been sometimes effective in clearing infection in experimentally infected rabbits. **Subcutaneous:** Route used in dogs and cats with cryptococcosis and potentially for other systemic mycoses. A daily dose of 0.5 to 0.8 mg/kg is added to 400 ml (cats) and 500 ml (dogs) of 0.45% saline/2.5% dextrose (Ch 57, ref. 83). This total fluid volume is given SC two or three times weekly to a cumulative level of 8-26 mg/kg, which is higher than IV regimen. Concentrations of >20 mg/L are irritating, cause SC abscesses, and should be avoided. The method is suited for outpatient treatment and does not require IV catheter maintenance. Blood levels are lower but more sustained, reducing toxicity and allowing for increased efficacy. **Combined with fat emulsion:** This has been done in an attempt to decrease nephrotoxicity. AMB deoxycholate is stable in combination with fat emulsions. A concentration of 0.5 to 2 mg/ml is stable in a 20% fat emulsion for 4 days at 25°C in fluorescent lighting and 7 days at 4-8°C in the dark. In one study (Ch 71, ref. 47) AMB was added to a commercial lipid preparation (see Handling above). The mixture, which was stored for up to 3 weeks, was given over 30-60 min at a starting dose of 1-1.5 mg/kg twice weekly with progressive increases to 1.6-2.5 mg/kg twice weekly and altered by

Infectious Diseases of the Dog and Cat, 3rd Edition

changes in serum urea and creatinine. The infusion was followed by 50 ml/kg of normal saline and then 10 ml/kg of 20% mannitol.

108.12.12.2 **ABCD:**

Given by IV infusion at a rate of 1 mg/kg/hr. A test dose (10 ml) should be infused first to check for adverse reactions. The rate of infusion can be increased if it is tolerated.

108.12.12.3 **L-AMB:**

Given by IV infusion over 60 to 120 min or longer with 5% dextrose as a diluent. Solution is diluted to 1-2 mg/ml.

108.12.12.4 **ABLCL:**

Given by IV infusion at 2.5 mg/kg/hr. With infusion times longer than 2 hr, the mixture should be shaken periodically to disperse any sediment.

108.12.13 **DOSAGE.**

ABD: A wide range of systemic dosages has been described in the veterinary literature. The range has been a total (cumulative) dose of 4-12 mg/kg given as alternate day or Mon-Wed-Fri treatments. Dogs usually receive accumulative doses of 8-12 mg/kg and cats 4-6 mg/kg. Lower dosages are used if adjunctive therapy with oral flucytosine or itraconazole is used. Higher dosages are given SC (see prior discussion). For IV use, the drug is given on these days at 0.15-0.5 mg/kg/day, which is continued until the final calculated total dosage is reached (usually 6 weeks) or when toxicity (elevated serum urea concentration) occurs. Daily doses are lower (0.15-0.25 mg/kg) for cats and higher (0.25-0.5 mg/kg) for dogs. The 0.5-mg/kg dose has a high risk of nephrotoxicity. Initial doses of 0.1 mg/kg for cats and 0.25 mg/kg for dogs are often given the first day and are gradually increased to 0.25 mg/kg and 0.5 mg/kg, respectively. Doses up to 1 mg/kg/day given 2-3 times weekly have been used in particularly resistant infections in dogs that tolerate the drug well. Treatment often lasts for 2-3 mo or longer, and early discontinuance can lead to a relapse. Treatment may require 11 mo in aspergillosis and 9 mo in sporotrichosis. A recommended dose for long-term treatment of sporotrichosis is 0.2-0.5 mg/kg IV given every 48 hr (Ch 57, ref. 144). Higher dosages can be used with SC route; see previously under administration. **Lipid formulations—ABCD, L-AMB, ABLCL:** Higher dosages are tolerated and used as outlined in the table that follows. Rates of infusion and total doses are individualized to each animal to ensure maximum efficacy while reducing the potential for systemic toxicity or adverse reactions. General guidelines are to administer lipid formulations at a level of 1 mg/kg given every 48 hr to a minimum cumulative total dosage of 12 mg/kg. In studies of people with invasive aspergillosis, doses of L-AMB of 3 mg/kg were no more effective than 1 mg/kg (Ch 57, ref. 30a). For human leishmaniasis, cumulative dosages of L-AMB which were shown to be curative have been as high as 20 mg/kg (Ch 71, ref. 61).

Lipid AMB mixtures prepared from ABD are dosed similarly to the commercial AMB lipid formulations. A cumulative dose of 10 mg/kg has been effective in one study (Ch 71, ref. 47) but not another (Ch 71, ref. 64). The dosage was higher and follow-up shorter in the former study which may explain this discrepancy.

1202

1203

Infectious Diseases of the Dog and Cat, 3rd Edition

INDICATIONS	INITIAL TEST DOSAGE ^a (mg/kg)	USUAL DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION
ABD (Fungizone)					
Dogs (mycoses)	0.25	0.25–0.5	IV	48 ^b	6 weeks
Cats (mycoses)	0.1	0.1–0.25	IV	48 ^b	6 weeks
Dogs and Cats (mycoses)	—	0.5–0.8	SC	48 ^b	3–10 weeks
Dogs (leishmaniasis)	—	0.5–0.8	IV	48 ^b	See ^c
L-AMB (AmBisome)					
Dogs (leishmaniasis)	0.5	3.0–3.3	IV	72–96	See ^d
Dogs (mycoses)	0.5	1–2.5	IV	48 ^b	4 weeks ^e
ABCD (Amphocil)					
Dogs (mycoses)	0.5	1–2.5	IV	48 ^b	4 weeks ^e
ABLC (Abelcet)					
Dogs (mycoses)	0.5	1–2.5	IV	48 ^b	4 weeks ^e

- a Only use this dose first to test for potential adverse reactions or azotemia; animals developing azotemia usually tolerate subsequent administration at the usual dosage.
- b Every 48 hr, or Monday (M), Wednesday (W), and Friday (F) on a weekly basis until the cumulative dosage is reached. For *Leishmania* the total cumulative dose for ABD is 15 mg/kg. Depending on the type and severity of the systemic mycosis, the cumulative dose for ABD ranges between 4 and 10 mg/kg. For lipid-base AMB, the cumulative dose is 8–12 mg/kg depending on the systemic mycosis.
- c Every 48 hr, or MWF, until a cumulative dose of 8 to 16 mg/kg is reached (Ch 71, ref. 46).
- d Every 72–96 hr, until a cumulative dose of 15 mg/kg is reached (Ch 73, ref. 150). May be possible to give the same cumulative dose with a lower level every 48 hr (some regimens suggest days 1,2,3 and 10 or days 1,2,3,4 and 10).
- e Every 48 hours, or MWF, or until a minimum cumulative dose of 12 mg/kg is reached (Ch 59, ref. 47) by using 1 mg/kg dose for susceptible yeast or systemic (dimorphic) fungal infections. For more resistant filamentous fungal infections, such as pythiosis, use a 2–2.5 mg dose until a cumulative dose of 24–30 mg/kg is reached. In people with invasive aspergillosis, clinical response to dosage increments of 1 mg/kg were comparable to those of 4 mg/kg at a significantly reduced cost (Ch 57, ref. 30a).

108.12.14 ADDITIONAL DOSAGES.

Blastomycosis, Table 59-1; histoplasmosis, Table 60-1; cryptococcosis, Table 61-5; coccidioidomycosis, Table 62-3; nasal aspergillosis, Table 64-1; disseminated aspergillosis, Table 64-3; dermal candidiasis and trichosporonosis, Table 65-2; candidiasis, Table 65-4; protothecosis, Table 69-1.

108.13 AMPICILLIN

108.13.1 CLASS.

Aminopenicillin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.13.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.13.3 MORE INFORMATION.

See AMOXICILLIN; Aminopenicillins, [Chapter 34](#); [Table 34-1](#).

108.13.4 PHARMACOKINETICS.

Orally up to 50% absorbed, but decreased by ingesta. Oral trihydrate form is less efficiently absorbed than anhydrate. In cats, oral suspension has lower bioavailability (18%) than capsules (42%). IM and SC sodium salt better absorbed than trihydrate. Absorption of anhydrate form is comparable between SC and IM sites. Better absorbed from SC tissues in the dorsal neck region than over the thoracic wall ([Ch 34](#), ref. 366). Penetrates body fluids and parenchymal organs (liver, lung). Only enters acutely inflamed meninges, CNS, eye, and prostate. One of few β -lactams that is metabolized and excreted by liver: biliary concentration is 40 times that in blood. About 50% excreted unchanged in urine.

108.13.5 SPECTRUM.

Gram positive: Non- β -lactamase *Staphylococcus*, *Streptococcus*. **Gram negative:** *Escherichia*, *Proteus*, *Pasteurella*. No advantage using this drug in conjunction with trimethoprim-sulfonamide because it adds very little to spectrum. Has better gram negative, but less anaerobic spectrum, than to natural and β -lactamase-resistant penicillins. See also AMOXICILLIN. **Anaerobes:** Not as effective as penicillin. **Ineffective:** Rickettsiae, mycoplasmas, mycobacteria, and fungi. Not effective against β -Lactamase-producing organisms.

1203

108.13.6 INDICATIONS.

Gram-negative infections caused by *Proteus* and *Escherichia*. Appropriate first choice for bacterial meningitis in dogs and cats. Dental prophylaxis, septicemia, urinary, respiratory, and soft tissue infections; prophylaxis with GI surgery when combined with gentamicin.

1204

108.13.7 CONTRAINDICATIONS.

Avoid in resistant infections caused by *Klebsiella*, *Pseudomonas*, *Enterobacter*. β -Lactamase is main cause of resistance. Safe in pregnancy. In hepatic cirrhosis, clearance is increased, and dose may have to be increased. Increase dose interval to 12 hr or reduce dose in severe renal failure.

108.13.8 ADVERSE REACTIONS.

Causes seizures with rapid IV administration; upsets normal intestinal microflora causing diarrhea.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.13.9 INTERACTIONS.

Reduces bioavailability of atenolol. Potential antagonism of activity when coadministered with chloramphenicol, tetracyclines, or erythromycin. See AMOXICILLIN.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection (IV, IM)	125 mg, 250 mg, 500 mg, 1g, 2g, 10g	<i>Omnipen-N</i> (Wyeth-Ayerst), <i>Polycillin-N</i> (Bristol)
	Oral capsules	250 mg, 500 mg	<i>Amcill</i> (Parke-Davis), <i>Principen</i> (Bristol-Myers Squibb)
	Powder for oral suspension	125 mg/5 ml, 250 mg/5 ml, 500 mg/5 ml	<i>Polycillin</i> , <i>Totacillin</i> (SmithKline Beecham)
Veterinary	Oral capsules (trihydrate) (dogs, cats)	125 mg, 250 mg, 500 mg	<i>Princillin</i> (Solvay)

	Powder for parenteral (SC, IM) suspension (trihydrate) (dogs, cats, cattle)	10-g, 25-g vials	<i>Polyflex</i> (Fort Dodge)
	Powder for parenteral (IV, SC) Injection (sodium salt) (horses)	1-g, 3-g vials	<i>Amp-Equine</i> (Pfizer Animal Health)

108.13.10 INTERNATIONAL PREPARATIONS.

Binotal, *Jenampin*, *Novapen*, *Penbritin*, *Principen*, *Rimacillin*, *Spectracil*, *Vidopen*.

108.13.11 HANDLING.

Reconstituted parenteral ampicillin sodium (30 mg/ml) in sodium chloride (0.9%) or lactated Ringer's is stable for 8 hr at room temperature and for 48 hr when refrigerated. More dilute concentrations (<20 mg/ml, in 5% dextrose) are stable 2-4 hr at room temperature and 8 hr if refrigerated. Whenever possible, use freshly prepared solutions of ampicillin sodium. Parenteral trihydrate suspension is stable for 3 mo at room temperature or 12 mo if refrigerated. Oral suspensions are stable for 1 week at room temperature or 2 weeks when refrigerated and should be discarded thereafter. Capsules and nonreconstituted powders are stored at room temperature. Ampicillin sodium solutions are incompatible with macrolides, aminoglycosides, tetracyclines, phenothiazines, and various other drugs; therefore, mixing with other compounds is not advised.

108.13.12 ADMINISTRATION.

Give PO on empty stomach. For IV, administer slowly over 10-15 min or as slower IV drip. IM or IV forms are used for severe infections that require highest dosages or when oral medication is contraindicated.

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>Dosage</i>				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Urinary infections	12.5	PO	12	3–7
	6.6	SC, IM	12	3–7
Soft tissue infections	10–20	PO, IM, SC	8	7
Pneumonia, systemic	22	PO, IV, SC	8	7–14
Meningitis, orthopedics	22	IV, IM, SC, PO	6–8	prn
Bacteremia, sepsis	20–40	IV, IM, SC	6–8	prn
Neonatal sepsis	50	IV, intraosseous	4–6	prn
Cats				
Urinary infections	20	PO	8–12	7–14

108.13.13 ADDITIONAL DOSAGES.

Canine distemper, [Table 3-5](#); canine viral enteritis, [Table 8-1](#); feline panleukopenia, [Table 10-2](#); feline infectious peritonitis, [Table 11-4](#); streptococcal infection, [Table 35-4](#); sepsis, [Table 38-6](#); salmonellosis, [Table 39-2](#); *Clostridium perfringens* diarrhea, [Table 39-10](#); leptospirosis, [Table 44-7](#); actinomycosis, [Table 49-2](#); nocardiosis, [Table 49-3](#); dermatophilosis, [Table 51-1](#); feline abscesses, [Table 52-3](#); musculoskeletal infections, [Table 86-4](#); bacteremia, [Table 87-6](#); respiratory infections, [Table 88-8](#); oral infections, [Table 89-4](#); urinary infections, [Table 91-10](#); CNS infections, [Table 92-5](#).

108.13.14 DISPENSING INFORMATION.

Give drugs to fasted (preferably >5 hr) dogs or at least 1 hr before or 2 hr after feeding ([Ch 34](#), ref. 206). Dry food interferes less with absorption than moist food.

1204

108.14 AMPICILLIN-SULBACTAM

1205

108.14.1 CLASS.

Aminopenicillin and β -lactamase inhibitor in a 2 : 1 ratio.

108.14.2 ACTION.

Bactericidal; inhibitor of bacterial cell wall synthesis and β -lactamase inhibitor.

108.14.3 MORE INFORMATION.

[Chapter 34](#); [Table 34-2](#); reference: [Ch 34](#), ref. 225.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.14.4 PHARMACOKINETICS.

Therapeutic levels attained within 15 min of IV or IM dose. Good tissue levels and penetrates peritoneal and interstitial fluids. Up to 85% excreted in urine within 8 hr (Ch 39, ref. 313). Both drugs eliminated at similar rate in dogs. Sulbactam has no intrinsic antibacterial activity but extends spectrum of ampicillin.

108.14.5 SPECTRUM.

Gram positive: *Staphylococcus*, *Streptococcus*, *Bacillus anthracis*, *Listeria monocytogenes*. **Gram negative:** *Escherichia*, *Klebsiella*, *Proteus*, *Salmonella*, *Enterobacter*, *Pasteurella*, *Acinetobacter*. **Anaerobes:** *Clostridium*, *Peptococcus*, *Peptostreptococcus*, *Bacteroides*, *Fusobacterium*. **Ineffective:** *Pseudomonas*.

108.14.6 INDICATIONS.

Skin and soft tissue, intraabdominal, orthopedic, and genitourinary infections caused by susceptible bacteria. Can substitute wherever amoxicillin-clavulanate is indicated and a parenteral formulation is desired.

108.14.7 CONTRAINDICATIONS.

Reduce dose in renal failure. Animals with known penicillin hypersensitivity.

108.14.8 ADVERSE REACTIONS.

Local pain with IM; thrombophlebitis or systemic allergic reactions with IV; diarrhea; vomiting; seizures with rapid IV infusions; increased hepatic transaminases. See also AMPICILLIN.

108.14.9 INTERACTIONS.

Coadministration of ampicillin and sulbactam to dogs has no effect on the pharmacokinetics of either drug (Ch 34, ref. 225). Do not mix with aminoglycosides during administration.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection (sodium)	1.5g (total), 3.0g (total)	UnaSyn (Pfizer)

Dosage

INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Adult human	1.5–3g	IV	6	prn
Dog and cat	50 mg/kg	IV	6–8	prn

108.14.10 HANDLING.

Dilute in sterile water, 0.9% NaCl, 5% dextrose or lactated Ringer's. Stability of drug is shortest for dextrose (2 hr at room temperature and 4 hr when refrigerated) and 8 or 48 hr, respectively, for both NaCl or sterile water. Maximum storage time for lactated Ringer's is 24 hr refrigerated. Do not mix with aminoglycosides. For IM, can be reconstituted with 2% lidocaine (without epinephrine).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.14.1 ADMINISTRATION.

IV or IM. For IV dose, give slowly over 10-15 min or give with 50-100-ml infusion fluid over 15-30 min. For IM, give deep.

108.14.12 ADDITIONAL DOSAGES:

Intrabdominal infections, [Table 89-21](#).

108.15 AMPROLIUM

108.15.1 CLASS.

Thiamine analogue.

108.15.2 ACTION.

Antiprotozoal; inhibits parasite's thiamine utilization (first-generation schizont).

108.15.3 MORE INFORMATION.

[Chapter 81](#); [Table 81-2](#); reference: [Ch 71](#), ref. 49.

108.15.4 PHARMACOKINETICS.

Unavailable.

108.15.5 SPECTRUM.

Coccidia.

108.15.6 INDICATIONS.

Coccidiosis; especially convenient for treating litters of animals.

108.15.7 APPROVED USES.

Veterinary: coccidiosis in lambs, calves, and poultry.

108.15.8 CONTRAINDICATIONS.

Limit duration of therapy for 2 weeks.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.15.9 ADVERSE REACTIONS.

Anorexia, diarrhea, depression. Unpalatable as undiluted liquid or paste. Anorexia may develop in puppies that eat more than 300 mg of amprolium on a daily basis. Prolonged high dosages can cause neurologic signs of thiamine deficiency, characterized by cervical ventroflexion, anisocoria, seizures. Should these develop, stop treatment and administer thiamine 1-10 mg/day IM or IV immediately.

108.15.10 INTERACTIONS.

Excess dietary thiamine can interfere with drug effectiveness.

1205

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Oral crumbles	1.25%	<i>Corid</i> (Merck AgVet; Merial)
	Oral solution	9.6%	<i>Corid</i>
	Soluble powder	20%	<i>Corid</i>

1206

108.15.11 HANDLING.

Store all products at room temperature.

108.15.12 ADMINISTRATION.

Can add soluble powder in food or water. Use only food or water additives, not both! If given in drinking water, offer this as the sole source of liquids to drink. For animals refusing food or water additive, place in gelatin capsules containing 20% powder. Can treat pups 6 weeks of age and older.

Dosage					
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)	
Dogs					
Coccidiosis (in capsules)					
Small pups (<10kg adult wt)	100 mg total dose, 20% powder	PO, gelatin capsules	24	7–12	
Large pups (=10kg adult wt)	200 mg total dose, 20% powder	PO, gelatin capsules	24	7–12	
Coccidiosis (in food): pups or bitches	250–300 mg total dose, 20% powder, on food	PO, on food	24	7–12	
Coccidiosis (in water): pups or bitches	30 ml of 9.6% solution, 3.8L (1gal) of water; no other drinking water provided	PO, in water	24	7–10	
Cats					
Coccidiosis (on food)	300–400 mg/kg	PO	24	5	
	110–220 mg/kg	PO	24	7–12	
Coccidiosis (in water)	1.5 teaspoon/gallon H ₂ O	PO	24	10	
Coccidiosis (in combination)					
Amprolium	150 mg/kg	PO	24	14	
and Sulfadimethoxine	25 mg/kg	PO	24	14	

Infectious Diseases of the Dog and Cat, 3rd Edition

108.15.13 ADDITIONAL DOSAGES:

coccidiosis, [Table 81-2](#).

108.15.14 DISPENSING INFORMATION.

Report signs of diarrhea or neurologic problems immediately to your veterinarian.

108.16.1 ATOVAQUONE

108.16.1 CLASS.

Hydroxynaphthoquinone.

108.16.2 ACTION.

Antiprotozoal; blocks cytochromes, resulting in inhibited nucleic acid and adenosine triphosphate synthesis.

108.16.3 MORE INFORMATION.

See [Chapter 68](#); Antiprotozoal Chemotherapy, [Chapter 71](#); [Table 71-1](#); [Chapter 77](#); [Table 77-3](#); reference: [Ch 71](#), ref. 38; 44; 10b.

108.16.4 PHARMACOKINETICS.

Highly lipid soluble. Low absorption from GI tract. Bioavailability is increased three times with food and especially fatty meals. Little or no metabolism. Very low CSF penetration. Enterohepatic cycling with prolonged fecal elimination. Minimal urinary excretion.

108.16.5 SPECTRUM.

Pneumocystis: slightly lower efficacy than trimethoprim-sulfonamide (TMS). May add azithromycin for some *Babesia* (*B. gibsoni*) infections. Effective against *Toxoplasma* bradyzoites experimentally. Not very effective against *Cryptosporidium*.

108.16.6 INDICATIONS.

Pneumocystosis when resistance or toxicity to TMS has occurred. TMS is often used first because of lower toxicity. Used in combination with azithromycin for treatment of *Babesia gibsoni* infection in dogs.

108.16.7 APPROVED USES.

Human: *Pneumocystis* pneumonia, malaria.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.16.8 CONTRAINDICATIONS.

Avoid in pregnancy, lactation. If cannot be taken with food owing to GI upsets, then use another drug.

108.16.9 ADVERSE REACTIONS.

Nausea, vomiting, diarrhea, dermal hypersensitivity, fetotoxic, hypoglycemia, anemia, neutropenia.

108.16.10 INTERACTIONS.

Competes for plasma protein binding with many drugs, but others such as diphenylhydantoin are not affected. Rifampin decreases activity. Rifampin and metoclopramide reduce its plasma concentrations.

1206

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	250 mg (discontinued in U.S.)	<i>Mepron</i> (Glaxo Wellcome)
	Oral solution	150 mg/ml	<i>Mepron</i>

1207

108.16.11 INTERNATIONAL PREPARATIONS.

Wellvone.

108.16.12 HANDLING.

Store in airtight containers at controlled room temperature.

108.16.13 ADMINISTRATION.

Absorption improved when given with meals (especially fatty). In people, >23 g of fat per meal is recommended.

Dosage^a				
INDICATIONS (Dogs)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Pneumocystosis	13.3 mg/kg ^b	PO	8	21
<i>Babesiagibsoni</i>	30 mg/kg	PO	12	7 ^c
	13.3 mg/kg	PO	8	10 ^d

a Maximum dose per administration is 750 mg. To facilitate absorption, administer with a fatty meal each time dose is given.

b Extrapolated from human dose.

c Parasite disappeared from blood after treatment; however PCR was still positive and the parasite was visible again after 30 days (Ch 71, ref. 56a).

d Ch 71, ref. 10b. In combination with azithromycin, this drug eliminated the infection or suppressed the parasitemia below the level of detection of organisms by PCR when dogs were monitored for up

Infectious Diseases of the Dog and Cat, 3rd Edition

to 120 days posttreatment. Many dogs had been treated previously with either diminazene or imidocarb without success.

108.16.14 ADDITIONAL DOSAGES.

Pneumocystosis, [Table 68-2](#); babesiosis, [Table 77-3](#).

108.16.15 DISPENSING INFORMATION.

Administer tablet with fat such as butter, tuna oil, ice cream, or meat fat.

108.17.1 AZITHROMYCIN

108.17.1 CLASS.

Macrolide. More stable and better absorbed than the parent drug erythromycin.

108.17.2 ACTION.

Bacteriostatic; inhibits bacterial RNA-dependent protein synthesis by binding to 50s subunit.

108.17.3 MORE INFORMATION.

CLARITHROMYCIN; references: [Ch 34](#), ref. 175; [Ch 34](#), ref. 344.

108.17.4 PHARMACOKINETICS.

Better absorption and tissue penetration than erythromycin; more stable in gastric acid than erythromycin. Food decreases bioavailability by up to 50%; however, with fasting, 97% absorbed in dog ([Ch 34](#), ref. 344); 58% absorbed PO in cats ([Ch 34](#), ref. 175) compared with 37% to 52% absorbed in people. Reaches higher concentrations in tissues, phagocytes, and macrophages than in blood, with slow release and antibacterial activity up to 4 days after single dose. Enters tissue fibroblasts and lysosomes of phagocytes. Successive doses increase tissue saturation. Tissue concentrations generally exceed those in plasma by 10-100 times. Transported by neutrophils to sites of inflammation. Concentrations up to 150 times blood levels in sputum, lung, liver, tonsils, nasal sinuses, stomach, kidney, female genital tract, prostate. Crosses the placenta and excreted in milk. Levels in brain and eye are lower than in other tissues but exceed those in blood. High tissue concentrations (5-100 times plasma) are sustained for a period after serum concentrations have declined. Biliary excretion (>50%) of unchanged drug is major route of elimination and metabolites are inactive. Only 6% urinary excretion.

108.17.5 SPECTRUM.

Gram positive: Some *Streptococcus*, variable *Staphylococcus*. **Gram negative:** *Salmonella*, *Bordetella*, *Helicobacter*, *Bartonella*. **Anaerobes:** *Propionibacterium*, *Clostridium*, and *Bacteroides*. **Others:** *Mycoplasma*, *Mycoplasma haemofelis*, *Chlamydia*, *Borrelia*, *Toxoplasma*, *Isospora*, *Cryptosporidium*, *Babesia*, *Mycobacterium avium-intracellulare* complex but less active than clarithromycin. **More Effective:**

Infectious Diseases of the Dog and Cat, 3rd Edition

Most active macrolide against *Toxoplasma*, in vitro activity against *Cryptosporidium* and *Pneumocystis*.

Ineffective: Less active than erythromycin against *Staphylococcus* and *Streptococcus* but more active against gram-negative bacteria and some anaerobes.

108.17.6 INDICATIONS.

Cryptosporidiosis, toxoplasmosis (with pyrimethamine), Lyme borreliosis; *Mycobacterium leprae* and *Mycobacterium avium-intracellulare* infections. Lower respiratory tract infections, enteropathogenic bacterial infections. Substitute for erythromycin with less GI irritation, lower dosing, but higher cost. Used in combination with atovaquone to treat *Babesia gibsoni* infection in dogs (Ch 71, ref. 10b). Used to treat *Mycoplasma haemofelis* and *Bartonella henselae* infections in cats. Not effective for *Chlamydomydia felis* infection in cats (Ch 34, ref. 288a).

108.17.7 CONTRAINDICATIONS.

Some reduction in dosage with hepatic and/or biliary dysfunction. Less of a concern with renal failure. Avoid with previous macrolide hypersensitivity.

108.17.8 ADVERSE REACTIONS.

GI irritation (vomiting, diarrhea, abdominal pain), hepatomegaly, cholestatic hepatitis, increased liver enzymes.

108.17.9 INTERACTIONS.

Some reduction in serum concentration with oral antacids. See ERYTHROMYCIN.

1207

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Capsules (dihydrate)	250 mg	<i>Zithromax</i> (Pfizer)
	Oral suspension	100 mg/5 ml, 200 mg/5 ml	<i>Zithromax</i>
Dog and cat	Capsules	M7 200 mg	<i>Aziplus</i> (Labyes)

1208

108.17.10 INTERNATIONAL PREPARATIONS.

Azithrocin, Azitromax, Ribotrex, Trozocina.

108.17.11 HANDLING.

Store capsules at controlled room temperature (<30°C). Reconstituted solution should be stored between 5–30°C.

108.17.12 ADMINISTRATION.

Do not mix with food or give oral antacids concurrently.

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>Dosage</i>				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Pyoderma, Systemic infections	5–10	PO	12	5–7
Skin infections	10	PO	12–24	10–20
Lyme borreliosis	5	PO, IV	12	10–20
<i>Babesiagibsoni</i> infection	10–11.6	PO	24	10 ^a
Cats				
Mycoplasmosis	5–15	PO	24	5 ^b
Bacterial infections	7–15	PO	12	5–7 ^c
Dogs and Cats				
Coccidiosis and Cryptosporidiosis	15	PO	12	7

a Ch 71, ref. 10b. The drug was crushed and reformulated in gelatin capsules for proper dosing.

b Then every 48–72 hr (Ch 34, ref. 187).

c A dosage of 15 mg/kg, given daily for 3 days and then twice weekly, was not effective in clearing chronically infected cats of *Chlamydophila* infection (Ch 34, ref. 288a).

108.17.13 ADDITIONAL DOSAGES.

Lyme borreliosis, Table 45-5; babesiosis, Table 77-3; cryptosporidiosis, Table 82-2.

108.17.14 DISPENSING INFORMATION.

Administer without food; give 1 hr before or 2 hr after a meal.

108.18 AZTREONAM

108.18.1 CLASS.

Monobactam.

108.18.2 ACTION.

Bactericidal; interferes with cell wall synthesis, especially gram-negative bacteria resistant to β -lactamases.

108.18.3 MORE INFORMATION.

See Chapter 34; Table 34-1.

108.18.4 PHARMACOKINETICS.

Poor GI absorption and must be given parenterally (IV or IM). Enters most body fluids, including CSF. Penetrates and effective in abscesses. Primarily renally excreted as unchanged drug. Widely distributed in

Infectious Diseases of the Dog and Cat, 3rd Edition

body tissues, including gallbladder, liver, lungs, kidneys, heart, intestine, prostate. Reaches saliva, bronchial secretions, bile, pericardial, pleural, peritoneal, synovial fluids. Reaches CNS at therapeutic concentration. Eliminated by kidney with 60%-70% as active drug. Hepatic dysfunction does not alter excretion.

108.18.5 SPECTRUM.

Gram positive: poor. **Gram negative:** *Pseudomonas*, *Escherichia*, *Enterobacter*, *Klebsiella*, *Proteus*, *Serratia*, *Citrobacter*. Wide activity against *only* gram-negative organisms. Synergistic with aminoglycosides in vitro against most strains of Enterobacteriaceae and other gram-negative aerobic and facultative bacilli. Little or no activity on gram-positive or anaerobic bacteria and intestinal microflora. **Anaerobes:** poor. **More effective:** gram negative. **Ineffective:** most other bacteria.

108.18.6 INDICATIONS.

Serious gram-negative infections of the urinary and lower respiratory tracts, meningitis, septicemia, skin, soft tissue, intraabdominal, genital infections. Could be considered as an alternative to aminoglycosides to avoid nephrotoxicity or to fluoroquinolones in young animals. Often as a single agent for resistant gram-negative pathogens such as *Escherichia*, *Klebsiella*, *Serratia*, *Pseudomonas*. Examples are nosocomial pneumonia and aspiration pneumonia (the latter use, in combination with clindamycin). With mixed infections, it should be used in combination with drugs against anaerobic and gram-positive bacteria. Can also combine with erythromycin, metronidazole, penicillins, vancomycin as a substitute for aminoglycosides.

108.18.7 CONTRAINDICATIONS.

Must reduce dosages in renal dysfunction. No significant interactions with gentamicin, nafcillin, cephadrine, clindamycin, metronidazole. Concurrent therapy needed if gram-positive aerobe or an anaerobe is suspected. Certain antibiotics (e.g., cefoxitin or imipenem) may induce β -lactamases in some gram-negative organisms making concurrent therapy with β -lactams such as aztreonam ineffective.

108.18.8 ADVERSE REACTIONS.

Dermal hypersensitivity reactions, local phlebitis with IV, and swelling at injection site with IM. Nausea, vomiting, diarrhea, dermatologic eruptions, pancytopenia, seizures. Transient increase in hepatic transaminases; icterus from hepatotoxicity.

108.18.9 INTERACTIONS.

Add to ampicillin for urinary tract infection caused by *Escherichia*. Use with clindamycin and metronidazole for intraabdominal abscesses. Combination therapy with metronidazole for anaerobes and combine with vancomycin for gram positives.

1208

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	500 mg; 1g, or 2g/vial	Azactam (Bristol-Myers Squibb)

1209

Infectious Diseases of the Dog and Cat, 3rd Edition

108.18.10 INTERNATIONAL PREPARATIONS.

Primbactam.

108.18.11 HANDLING.

IV solutions of 2% (wt/vol) or less can be prepared with 0.9% NaCl or 5% dextrose. Can also add clindamycin phosphate, gentamicin, tobramycin sulfate, or cefazolin sodium. Stable for 48 hr at room temperature or 7 days when refrigerated. May be stored frozen at 20°C for 3 mo. Once thawed, should be used within 24-72 hr. Should not be refrozen. Incompatible in solution with AMB, nafcillin, cephadrine, metronidazole.

108.18.12 ADMINISTRATION.

For IM use, give deep in large muscle. It is well tolerated and need not be mixed with local anesthetics. IV use recommended for animals with bacteremia, abscesses, severe overwhelming infections. Give IV infusion slowly over 20-60 min.

Dosage

INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Human^a	1-2g total	IV, IM	8-12	prn

a For dogs and cats, an established dose is not available; the pediatric human dose has not been established, but the drug has a wide margin of safety.

108.18.13 ADDITIONAL DOSAGES.

None.

108.18 BACILLE CALMETTE-GUÉRIN (BCG): SEE [CHAPTER 2](#)

108.20 BAQUILOPRIM-SULFONAMIDE

108.20.1 CLASS.

Sulfonamide and diaminopyridine in 1 : 5 ratio.

108.20.2 ACTION.

Bactericidal, antibacterial, also antiprotozoal; folic acid synthesis inhibitors affecting two steps.

108.20.3 MORE INFORMATION.

See TRIMETHOPRIM-SULFONAMIDE, ORMETOPRIM-SULFONAMIDE and [Chapter 34](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.20.4 PHARMACOKINETICS.

Similar to trimethoprim- sulfonamide but longer half-life in dogs (15 hr baquiloprim; 13.2 hr sulfadimethoxine). Rapid and complete absorption; maintains antibacterial inhibitory effectiveness in plasma for up to 48 hr after a single dose. Both drugs are metabolized by the liver and are excreted in bile. Dogs do not acetylate sulfonamides, which reduces their nephrotoxicity. Unchanged drug is also excreted in the urine.

108.20.5 SPECTRUM.

See ORMETOPRIM-SULFONAMIDE, TRIMETHOPRIM-SULFONAMIDE. **Aerobes:** Synergistic against *Staphylococcus intermedius*, *Streptococcus canis*, *E. coli*, and *Proteus mirabilis*. **Anaerobes:** in vitro, but not in vivo; therefore, not recommended for anaerobic infections. **Others:** *Coccidia*. **Ineffective:** anaerobic infections.

108.20.6 INDICATIONS.

For coccidiosis, canine pyoderma and urinary tract infections.

108.20.7 CONTRAINDICATIONS.

Not for use in dogs with sulfonamide hypersensitivity, hepatic dysfunction, blood dyscrasias, or pregnancy. Not for use in cats.

108.20.8 ADVERSE REACTIONS.

Similar to TRIMETHOPRIM- SULFONAMIDE.

108.20.9 INTERACTIONS.

See TRIMETHOPRIM-SULFONAMIDE.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets ^a	600 mg (100 mg baquiloprim and 500 mg sulphamethoxine or sulphadimidine)	<i>Dazokan</i> (Merial)
		60 mg (10 mg baquiloprim and 50 mg sulphamethoxine or sulphadimidine)	<i>ZaquilanC</i> (Schering-Plough Animal Health)

^a Not available in the U.S.

108.20.10 HANDLING.

Store in airtight, light-proof containers at room temperature.

108.20.11 ADMINISTRATION.

Can be given with food. Supply plenty of water at all times.

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>Dosage</i>				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE (hr)	INTERVAL (days)	DURATION
Coccidiosis	30	PO	48	4
Urinary infections	30	PO	48	10
Pyoderma	30	PO	48	21 ^a

a Give drug every 24 hr for the first 2 days.

1209

108.20.12 ADDITIONAL DOSAGES.

1210

None.

108.20.13 DISPENSING INFORMATION.

This drug can be given with food. Make sure the animal has unlimited access to drinking water while on this medication.

108.21 CARBENICILLIN

108.21.1 CLASS.

Carboxypenicillin.

108.21.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.21.3 MORE INFORMATION.

See Penicillins, [Chapter 34](#); [Table 34-1](#).

108.21.4 PHARMACOKINETICS.

Carbenicillin is destroyed by gastric acid, resulting in poor GI absorption. Indanyl carbenicillin is more stable, being partially (30%-50%) absorbed. When given parenterally, enters many tissues and body fluids in therapeutic concentration but only in the CSF with meningeal inflammation. Primarily (80%) renal excretion of unchanged drug. Low biliary excretion. Difficult to achieve sufficient blood concentration when given PO so reserved for treatment of urinary tract infection. Carindacillin, the indanyl ester, is better absorbed from the GI tract and is hydrolyzed to the active drug after absorption. Its use is limited to treatment of urinary tract infections caused by *Pseudomonas* and other susceptible gram-negative organisms.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.21.5 SPECTRUM.

Gram positive: *Staphylococcus*. **Gram negative:** *Escherichia*, *Proteus*, *Salmonella*, *Enterobacter*, *Citrobacter*, *Pseudomonas*, *Serratia*. **Anaerobes:** *Clostridium*, *Peptococcus*, *Peptostreptococcus*, *Bacteroides*, *Fusobacterium*.

108.21.6 INDICATIONS.

Parenteral formulation for treating systemic infections. Acute and chronic upper and lower urinary tract infection, including prostatitis and cystitis. Oral use should be restricted in treating urinary infections caused by gram-negative bacteria or *Pseudomonas* strains resistant to other drugs, but high dosages are needed for effective therapy. Ticarcillin or piperacillin are sometimes preferred over this drug.

108.21.7 CONTRAINDICATIONS.

Dosage reduction in renal failure.

108.21.8 ADVERSE REACTIONS.

GI side effects. Occasional hypersensitivity reactions, reversible neutropenia, occasional eosinophilia, hypokalemia. Neurotoxicity at high doses, with impaired renal excretion. In people, platelet malfunction can result in prolonged bleeding times.

108.21.9 INTERACTIONS.

Inactivates aminoglycosides in vitro. Can be given with aminoglycosides by alternative route to enhance activity against *Pseudomonas*.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Film-coated oral tablets (indanyl sodium)	500 mg total containing 382 mg, carbenicillin	<i>Geocillin</i> (Roerig)
	Parenteral powder (sodium) ^a	1-g, 2-g, 5-g, 10-g vials	<i>Geopen</i> (Roerig), <i>Pyopen</i> (SmithKline Beecham)

^a No longer available in U.S.

108.21.10 INTERNATIONAL PREPARATIONS.

Carbapen, *Carindapen*.

108.21.11 HANDLING.

Oral tablets should be stored in dry, airtight containers at room temperature and are stable indefinitely. A suspension can be prepared by crushing six, 382-mg tablets and adding sufficient water to bring the volume to 60 ml. Shaken and refrigerated, the 38.2 mg/ml solution is stable for 3 days. Because of the bitter taste, the solution or crushed tablets can be added to a syrup before administration. The powder for parenteral injection is stored at room temperature and once reconstituted is stable for 24 hr at room temperature, 72 hr if

Infectious Diseases of the Dog and Cat, 3rd Edition

refrigerated and 1 mo if frozen. With IV solution, up to 15% of solution activity is reduced in 4 hr at 25°F and NaCl but up to 8 hr in dextrose solutions. IV solution is incompatible with AMB, chloramphenicol, gentamicin, kanamycin, carbenicillin, oxytetracycline.

108.21.12 ADMINISTRATION.

Parenteral solution can be given IM and can be reconstituted with lidocaine (0.5% without epinephrine) or IV as a slow infusion. Minimum dilution is 1 g/7 ml given over a minimum of 15 min.

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Urinary	22–33	PO	8	7–10
Systemic infections	22–33	IV	6–8	prn

108.21.13 ADDITIONAL DOSAGES.

Gram-negative bacteria, [Table 37-3](#); bacteremia and endocarditis, [Table 87-6](#); respiratory disease, [Table 88-8](#).

1210

108.22 CASPOFUNGIN

1211

108.22.1 CLASS.

Echinocandin. Water soluble derivative of pneumocandin B

108.22.2 ACTION.

Cyclic hexapeptide that interferes with cell wall biosynthesis by noncompetitive inhibition of 1,3-β-D-glucan synthase, an enzyme involved in fungal but not mammalian cell wall synthesis. Inhibits hyphal tip and branch point growth converting mycelium to small clumps. Generally fungicidal in vitro but fungistatic against *Aspergillus*. Antifungal and fungicidal against hyphal organisms such as dermatophytes, *Aspergillus*, and *Sporothrix*. Also effective against yeasts such as a variety of *Candida* spp. Fungal growth required for effectiveness.

108.22.3 MORE INFORMATION.

Reference [Ch 57](#), ref. 126; 29.

108.22.4 PHARMACOKINETICS.

Poorly absorbed from the GI tract and must be given parenterally. Liver metabolizes drug; however not via the cytochrome P-450 enzyme system, so has less interaction with other hepatically metabolized drugs. Only small amounts of unchanged drug appear in the urine. Daily IV administration leads to drug accumulation with a steady state by 2–3 weeks.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.22.5 SPECTRUM.

Activity against mold (filamentous), dimorphic, and yeast fungi. It has been effective against mouse infections with *Pneumocystis carinii* (Ch 57, ref. 29).

108.22.6 INDICATIONS.

Has been used in AMB and azole-resistant aspergillosis or candidiasis in people. Only approved for the treatment of invasive aspergillosis for people who are refractory to, or do not tolerate, conventional antifungals.

108.22.7 CONTRAINDICATIONS.

Reduce dosage in hepatic dysfunction.

108.22.8 ADVERSE REACTIONS.

Histamine-mediated reactions, observed in people, are characterized by urticaria and pruritus. Injection-site irritation, vomiting, diarrhea, and increased serum ALP have also been observed.

108.22.9 INTERACTIONS.

Clearance of the drug is reduced by concurrent cyclosporin treatment. Dexamethasone, phenytoin, and rifampicin reduce caspofungin concentrations in people.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	IV solution	50 mg, 70 mg vials	Cancidas (Merck)

108.22.10 INTERNATIONAL PREPARATION.

Same.

108.22.11 HANDLING.

The vial, which is stored refrigerated, is equilibrated to room temperature. Normal saline is added to the final designated concentration, and the solution is mixed until it is clear. The concentration is 5-7 mg/ml final concentration. The calculated dose is added to a 250-ml or greater bag of normal saline.

108.22.12 ADMINISTRATION.

Infused over 1 hr. Should not be mixed or co-infused with other medications. Average duration of therapy is 1 mo.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage

INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Invasive aspergillosis	50 mg ^a	IV	24	56–84

a Extrapolated total human daily dose. This might be suitable for very large dogs; however it is likely that a lower dose will be indicated. A daily dose of 70 mg is generally used for loading the first day in treatment of human infections.

108.22.13 ADDITIONAL DOSAGES.

None.

108.22.14 DISPENSING INFORMATION.

Reconstituted vials of drug are stable for 1 hr refrigerated. The diluted drug in infusion bag is stable for 24 hr.

108.23.1 CEFACLOR

108.23.1 CLASS.

Second-generation cephalosporin.

108.23.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.23.3 MORE INFORMATION.

See Cephalosporins, [Chapter 34](#); [Table 34-4](#).

108.23.4 PHARMACOKINETICS.

Well absorbed after oral administration to fasting animals, but absorption is delayed with feeding. The majority of drug is excreted in the urine unchanged.

108.23.5 SPECTRUM.

Gram positive: *Staphylococcus*, *Streptococcus*. **Gram negative:** *Escherichia*, *Salmonella*, *Klebsiella*, *Proteus mirabilis*. **Anaerobes:** gram negatives, including *Bacteroides*. **Ineffective:** *Pseudomonas*, *Acinetobacter*, *Enterococcus*, *Serratia*, other *Proteus*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.23.6 INDICATIONS.

Otitis media, sinusitis caused by β -lactamase-resistant organisms, lower respiratory tract infections, pyoderma, urinary infections. More active than first-generation drugs against gram-negative bacteria.

108.23.7 CONTRAINDICATIONS.

Known cephalosporin or penicillin hypersensitivity. Reduce dosages in renal failure.

108.23.8 ADVERSE REACTIONS.

Systemic allergy, previous hypersensitivity, vomiting, diarrhea, increased liver enzymes, mild eosinophilia.

108.23.9 INTERACTIONS.

Potentiates anticoagulant rodenticides.

1211

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules	250 mg, 500 mg	Ceclor (Eli Lilly), generic (various)
	Powder for oral suspension	125 or 325 mg/5 ml	Ceclor; generic

1212

108.23.10 INTERNATIONAL PREPARATIONS.

Alfatil, Cefabiocin, Cef-Diolan, Distaclor, Kefolor, Pancef.

108.23.11 HANDLING.

Refrigerate suspension after reconstituting; stable for 2 weeks. No definitive data exist for freezing and thawing of oral suspension, but it is thought to be unstable after a similar time period after thawing. Store capsules at controlled room temperature (15–30°C).

108.23.12 ADMINISTRATION.

Administer to fasting animal because food in stomach interferes with absorption. Maximum daily dose is 1 g. Twice-daily dosing has not been as effective as three-times daily dosing in human clinical studies.

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Skin, soft tissue infections	7	PO	8	21–30
Systemic, lower respiratory infections	10–13	PO	8	14

Infectious Diseases of the Dog and Cat, 3rd Edition

108.23.13 ADDITIONAL DOSAGES.

None.

108.23.14 DISPENSING INFORMATION.

Store liquid in refrigerator and shake well before using. Discard unused portions after 2 weeks. Give at least 1 hr before or 2 hr after meals.

108.24.1 CEFADROXIL

108.24.1 CLASS.

First-generation cephalosporin (longer acting derivative of cephalexin).

108.24.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.24.3 MORE INFORMATION.

See Cephalosporins, [Chapter 34](#); [Tables 34-3](#) and [34-4](#).

108.24.4 PHARMACOKINETICS.

Rapidly absorbed after oral administration even in presence of food. Feeding may slow the onset of peak absorption and maintain higher serum levels of drug for longer periods in dogs ([Ch 34](#), ref. 57). Stable in the presence of gastric acid. More than 90% excreted unchanged in the urine within 24 hr. Slower absorption and longer excretion period than cephalexin or cephadrine, allowing for 12-hr dosing and higher serum levels.

108.24.5 SPECTRUM.

Gram positive: β -hemolytic *Streptococcus*, *Staphylococcus*, and others. **Gram negative:** *Escherichia*, *Proteus mirabilis*, *Klebsiella*, *Pasteurella*. **Anaerobes:** poor activity. **Ineffective:** most *Enterococcus*, *Enterobacter*, other *Proteus*, *Acinetobacter*.

108.24.6 INDICATIONS.

Urinary tract infections caused by susceptible gram-negative bacteria. Skin (pyoderma), respiratory, orthopedic, or systemic infections caused by *Staphylococcus* or *Streptococcus*. Good absorption and decreased frequency of administration are advantages over other first-generation cephalosporins.

108.24.7 CONTRAINDICATIONS.

Known cephalosporin or penicillin hypersensitivity; reduce dose in renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.24.8 ADVERSE REACTIONS.

Vomiting, diarrhea, depression, anorexia, polydipsia, polyuria, salivation ([Ch 34](#), ref. 209). Hypersensitivity reactions. No teratogenic or infertility problems have been seen in laboratory animals receiving high doses.

108.24.9 INTERACTIONS.

False-positive Coombs' test results in people. False-positive urine glucose with copper reduction (Clinitest) methods.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral suspension (monohydrate)	125 mg, 250 mg, 500 mg/5 ml	<i>Duricef</i> (Mead-Johnson), <i>Ultracef</i> (Bristol), generics (various)
	Capsules (monohydrate)	50 mg, 100 mg, 200 mg, 500 mg 1g	<i>Duricef</i> , <i>Ultracef</i> , generics
Veterinary	Oral tablets	50 mg, 100 mg, 200 mg, 1g	<i>Cefa-tabs</i> (Fort Dodge, Willows Francis Vet), <i>Cefa-cure</i> (Mycofarm)
	Oral liquid	50 mg/ml in 15-ml and 50-ml dropper bottles	<i>Cefa-drops</i> (Fort Dodge)

108.24.10 INTERNATIONAL PREPARATIONS.

Bidocef, *Cefadril*, *Ceoxil*, *Cephos*, *Crenodyn*, *Duracef*, *Kefroxil*, *Moxacef*, *Oracéfal*, *Sedral*.

108.24.11 HANDLING.

Shake suspension before use; keep container tightly closed in refrigerator; discard unused portion after 14 days. Store tablets in airtight, moisture-proof containers at room temperature.

108.24.12 ADMINISTRATION.

Food does not reduce or delay absorption. Liquid has orange-pineapple flavor.

1212

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Urinary tract infections				
<i>Cat</i>	22	PO	24	≥21
<i>Dog</i>	11–22	PO	12	7–30
Skin, pyoderma	22–35	PO	12	3–30
Systemic, orthopedic infections	22	PO	8–12	30

1213

108.24.13 ADDITIONAL DOSAGES.

Canine pyoderma, [Table 85-3](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.24.14 DISPENSING INFORMATION.

Can be given without regard to meals. Giving with food may help reduce GI side effects.

108.25.1 CEFAZOLIN

108.25.1 CLASS.

First-generation cephalosporin.

108.25.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.25.3 MORE INFORMATION.

See Cephalosporins, [Chapter 34](#); [Table 34-4](#); references: [Ch 34](#), ref. 235; 318.

108.25.4 PHARMACOKINETICS.

Not absorbed from GI tract. Given parenterally, it enters many tissues and body fluids. Primarily excreted by kidneys unchanged in urine. Some is excreted in bile to achieve therapeutic concentrations. Longer half-life and ability to reach higher tissue concentrations gives advantage for surgical prophylaxis over cephalothin and cephapirin in which aerobic infections are anticipated. Good levels achieved in bone, especially with inflammation. Does not penetrate CSF, even with inflamed meninges.

108.25.5 SPECTRUM.

Gram positive: *Staphylococcus*, β -hemolytic *Streptococcus*. **Gram negative:** some *Enterobacter*, *Escherichia*, *Klebsiella*, *Proteus mirabilis*. **Anaerobes:** poor activity. **Ineffective:** *Proteus vulgaris*, *Enterobacter cloacae*, *Serratia*, *Pseudomonas*.

108.25.6 INDICATIONS.

Surgical prophylaxis, for prolonged orthopedic procedures, for reducing postoperative infections of surgical wounds and intraabdominal or biliary surgery. Greatest activity against *Escherichia* and *Klebsiella* compared with others in its class. Respiratory, genitourinary, biliary tract, bone, and joint infections, sepsis.

108.25.7 CONTRAINDICATIONS.

Previous penicillin or cephalo- sporin hypersensitivity. Reduce dose in renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.25.8 ADVERSE REACTIONS.

Few; hypersensitivity to cephalosporins, diarrhea, neutropenia, leukopenia, eosinophilia, thrombocytopenia, increased liver enzymes, phlebitis with IV, pain on IM injection.

108.25.9 INTERACTIONS.

False-positive urine glucose measurements with nonenzymatic methods.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection	500 mg, 1g, 5g, 10g, 20g	<i>Ancef</i> (SmithKline Beecham), <i>Kefzol</i> (Eli Lilly)

108.25.10 HANDLING.

Reconstitute in sterile water for IV; can also use 0.9% NaCl for IM; however, not advised because crystals may form in NaCl solution. Stable for 24 hr at room temperature and 96 hr when refrigerated; up to 12 weeks if frozen. Can be mixed with 5% dextrose, lactated Ringer's, 0.9% NaCl for infusion. Avoid admixture with many other drugs, including aminoglycosides, tetracyclines, macrolides, barbiturates. Powder has been mixed in acrylic bone cement for prophylaxis with surgical implants.

108.25.11 ADMINISTRATION.

Inject IM in large muscle mass. Inject IV slowly into vein or through IV tubing access over 3-5 min. For surgical prophylaxis, give IV dose once immediately before surgical incision and repeat SC 6 hr later (Ch 34, ref. 318).

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Surgical prophylaxis	8	IV	1	^a
	20–22	IV	2	^a
Systemic infections	5–25	IM, IV	6–8	prn
Orthopedic infections	22	IV, IM, SC	6–8	≥7
Sepsis, bacteremic	15–25	IV, IM, SC	4–8	≥7
Cats				
Systemic infections	33	IM, IV	8–12	prn
^a Just before and during surgery (Ch 86, ref. 131). If surgery lasts >90 min then a second dose is given.				

1213

108.25.12 ADDITIONAL DOSAGES.

1214

Parvoviral enteritis, Table 8-1; endotoxemia, Table 38-6; musculoskeletal infections, Table 86-4; bacteremia and endocarditis, Table 87-6; respiratory infections, Table 88-8; topical intraocular use, Table 93-4.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.26.1 CEFEPIME

108.26.1 CLASS.

Fourth-generation cephalosporin.

108.26.2 ACTION.

Bactericidal; has enhanced ability to penetrate outer cell membrane of gram-negative bacteria. Has better gram-positive coverage than third-generation cephalosporins.

108.26.3 MORE INFORMATION.

See Cephalosporins, [Chapter 34](#); [Table 34-4](#).

108.26.4 PHARMACOKINETICS.

Poor oral bioavailability. Higher blood levels after IV than IM use. Penetrates blood-CSF barrier. Renal excretion with minimal metabolism.

108.26.5 SPECTRUM.

Gram positive: many, including *Staphylococcus*. **Gram negative:** many Enterobacteriaceae. **Anaerobes:** variable activity. **Others:** *M. avium-intracellulare* complex. **Most effective:** resistant gram-negative bacteria. Similar to third-generation drugs; however, good antipseudomonal activity similar to ceftazidime. Good β -lactamase stability and good gram-positive activity. Has activity against some Enterobacteriaceae that are resistant to cefotaxime and ceftazidime. **Ineffective:** not active against methicillin-resistant strains of *Staphylococcus*, *Enterobacter*, *Clostridium*, *Bacteroides*.

108.26.6 INDICATIONS.

Severe infections of lower respiratory, urinary, and female reproductive tracts; skin and soft tissue infections; pneumonia; meningitis. For treatment of infections caused by bacteria resistant to other antibiotics.

108.26.7 APPROVED USES.

Gram-negative pneumonia.

108.26.8 CONTRAINDICATIONS.

Reduced dosage in renal failure. Previous hypersensitivity to cephalosporins.

108.26.9 ADVERSE REACTIONS.

Eosinophilia, leukopenia, phlebitis, increased serum hepatic enzyme activities, gastrointestinal signs.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.26.10 INTERACTIONS.

In vitro synergy with quinolones, aminoglycosides, β -lactamase inhibitors. Antagonistic activity with imipenem or polymyxin B. Combine with metronidazole or clindamycin in intraabdominal infections. Should closely monitor renal function in animals receiving cefepime with aminoglycosides.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection (as hydrochloride)	500 mg, 1g, 2g	Maxipime (Bristol-Myers Squibb)

108.26.11 INTERNATIONAL PREPARATIONS.

Axépin.

108.26.12 HANDLING.

Reconstitute powder with 0.9% NaCl, 5% dextrose, 0.5%-1% lidocaine, or bacteriostatic water.

108.26.13 ADMINISTRATION.

IV; give slowly over 30 min. Can add to 0.9% NaCl, 5% dextrose, and lactated Ringer's.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (HR)	DURATION (days)
Dogs and Cats^a	40 mg/kg	IV, IM	6	prn
^a This is the IV dose for treating sensitive bacteria as determined by pharmacokinetic data in dogs (Ch 34, ref. 122). This dosage will maintain plasma concentrations >2 mg/ml for the entire period.				

108.26.14 ADDITIONAL DOSAGES.

None.

108.26.15 DISPENSING INFORMATION.

Diarrhea may develop during use of this drug.

108.27 CEFIXIME

108.27.1 CLASS.

Third-generation cephalosporin for oral administration.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.27.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis. Very stable to β -lactamase.

108.27.3 MORE INFORMATION.

See CEFPODOXIME; references: [Ch 34](#), ref. 26; 215

108.27.4 PHARMACOKINETICS.

First licensed third-generation *oral* cephalosporin: rapid oral absorption in absence of food; food impairs its bioavailability in dogs; bioavailability is 40%-55%; suspension achieves higher blood concentrations than tablet; high serum protein binding; lower concentrations in tissues (uterus, ovaries) and fat; tissue concentration may increase with repeated dosing; very high levels in urinary tract. Eliminated in urine by glomerular filtration but reabsorbed by tubules to prolong activity ([Ch 34](#), ref. 26). The long half-life (7 hr) of cefixime in dogs compared to other cephalosporins relates to this renal reabsorption.

108.27.5 SPECTRUM.

Gram positive: *Streptococcus*, *Rhodococcus*. **Gram negative:** *Escherichia*, *Proteus*, *Klebsiella*. **Anaerobes:** minimal activity (unlike other third-generation drugs). **Ineffective:** *Pseudomonas*, *Enterococcus*, *Staphylococcus*, *Actinomyces*, *Bordetella*, *Listeria*, *Enterobacter*, *Clostridium*, *Bacteroides*.

108.27.6 INDICATIONS.

Urinary and upper respiratory tract infections (pharyngitis, bronchitis) caused by susceptible organisms and resistant to more commonly used drugs. One of few orally administered third-generation cephalosporins.

1214

Quinolones and aminoglycosides are often more effective against gram-negatives than cefixime. In addition susceptibility, of *E. coli* isolated from dogs to cefixime, has decreased over the last decade ([Ch 34](#), ref. 285).

1215

108.27.7 CONTRAINDICATIONS.

Reduce dosage in renal failure.

108.27.8 ADVERSE REACTIONS.

GI disturbances, abdominal pain, vomiting, dermal hypersensitivity (fever, urticaria, pruritus).

108.27.9 INTERACTIONS.

False-positive results with nonenzymatic test results for urine glucose. False-positive urine ketone test results using nitroprusside.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets (film coated as trihydrate)	200 mg, 400 mg	<i>Supran</i> (Teva Pharm), <i>Suprax</i> (Lederle)
	Oral suspension (strawberry flavor)	100 mg/5 ml	<i>Suprax</i>

108.27.10 INTERNATIONAL PREPARATIONS.

Aerocef, Cefspan, Cephoral, Denvar, Fixim, Necopen, Oroken, Tricef, Unixime.

108.27.11 HANDLING.

Store capsules in airtight containers at room temperature.

108.27.12 ADMINISTRATION.

Possibly give once daily in urinary infections as a result of long half-life.

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE, (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Urinary infections	5.0	PO	12–24	7–14 ^a
Respiratory, systemic infections	12.5	PO	12	7–14 ^a
^a Duration may vary according to chronicity of infection.				

108.27.13 ADDITIONAL DOSAGES.

None.

108.27.14 DISPENSING INFORMATION.

Give on an empty stomach.

108.28 CEFOPERAZONE SODIUM

108.28.1 CLASS.

Third-generation cephalosporin.

108.28.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.28.3 MORE INFORMATION.

See Cephalosporins, [Chapter 34](#); [Table 34-4](#).

108.28.4 PHARMACOKINETICS.

Longer half-life than others in its class permitting 12-hr dose interval. Not absorbed from the GI tract. After parenteral injection, distributed widely in tissues and body fluids. Erratic penetration of the CNS and CSF, better if meningitis present. Primarily (70%) excreted in bile; remainder unchanged in urine.

108.28.5 SPECTRUM.

Gram positive: *Staphylococcus* spp, *Streptococcus*, but less active against these than other cephalosporins.

Gram negative: *Escherichia*, *Klebsiella*, *Enterobacter*, *Proteus*, *Serratia*, *Pseudomonas*. Second most active cephalosporin against *Pseudomonas*. **Anaerobes:** *Peptococcus*, *Peptostreptococcus*, *Clostridium*, *Bacteroides*.

108.28.6 INDICATIONS.

Severe infections, resistant to other drugs, in the lower respiratory tract, peritoneal cavity, skin, genital and urinary tracts, and septicemia. *Pseudomonas* infections.

108.28.7 CONTRAINDICATIONS.

Avoid or reduce dosage with hepatic failure or biliary obstruction. Normal dosage in renal failure.

108.28.8 ADVERSE REACTIONS.

Local or systemic hypersensitivity; vitamin K deficiency and hemorrhage or neutropenia with prolonged administration; transient diarrhea; azotemia or serum hepatic enzyme increases.

108.28.9 INTERACTIONS.

Do not mix directly with an aminoglycoside, and if both are given through the same IV set, use this drug first and flush in between.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Sterile crystalline powder for injection or premixed iso-osmotic solution	1-g, 2-g vials	<i>Cefobid</i> (Pfizer, Roerig)

108.28.10 INTERNATIONAL PREPARATIONS.

Bioperazone, *Cefazone*, *Céfobis*, *Cefogram*, *Cefoneg*, *Dardum*, *Ipazone*, *Mediper*, *Perocef*, *Zoncef*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.28.1.1 HANDLING.

Protect sterile powder from light before reconstitution. Reconstitute with 5% dextrose or lactated Ringer's. 1215

Can dilute with epinephrine-free lidocaine for IM use. Stable for 24 hr at room temperature, 5 days if refrigerated, or 3-5 weeks when frozen. IM or IV solution is stable for 48 hr at room temperature and 5 days in refrigeration (5°C) and 3 weeks if frozen (−20°C). Do not refreeze once thawed. 1216

108.28.1.2 ADMINISTRATION.

Intermittent infusions should be given over 15-30 min. Continuous infusions should be given at a concentration of 2-25 mg/ml.

<i>Dosage</i>				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Soft tissue infections	22 ^a	IV, IM	12	7–14
Bacteremia, sepsis	22 ^a	IV, IM	6–8	prn

a Human dose extrapolation.

108.28.1.3 ADDITIONAL DOSAGES.

None.

108.29. CEFOTAXIME SODIUM

108.29.1 CLASS.

Third-generation cephalosporin.

108.29.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.29.3 MORE INFORMATION.

See [Chapter 34](#), Cephalosporins; [Table 34-4](#); Reference [Ch 34](#), ref. 361a.

108.29.4 PHARMACOKINETICS.

Not absorbed from GI tract. Well absorbed after IM administration. When given parenterally, attains therapeutic concentration in many tissues, including prostate, bone, and both pleural and peritoneal fluids. Enters the aqueous humor and CSF. Relatively rapid clearance of the drug in septicemic dogs given 10 mg/kg or 20 mg/kg doses requires a dosage interval of ≤12 hr, as the half-life at 10 mg/kg was 0.8, 1.48, and 1.52 hr for the IV, SC, and IM routes, respectively ([Ch 34](#), ref. 361a). Metabolized by hepatic esterases to a

Infectious Diseases of the Dog and Cat, 3rd Edition

biologically active form, desacetylcefotaxime, which prolongs the drug's clinical effect. Attains therapeutic levels in meninges with or without inflammation. Primarily renal excretion.

108.29.5 SPECTRUM.

Gram positive: *Streptococcus* and *Staphylococcus* (with and without β -lactamase). More active than other third-generation drugs. **Gram negative:** most Enterobacteriaceae: *Acinetobacter*, *Citrobacter*, *Escherichia*, *Klebsiella*, *Proteus*, *Serratia*, some *Pseudomonas*. Synergistic with aminoglycosides. **Anaerobes:** variable activity against *Bacteroides*, *Clostridium*, *Fusobacterium*, *Peptococcus*, *Peptostreptococcus*. **Others:** *Borrelia*. **More effective:** most active third-generation drug against *Staphylococcus*, *Leptospira*. **Ineffective:** *Listeria*.

108.29.6 INDICATIONS.

Initial empiric therapy in bacterial sepsis. Also good for problematic or recurrent lower respiratory tract, genitourinary, soft tissue, skin, and intraabdominal infections, bone and joint and CNS infections, and surgical prophylaxis. Inconsistent against *Pseudomonas*.

108.29.7 CONTRAINDICATIONS.

Reduce dose in renal failure.

108.29.8 ADVERSE REACTIONS.

Local irritation, systemic hypersensitivity, GI signs. Altered bowel flora with diarrhea. Occasional granulocytopenia, increased nephrotoxicity when combined with aminoglycosides or other cephalosporins. Cardiac arrhythmias if infused too rapidly IV.

108.29.9 INTERACTIONS.

Possibly synergistic with aminoglycosides but should not be mixed together for simultaneous administration.

108.29.10 INTERNATIONAL PREPARATIONS.

Cefacron, *Zariviz*.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection	1g, 2g	<i>Claforan</i> (Hoechst-Roussel)
	Frozen, premixed in 5% dextrose in plastic containers	1g, 2g	<i>Claforan</i>

108.29.11 HANDLING.

Store powder at room temperature, reconstitute with sterile water. Stable for 24 hr at room temperature, 10 days when refrigerated, and 13 weeks if frozen. When further diluted in IV fluids, only stable for 5 days if refrigerated. Unstable in alkaline solutions. Stable in 0.9 NaCl, 5% dextrose, lactated Ringer's. Powder and solutions darken with storage without affecting activity.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.29.12 ADMINISTRATION.

IV or IM, dosing interval shortens with increasing severity of infection. Never mix directly with aminoglycosides; can combine as separate infusions. Solution of 1 g Claforan in 14 ml of sterile water is isotonic. For IM give deep into large muscle and aspirate before injection. Use multiple sites with dose greater than 1 g. For IV infusion, 1 or 2 g may be reconstituted in 50 or 100 ml of 0.9% saline or 5% dextrose and be given over 30 min. IV preferred for septicemia, peritonitis, meningitis, or immunocompromised animals. Administer IV, 1 or 2 g in 10 ml sterile water over 3-5 min but not concurrently with other solutions. For surgical prophylaxis, give dose 30-90 min before operative incision. Maximum dose: 1 g for medium-size dogs, 2 g for large dogs.

1216

1217

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Soft tissue infections	10-20	IV, IM, SC	8	≤7
Orthopedic infections	20-40	IV, IM, SC	8-12	≤7
Severe bacteremia ^a	20-80	IV	6-8	prn
Cats				
Severe bacteremia	20-80	IV, IM	6	prn

a IN septicemic dogs given 10-20 mg/kg IV, SC, or IM the drug was rapidly cleared with a maximum allowable dosage interval of 12 hours (Ch 34, ref. 361a).

108.29.13 ADDITIONAL DOSAGES.

Gram-negative infections, Table 37-3; Lyme borreliosis, Table 45-5; nocardiosis, Table 49-3; bacteremia and endocarditis, Table 87-6; respiratory infections, Table 88-8; intraabdominal infections, Table 89-21; CNS infections, Table 92-5.

108.30 CEFOTETAN DISODIUM

108.30.1 CLASS.

Cephameycin, like CEFOXITIN, with similar properties to second-generation cephalosporin.

108.30.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis inhibitor.

108.30.3 MORE INFORMATION.

See CEFOXITIN; Chapter 34; reference: Ch 34, ref. 297.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.30.4 SPECTRUM.

See CEFOXITIN.

108.30.5 INDICATIONS.

Cost-effective replacement for cefoxitin. See CEFOXITIN.

108.30.6 CONTRAINDICATIONS.

See CEFOXITIN; prior penicillin or cephalosporin hypersensitivity. Reduce dose in renal failure.

108.30.7 ADVERSE REACTIONS.

Vomiting after IV bolus infusion. Cutaneous eruptions, angioedema. Coagulation disturbances with vitamin K antagonism. Neutropenia, anemia, eosinophilia.

108.30.8 INTERACTIONS.

Potentiate aminoglycoside nephrotoxicity. Unpredictable synergism with penicillins.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	1g, 2g	<i>Cefotan</i> (Stuart Pharmaceuticals)

108.30.9 INTERNATIONAL PREPARATIONS.

Apacef, Ceftenon, Cepan, Darvilen, Yamatetan.

108.30.10 HANDLING.

Reconstitute with sterile water; for IM use can add lidocaine. For IV infusion, can add to 5% dextrose or 0.9% NaCl. Stable for 24 hr at room temperature, 96 hr if refrigerated, and at least 1 week if frozen. In dextrose 10% or Ringer's, with cefotetan 0.5 to 30 mg/ml, can freeze at -20°C for 30 weeks and thaw in microwave oven before use. Do not mix in solutions containing aminoglycosides.

108.30.11 ADMINISTRATION.

IV route preferred for bacteremia or severe infections. Bolus administration via IV catheter over 3-5 min. Flush catheter with heparinized saline (10 U/ml) after injection. Do not coadminister with other drugs. For surgical prophylaxis, begin infusion of 1 g 30-60 min before surgery.

108.30.12 ADDITIONAL DOSAGES.

Musculoskeletal infections, [Table 86-4](#); respiratory infections, [Table 88-8](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>Dosage</i>				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Soft tissue infections	30	SC	12	≤7
Bacteremia, sepsis	30	IV, SC	8	prn

1217

108.31.1 CEFOTETAN

1218

108.31.1 CLASS.

Cephamycin, like CEFOTETAN, with similar properties to second-generation cephalosporins.

108.31.2 ACTION.

Bactericidal; bacterial cell wall synthesis inhibitor.

108.31.3 MORE INFORMATION.

See CEFOTETAN; [Chapter 34](#), cephalosporins, [Table 34-4](#); surgical infections, [Table 55-5](#); reference: [Ch 34](#), ref. 297.

108.31.4 PHARMACOKINETICS.

Not absorbed from the GI tract. Must use parenteral administration. Reaches therapeutic concentrations in many tissues, including kidney and lung. Little penetration of CSF, even with inflamed meninges. Primarily excreted unchanged in the urine.

108.31.5 SPECTRUM.

Gram positive: *Staphylococcus*, hemolytic *Streptococcus*. **Gram negative:** *Escherichia*, *Klebsiella*, *Proteus*. **Anaerobes:** *Bacteroides*, *Clostridium*, *Peptococcus*, *Peptostreptococcus*. **Ineffective:** *Salmonella*, *Pseudomonas*, *Enterococcus*. Has a similar spectrum to cefotetan.

108.31.6 INDICATIONS.

Gram-negative sepsis, gingivitis, pyothorax, polymicrobial infections with renal impairment, surgical prophylaxis, intraabdominal bowel rupture, osteomyelitis. Especially effective for surgical prophylaxis when anaerobic infections (e.g., *Bacteroides fragilis*) are expected (colon surgery).

108.31.7 CONTRAINDICATIONS.

Reduce dosage in renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.31.8 ADVERSE REACTIONS.

Local tissue irritation when given IM or SC. Vomiting after IV bolus injection, cutaneous eruptions, angioedema. Can cause hemolytic anemia, thrombocytopenia, granulocytopenia, increased hepatic enzymes, azotemia.

108.31.9 INTERACTIONS.

Increased nephrotoxicity has been observed when combined therapy with aminoglycosides has been used.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	1-g, 2-g vials	<i>Mefoxin</i> (Merck)

108.31.10 INTERNATIONAL PREPARATIONS.

Betacef, Cefaxicina, Cefociclin, Mefoxitin, Stovaren, Tifox.

108.31.11 HANDLING.

Store powder at room temperature. IV, reconstitute with 9.7 ml bacteriostatic water to 100 mg/ml solution; stable for 24 hr at room temperature, 1 week if refrigerated, 30 weeks when frozen. Times vary with other diluents. Powder and solutions darken with storage, but this does not affect potency. SC and IM, can dilute in 0.5% lidocaine (without epinephrine) to minimize irritation after injection.

108.31.12 ADMINISTRATION.

Bolus administration via IV catheter over 3-5 min. Flush catheter with heparinized saline (10 U/ml) after injection.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Soft tissue infections	30	SC	8	prn ^a
	30	IV	5	prn ^a
Bacteremia	15–30	IV, IM, SC	6–8	prn ^a
Orthopedic infections ²²		IV, IM	6–8	prn ^a
Cats				
Systemic infection	25–30	IV, IM	8	prn ^a

^a Use to control initial infection, then switch to orally administered drugs for longer therapy.

108.31.13 ADDITIONAL DOSAGES.

Anaerobic infections, [Table 41-12](#); musculoskeletal infections, [Table 86-4](#); bacteremia and endocarditis, [Table 87-6](#); respiratory infections, [Table 88-8](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.32.32 CEFPODOXIME PROXETIL

108.32.1 CLASS.

Third-generation cephalosporin. A pro-drug; active metabolite is cefpodoxime.

108.32.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis. Stable in the presence of many β -lactamases.

108.32.3 MORE INFORMATION.

See CEFIXIME; [Chapter 34](#), cephalosporins; [Table 34-4](#).

108.32.4 PHARMACOKINETICS.

One of few oral drugs of its class. The oral form is given as the proxetil ester, which is hydrolyzed by the intestinal epithelium to active drug at the time of absorption. Oral bioavailability in fasting beagle dogs was $63.1 \pm 5.3\%$, according to the supplied product information. Excreted primarily unchanged in urine, with an elimination half-life of approximately 5 hr after PO administration. In dogs, 5 mg/kg or 10 mg/kg dose increases maximum plasma concentration to $\sim 8 \mu\text{g/ml}$ or $\sim 16 \mu\text{g/ml}$, respectively.

108.32.5 SPECTRUM.

Gram positive: *Streptococcus*, *Staphylococcus*. **Gram negative:** *Escherichia*, *Klebsiella*, *Pasteurella*, 1218
Proteus. **Not active** against most obligate anaerobes, *Pseudomonas* spp, or enterococci. Activity is generally 1219
not as broad as the parenterally administered third-generation drugs, partially because of lower achieved concentrations.

108.32.6 INDICATIONS.

Upper respiratory and urinary tract infections, pyoderma, otitis media not responding to other drugs.

108.32.7 CONTRAINDICATIONS.

Reduce dose in renal failure; no adjustment needed with hepatic dysfunction. Safe in pups over 18 days of age. Avoid in patients with hypersensitivity to penicillin or cephalosporin. Safety in lactating or pregnant animals or breeding males has not been established.

108.32.8 ADVERSE REACTIONS.

Low prevalence. Diarrhea, vomiting, eosinophilia, allergic reactions. The drug was given at up to 40 times the typical daily oral dose for 13 weeks in adults and 28 days in pups of 18-23 days of age. Blood dyscrasias, including neutropenia, may be observed with high doses, and if observed, the drug should be discontinued.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.32.9 INTERACTIONS.

Drugs that increase gastric pH interfere with absorption. As with other cephalosporins, may cause a positive Coombs' test.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Oral tablets	100 mg, 200 mg	<i>Simplicef</i> (Pharmacia & Upjohn, division of Pfizer Animal Health)
Human	Oral tablets	100 mg, 200 mg	<i>Vantin</i> (Pharmacia & Upjohn)
	Granules for oral suspension; lemon cream flavored	500 mg/5 ml, 100 mg/5 ml	<i>Vantin</i>

108.32.10 INTERNATIONAL PREPARATIONS.

Banan, Biocef, Céfodox, Orelox, Ortreton, Podomexef.

108.32.11 HANDLING.

Store tablets in air-tight vials at controlled room temperature 20–25°C (68–77°F). Mix granules in distilled water, store in refrigerator for up to 2 weeks.

108.32.12 ADMINISTRATION.

Food increases absorption. Drug can be given with or without food.

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Skin, soft tissue infections	5–10	PO	24	5–7 ^a
^a Treatment of acute infection should be for at least 5–7 days or for 2–3 days beyond the cessation of clinical signs. Recommended maximum interval is to 28 days.				

108.32.13 ADDITIONAL DOSAGES.

None.

108.32.14 DISPENSING INFORMATION.

Give drug with meals.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.33.0 CEFATAZIDIME

108.33.1 CLASS.

Third-generation cephalosporin.

108.33.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.33.3 MORE INFORMATION.

See [Chapter 34](#), cephalosporins, [Table 34-4](#); CNS infections, [Table 92-3](#).

108.33.4 PHARMACOKINETICS.

Not absorbed PO; given parenterally. Highest levels in myocardium, bone, skeletal muscle. Good penetration into CSF and synovial, peritoneal, aqueous, lymphatic, and blister fluids. Primarily (80%-90%) excreted renally as unchanged drug.

108.33.5 SPECTRUM.

Variable activity against gram-positive bacteria and anaerobes. See CEFTRIAXONE. **More effective:** most active cephalosporin against *Pseudomonas*. Ninety-six percent of isolates of *Pseudomonas* from dogs had susceptible MICs (≤ 4 ug/ml) while they had 77%, 92%, and 90% susceptibility to gentamicin, amikacin, and ciprofloxacin, respectively ([Ch 34](#), ref. 265).

108.33.6 INDICATIONS.

In people, primarily for *Pseudomonas* sepsis; also gram-negative sepsis, meningitis, osteomyelitis, peritonitis, pneumonia. Used in immunosuppressed states (neutropenia) with fever of unknown origin and suspected bacteremia. Has been used in treating nosocomial gram-negative bacterial infections alone and in combination with other drugs. May use with aminoglycosides or clindamycin for severe infections or when antimicrobial resistance is anticipated.

108.33.7 CONTRAINDICATIONS.

Renal failure must reduce dosage. No adjustments for hepatic dysfunction.

108.33.8 ADVERSE REACTIONS.

See CEFTRIAXONE. GI signs, which are generally mild in dogs, may develop even with parenteral administration ([Ch 34](#), ref. 265).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.33.9 INTERACTIONS.

May increase risk of nephrotoxicity with coadministered aminoglycosides.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection	500g, 1-g, 2-g vials	<i>Fortaz</i> (Glaxo Wellcome), <i>Tazicef</i> (SmithKlineBeecham), <i>Tazidime</i> (Lilly)

1219

108.33.10 INTERNATIONAL PREPARATIONS.

Ceftim, *Ceptaz*, *Fortam*, *Fortum*, *Glazidim*, *Kefadim*, *Kefamin*, *Kefazim*, *Kefzim*, *Panzid*, *Potendal*, *Spectrum*, *Starcef*.

1220

108.33.11 HANDLING.

Reconstitute with sterile water, stable for 24 hr at room temperature and 7-10 days if refrigerated. Stable in 0.9% NaCl, Ringer's, or 5% dextrose. Less stable in bicarbonate. Not recommended to mix with aminoglycosides or metronidazole.

108.33.12 ADMINISTRATION.

IV inject over 3-5 min. Administer separately from aminoglycosides. Can mix with 1% lidocaine (without epinephrine) for IM use.

<i>Dosage</i>				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Orthopedic infections	25	IV, IM, SC	8-12	prn ^a
Soft tissue infections	20-40	IV, IM, SC	12	prn ^a
Sepsis, bacteremia	30	IV, IM, SC	4-8 ^b	prn ^a
Cats				
Systemic infections	25-30	IV, IM, intraosseous	8-12	prn ^a

a Use for initial control of infection, then switch to an orally administered drug with similar spectrum of activity.

b At 30 mg/kg, serum concentration exceeded effective MIC for 4 hr (Ch 34, ref. 265). The 4-hr interval of administration should be used to maintain efficacy against systemic *Pseudomonas* infections. Continuous IV infusion is another effective alternative.

108.33.13 ADDITIONAL DOSAGES.

Gram-negative bacteria, Table 37-3.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.34.1 CEFTIOFUR

108.34.1 CLASS.

Third-generation cephalosporin.

108.34.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.34.3 MORE INFORMATION.

See [Chapter 34](#), Cephalosporins, [Table 34-4](#); reference: [Ch 34](#), ref. 47.

108.34.4 PHARMACOKINETICS.

Rapid blood levels after SC dose, approximately 50% of urinary excretion is metabolites (primarily desfuoylceftiofur) and 50% active drug. Half-life in dog is 6-7 hr.

108.34.5 SPECTRUM.

Gram positive: some *Streptococcus*, *Staphylococcus*. **Gram negative:** *Escherichia*, *Proteus*, *Klebsiella*, *Salmonella*, *Pasteurella*. **Anaerobes:** some but inconsistent; in vitro effective against *Fusobacterium* but poor for *Bacteroides*. **Ineffective:** *Pseudomonas*, *Enterococcus*, *Bordetella*.

108.34.6 INDICATIONS.

Urinary tract infections.

108.34.7 CONTRAINDICATIONS.

Recommendations uncertain with previous hypersensitivity reaction, breeding, or pregnancy.

108.34.8 ADVERSE REACTIONS.

Dose and duration related myelosuppression with anemia, leukopenia, and thrombocytopenia, especially at dosages of 6.6 mg/kg once daily.

108.34.9 INTERACTIONS.

May expect synergistic antibacterial activity, but nephrotoxic potential is increased when used in combination with aminoglycosides.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary Dogs, cattle	Sterile powder for injection	1-g, 4-g vials of 20 and 80 ml, respectively	<i>Naxcel</i> (Pharmacia & Upjohn)
Swine	Oil suspension as HCl	5g	<i>Excenel</i> (Pharmacia & Upjohn)

108.34.10 HANDLING.

Unreconstituted powder: stable if refrigerated for extended periods, avoid light. Reconstitute with sterile water for injection. Reconstituted solution: refrigerate for 7 days or room temperature for 12 hr; can be aliquoted in syringes and frozen (-20°C) for 8 weeks but thaw at room temperature (never warmer). Never use a single multidose vial more than 20 times.

108.34.11 ADMINISTRATION.

Preferably, administer at least twice daily for other than urinary tract infections. At a single 2.2-mg/kg dose, plasma concentrations meet or exceed minimal inhibitory concentrations (MICs) for some organisms such as *Klebsiella*, *Proteus*, various *Streptococcus*, *Pseudomonas*, and *Escherichia* at 18-24 hr. With twice-daily dosing, MICs for *S. intermedius* might be adequate but insufficient for some *Streptococcus*, *Pseudomonas*, *Bordetella*, and *Klebsiella*. Higher than recommended dosages to affect these organisms may be myelotoxic.

1220

Dosage				
INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Urinary infections	2.2	SC	24	5-14
Systemic, soft tissue infections	2.2	SC	12	5-14
	4.4	SC	24	5-14
Sepsis, bacteremia	4.4	SC	12	2-5

1221

108.34.12 ADDITIONAL DOSAGES.

Respiratory disease, [Table 88-8](#).

108.34.13 DISPENSING INFORMATION.

Return for recheck CBC count weekly.

108.35 CEFTIZOXIME

108.35.1 CLASS.

Third-generation cephalosporin.

108.35.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.35.3 MORE INFORMATION.

See [Chapter 34](#), cephalosporins; CNS infections, [Table 92-3](#).

108.35.4 PHARMACOKINETICS.

Not absorbed by PO route. Penetrates many tissues and has therapeutic concentrations in virtually all body fluids. Penetrates meninges with and without inflammation. Not metabolized and primarily renal excretion of unchanged drug.

108.35.5 SPECTRUM.

Similar to CEFOTAXIME. **Gram positive:** *Streptococcus*, *Staphylococcus* (methicillin susceptible). **Gram negative:** *Escherichia*, *Klebsiella*, *Proteus*, *Enterobacter*; low activity against *Pseudomonas*. **Anaerobes:** *Bacteroides*. **More effective:** most active cephalosporin against *Bacteroides*. **Ineffective:** *Enterococcus*, some *Pseudomonas*.

108.35.6 INDICATIONS.

Primarily lower respiratory tract infections; urinary, intraabdominal, skin, bone and joint infections; septicemia, meningitis.

108.35.7 CONTRAINDICATIONS.

Allergies to this class. Reduce dose in renal failure.

108.35.8 ADVERSE REACTIONS.

Hypersensitivities, local and systemic. Transient elevation in serum hepatic enzymes, anemia, leukopenia, thrombocytopenia.

108.35.9 INTERACTIONS.

Although not reported, increased nephrotoxicity is expected with concurrent therapy with cephalosporins and aminoglycosides.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder or frozen solution for injection	1g, 2g	Cefizox (Fujisawa)

108.35.10 INTERNATIONAL PREPARATIONS.

Ceftix, *Epocelin*, *Eposerin*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.35.11 HANDLING.

Thaw plastic container at room temperature and squeeze bag to check for leaks. No additives should be introduced. After thawing, stable for 24 hr at room temperature or 10 days if refrigerated.

108.35.12 ADMINISTRATION.

IM in a large muscle, 2-g doses should be divided at different sites. IV bolus infusion over 3-5 min or infusion in 50-100 ml of 0.9% NaCl, 5% or 10% dextrose, lactated Ringer's, or Ringer's. Stable for 24 hr at room temperature or 96 hr if refrigerated.

Dosage				
INDICATIONS (Dogs)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Urinary infections	50 ^a	IV, IM	12	prn
Respiratory, systemic infections	25-50 ^a	IV, IM	8	prn

a Extrapolated human dosage.

108.35.13 ADDITIONAL DOSAGES.

None.

1221

108.36 CEFTRIAXONE

1222

108.36.1 CLASS.

Third-generation cephalosporin.

108.36.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.36.3 MORE INFORMATION.

See [Chapter 34](#), cephalosporins, [Table 34-4](#); CNS infections, [Table 92-3](#).

108.36.4 PHARMACOKINETICS.

Inactivated in stomach and must be given parenterally. Very soluble and can be given IV or IM. Highly protein bound. Achieves high levels in the CSF. Dual elimination, with 40% excreted in bile, 60% in urine. Longest half-life of third-generation drugs, making once-daily dosing possible.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.36.5 SPECTRUM.

Gram positive: some *Staphylococcus* (some β -lactamase-producing but not methicillin-resistant strains), some *Streptococcus*. **Gram negative:** *Enterobacter*, *Escherichia*, *Klebsiella*, *Proteus*, *Serratia*, *Citrobacter*, *Providencia*, *Shigella*, *Acinetobacter*, some *Salmonella* and *Pseudomonas*. **Anaerobes:** variable against *Bacteroides* and *Clostridium*. **Others:** *Borrelia*. **More effective:** *Borrelia*. **Ineffective:** *Enterococcus*.

108.36.6 INDICATIONS.

Lower respiratory tract, skin and soft tissue, urinary tract, bone, joint, intraabdominal, genital infections. It has been used to treat meningitis caused by susceptible strains (often gram negatives); gram-negative sepsis. Treatment of severe multisystemic gram-negative bacterial infections when toxicity of aminoglycosides or resistance to quinolones is of concern. Best option for treating systemic manifestations (meningitis, arthritis) of Lyme borreliosis. Used for surgical prophylaxis as a preoperative and intraoperative infusion for abdominal contamination by bowel, genital, or biliary sources.

108.36.7 CONTRAINDICATIONS.

Avoid with icterus. Reduce doses in renal failure. Previous cephalosporin or penicillin hypersensitivity.

108.36.8 ADVERSE REACTIONS.

Diarrhea. Local pain on injection, systemic hypersensitivity, blood dyscrasias, diarrhea, rise in serum liver enzyme activity. Biliary crystal deposition and sludging, vitamin K antagonism, mild or transient azotemia, and hypercreatininemia.

108.36.9 INTERACTIONS.

Incompatible with many other antimicrobials in solution.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection in vials or infusion bottles	250 mg, 500 mg, 1g, 2g	<i>Rocephin</i> (Roche)

108.36.10 INTERNATIONAL PREPARATIONS.

Hosbocin, Rocephalin, Rocefalin, Rocefin, Rocephine.

108.36.11 HANDLING.

Store powder for injection away from light at controlled room temperature. Diluents can include sterile water, 0.9% NaCl, 5% dextrose. Solutions are stable for 1-3 days at room temperature, 3-10 days if refrigerated; concentrations at or below 100 mg/ml have the longest stability. Lower concentration (10-40 mg/ml) can be stored frozen (-20°C) for 36 weeks.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.36.12 ADMINISTRATION.

Avoid infusion or mixing with any other drugs. IV or IM administration for up to 14 days as necessary. For IM, may be diluted with lidocaine 1% without epinephrine. Available as IM convenience kit containing proper diluent. Use 0.9-ml diluent/250-mg drug. For IV, use 10-40 mg/ml and give by infusion over 30 min.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Meningitis, borreliosis	15–50 ^a	IM, IV	12	4–14
Preoperative, intraoperative	25 ^a	IM, IV	24	1
Skin, genitourinary infections	25 ^a	IM	24	7–14
Cats				
Systemic infections	25–50	IV, IM, intraosseous	12	prn

^a Maximum dose per administration is 1g for humans.

108.36.12 ADDITIONAL DOSAGES.

Lyme borreliosis, [Table 45-5](#).

1222

108.37 CEFUROXIME AXETIL OR SODIUM

1223

108.37.1 CLASS.

Second-generation cephalosporin.

108.37.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.37.3 MORE INFORMATION.

See [Chapter 34](#), cephalosporins; [Table 34-4](#).

108.37.4 PHARMACOKINETICS.

Oral axetil ester: a prodrug that is hydrolyzed releasing cefuroxime by esterases in intestinal mucosa and blood. Better absorption with food. Parenteral sodium salt: only drug among the first- and second-generation classes to enter the CSF in absence of meningitis and good therapeutic levels with meningeal inflammation. Longer half-life than cefaclor allows twice-daily dosing. Excreted unchanged in urine.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.37.5 SPECTRUM.

Gram positive: *Staphylococcus* and *Streptococcus*. **Gram negative:** *Escherichia*, *Klebsiella*, *Enterobacter*.
Ineffective: high-resistance β -lactamase-producing organisms. Ineffective against *Enterococcus* and methicillin-resistant *Staphylococcus*.

108.37.6 INDICATIONS.

Oral, for penicillin-resistant gram-positive infections of skin and upper respiratory tract. Parenteral, also used to treat lower respiratory tract, CNS, and orthopedic infections.

108.37.7 CONTRAINDICATIONS.

Reduce dose in renal failure. Previous hypersensitivity to penicillin or cephalosporin.

108.37.8 ADVERSE REACTIONS.

Very bitter taste if tablet is bitten or ground up for administration. Adding to dairy products (milk or chocolate milk) may improve absorption and palatability. Some GI upsets may occur with oral axetil preparation. Neutropenia, leukopenia, and eosinophilia have been observed with parenteral sodium drug.

108.37.9 INTERACTIONS.

Increased risk of nephrotoxicity when combined with aminoglycoside.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets (as axetil)	125 mg, 250 mg, 500 mg	<i>Ceftin</i> (Glaxo Wellcome)
	Oral suspension (as axetil)	125 mg/5 ml	<i>Ceftin</i>
	Powder for injection (as sodium salt)	750 mg, 1.5g, 7.5g	<i>Kefurox</i> (Lilly), <i>Zinacef</i> (Glaxo Wellcome)

108.37.10 INTERNATIONAL PREPARATIONS.

Biociclin, *Biofurex*, *Bioxima*, *Cefamar*, *Cefoprim*, *Cefumax*, *Cefur*, *Cefurex*, *Cefurin*, *Cepazine*, *Ceurocef*, *Colifossim*, *Curoxim*, *Deltacef*, *Duxima*, *Elobact*, *Kefox*, *Nivador*, *Selan*, *Zinnat*, *Zoref*.

108.37.11 HANDLING.

Powder and solutions should be stored protected from light; they darken with storage, but potency is unaffected. When reconstituted, stock solutions of parenteral drug are stable for 24 hr at room temperature and for 48 hr when refrigerated. Dilutions of stock for administration, can be added to 0.9% NaCl or 5% or 10% dextrose. These solutions (1-30 mg/ml) are stable for 7 days when refrigerated; when frozen (-20°C), the solution is stable for 6 mo and should be thawed slowly but not with a microwave, which destroys 85% of activity. Should not add to aminoglycoside-containing solutions, although these can be given separately.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.37.12 ADMINISTRATION.

Oral; advantage over cefaclor is that food enhances absorption and bioavailability. Tablets should be administered whole because of bitter taste, if dose needs are less, use oral suspension. Parenteral; IV is preferred route for systemic infections. IM; can give in large muscle mass; should aspirate first to avoid inadvertent IV inoculation.

Dosage				
INDICATIONS (Dogs)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Prophylaxis for surgery	20	IV	30 min prior and every 2 hr	During surgery
Soft tissue infections	10 ^a	PO	12	10
Systemic infections	15 ^a	IV	8	prn
Meningitis	30 ^a	IV	8	prn

^a Extrapolated human dosage.

108.37.13 ADDITIONAL DOSAGES.

None.

108.37.14 DISPENSING INFORMATION.

Give tablets whole; do not break or crush if put on food. Give with meals.

108.38 CEPHALEXIN

108.38.1 CLASS.

First-generation cephalosporin.

108.38.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.38.3 MORE INFORMATION.

See [Chapter 34](#), cephalosporins; [Table 34-4](#); references: [Ch 34](#), ref. 196; 197.

108.38.4 PHARMACOKINETICS.

Well absorbed orally (57%-75% bioavailable). Distributed to most tissues, with highest concentrations in kidney, lung, trachea, and skin of dogs. Also penetrates muscle and bone in therapeutic concentrations. Excreted unchanged in urine and bile. Does not penetrate CNS or CSF.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.38.5 SPECTRUM.

Gram positive: *Staphylococcus*, *Streptococcus*. **Gram negative:** *Escherichia*, *Klebsiella*, *Proteus mirabilis*, *Pasteurella multocida*. **Ineffective:** *Pseudomonas*, *Aerobacter*, some *Proteus*, *Bacteroides*, *Enterococcus*.

108.38.6 INDICATIONS.

Skin infections, chronic canine staphylococcal pyoderma; urinary tract infections, pneumonia, localized soft tissue infections, upper respiratory tract infections.

1223

108.38.7 CONTRAINDICATIONS.

Previous hypersensitivity to cephalosporins or penicillins. Some reduction in frequency of administration to every 12-24 hr in animals with renal failure.

1224

108.38.8 ADVERSE REACTIONS.

Dogs: vomiting, diarrhea, excitement or depression, anorexia, salivation (Ch 34, ref. 209). Cats: vomiting, diarrhea, pyrexia, salivation, occasional hypersensitivity reactions, cholestatic jaundice.

108.38.9 INTERACTIONS.

Positive Coombs' tests have been seen in people treated with cephalosporins. False-positive urine glucose results have been observed in dogs with nonenzymatic test methods (Ch 34, ref. 306c).

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for oral suspension	125 mg/5 ml, 250 mg/5 ml,	<i>Keflex</i> (Dista), generic (many)
		500 mg/5 ml	
Veterinary	Capsules, tablets	250 mg, 500 mg, 1 g	<i>Keflex</i>
	Oral tablets	50 mg, 250 mg	<i>Ceporex</i> (Mallinckrodt)
	Oral drops	100 mg/ml	<i>Ceporex</i>
	Injectable solution	18 mg/ml	<i>Ceporex</i>

108.38.10 INTERNATIONAL PREPARATIONS.

Abiocef, *Biocef*, *Bioporina*, *Bioscefal*, *Cefact*, *Cefadina*, *Cefadine*, *Cefadros*, *Cefalorex*, *Cefanex*, *Ceferran*, *Cepexin*, *Cephalobene*, *Cepo*, *Ceporexin*, *Ceporexine*, *Cerexin*, *Cilicef*, *Coliceflor*; *Defaxina*, *Domucef*, *Efemida*, *Fexin*, *Ibilex*, *Janocilin*, *Keflet*, *Keforal*, *Keftab*, *Lafarin*, *Latoral*, *Lenocef*, *Lorexina*, *Novo-Lexin*, *Nu-Cephalex*, *Oracef*, *Ospexin*, *Talinsul*, *Ultralexin*, *Zartan*, *Zetacef*.

108.38.11 HANDLING.

Oral suspension: refrigerate once reconstituted and discard after 14 days. Capsules: store away from moisture in airtight containers at room temperature.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.38.12 ADMINISTRATION.

Generally given orally with little or no side effects other than occasional diarrhea. Injectable for IM use: localized tissue reaction may occur, massage injection site. Food delays absorption and elimination to a minor degree.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Pyoderma	30–35	PO	12	21–42 ^a
Respiratory infections	20–40	PO	8	7–14 ^a
Systemic infections	25–45	PO	8	14–28 ^a
Orthopedic infections	22–30	PO	6–8	28 ^a
Cats				
Soft tissue infections	30–50	PO	12	14–28 ^a
Systemic infections	35	PO	6–8	14–28 ^a

^a Guideline: treat for 5–7 days beyond resolution of clinical disease or preferably negative culture. For susceptible staphylococci, dosing every 12 hr may be adequate for most tissues; however, infection with more cephalosporin-resistant organisms such as *E. coli*, outside the urinary tract, may require higher levels of dosing on the 8-hr interval (Ch 34, ref. 57).

108.38.13 ADDITIONAL DOSAGES.

Streptococcal infections, Table 35-2; anaerobic infections, Table 41-12; canine pyoderma, Table 85-3; musculoskeletal infections, Table 86-4; respiratory disease, Table 88-8; urinary infections, Table 91-10.

108.38.14 DISPENSING INFORMATION.

Food may be given with medication to prevent vomiting. Absorption, as a result peak serum concentration, may be reduced slightly after feeding of dogs (Ch 34, ref. 57). The duration of activity is minimally changed by feeding. Oral suspension should be shaken well before using.

108.39 CEPHAPIRIN

108.39.1 CLASS.

First-generation cephalosporin.

108.39.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.39.3 MORE INFORMATION.

See [Chapter 34](#), Cephalosporins, [Table 34-4](#).

108.39.4 PHARMACOKINETICS.

Not absorbed from the GI tract after PO administration. Widely distributed into some body fluids (synovial, pleural, peritoneal) but poorly into aqueous humor and CSF. Penetrates many tissues, including bone but not prostate.

108.39.5 SPECTRUM.

Gram positive: *Staphylococcus*, hemolytic *Streptococcus*. **Gram negative:** *Escherichia*, *Klebsiella*, *Proteus*.

108.39.6 INDICATIONS.

Perioperative surgical prophylaxis, septicemia, pneumonia, osteomyelitis.

108.39.7 CONTRAINDICATIONS.

Reduce dose in renal failure.

108.39.8 ADVERSE REACTIONS.

Pain on injection, phlebitis.

108.39.9 INTERACTIONS.

Use cautiously with nephrotoxic drugs such as aminoglycosides.

1224

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection	500 mg, 1g, 2g, 1g, 2g,	<i>Cefadyl</i> (Bristol), generics (many)

1225

108.39.10 HANDLING.

Powder stored at room temperature is stable for 2 yrs. Reconstitute with sterile water. Stable at room temperature for 24 hr or 10 days if refrigerated and 14 days if frozen. Compatible with 0.9% NaCl, dextrose, Ringer's, lactated Ringer's.

108.39.11 ADMINISTRATION.

Infuse IV slowly over 3-5 min or give with IV fluids.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Soft tissue infections	10–20	IV, IM, SC	6–8	prn
Bacteremia, endotoxemia	11–30	IV	4–8	prn

108.39.12 ADDITIONAL DOSAGES.

Canine distemper, [Table 3-5](#); feline panleukopenia, [Table 10-2](#); bacteremia or endocarditis, [Table 87-6](#); oral infections, [Table 89-4](#); CNS infections, [Table 92-5](#).

108.40.1 CEPHAZOLIN

108.40.1 CLASS.

First-generation cephalosporin.

108.40.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.40.3 MORE INFORMATION.

See CEPHAPIRIN; [Chapter 34](#), cephalosporins, [Table 34-4](#).

108.40.4 PHARMACOKINETICS.

Poorly absorbed from GI tract. After IM or IV injection, enters many tissues and body fluids, including bone and peritoneal, pleural, and synovial fluids. Does not enter CSF appreciably. Predominantly excreted unchanged in urine.

108.40.5 SPECTRUM.

See CEPHALEXIN, PENICILLIN G, or CEPHAPIRIN.

108.40.6 INDICATIONS.

Surgical prophylaxis, biliary tract, and intraabdominal infections and bacteremia.

108.40.7 CONTRAINDICATIONS.

See CEPHALEXIN.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.40.8 ADVERSE REACTIONS.

IM injections are painful and IV can cause thrombophlebitis. See also CEPHALEXIN.

108.40.9 INTERACTIONS.

See CEPHRADINE.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection (as sodium)	1g	Ancef (Smith Kline Beecham), Kefzol (Lilly)

108.40.10 INTERNATIONAL PREPARATIONS.

Acef, Areuzolin, Baktzil, Biazolina, Brizolina, Caricef, Cefabiozim, Cefacidal, Cefadrex, Cefamezin, Cefazil, Cilicef, Elzogram, Fazoplex, Firmacef, Gramaxin, Izacef, Kefol, Recef, Sicef, Tasep, Totacef, Zolicef, Zolin, Zolival.

108.40.11 HANDLING.

Should reconstitute in sterile water. Store in light-proof containers. Incompatible with aminoglycosides and basic solutions in which hydrolysis occurs, and at pH < 4.5, the drug precipitates. Crystal formation occurs if reconstituted with 0.9% NaCl and should be avoided.

108.40.12 ADMINISTRATION.

Give by deep IM injection or slow (3-5 min) IV infusion.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Soft tissue infections	22	IM, IV	8	prn
Surgical infections	22	IV	^a	1
^a Just before or during surgical procedure.				

108.40.13 ADDITIONAL DOSAGES.

None.

1225

108.41 CEPHRADINE

1226

108.41.1 CLASS.

First-generation cephalosporin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.41.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.41.3 MORE INFORMATION.

See [Chapter 34](#), cephalosporins; [Table 34-4](#).

108.41.4 PHARMACOKINETICS.

See CEPHALEXIN. Better absorbed orally (90% bioavailable).

108.41.5 SPECTRUM.

Gram positive: *Staphylococcus*, hemolytic *Streptococcus*. **Gram negative:** *Escherichia*, *Klebsiella*, *Proteus*.

108.41.6 INDICATIONS.

Oral treatment of respiratory, skin, and urinary tract infections; parenteral treatment for septicemia, osteomyelitis, and perioperative prophylaxis.

108.41.7 CONTRAINDICATIONS.

See CEPHALEXIN.

108.41.8 ADVERSE REACTIONS.

Dogs: vomiting, diarrhea, anorexia, polydipsia, polyuria.

108.41.9 INTERACTIONS.

False-positive results on urine protein tests using sulfosalicylic acid. Monitor renal function if used in combination with aminoglycosides.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules	250 mg, 500 mg	<i>Velosef</i> (Apothecon), generics (many)
	Powder for oral suspension (fruit-flavored)	125 mg/5 ml, 250 mg/5 ml	<i>Anspor</i> (SmithKline Beecham)
	Powder for injection	250 mg, 500 mg, 1g, 2g	<i>Velosef</i>

108.41.10 INTERNATIONAL PREPARATIONS.

Cefamid, *Cefrasol*, *Cefril*, *Cefral*, *Celex*, *Cesporan*, *Ecosporina*, *Kelsef*, *Lisacef*, *Sefril*, *Septasef*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.41.1.1 HANDLING.

Store powders and capsules below 86°F, and keep bottle closed tight away from light. Oral suspension stable 7 days at room temperature, 14 days if refrigerated. Compatible with most IV solutions except Ringer's or lactated Ringer's or calcium-containing solutions. Do not mix with other antibiotics given concurrently. Reconstituted solutions of less than 50 mg/ml are stable for 10 hr at room temperature and 48 hr if refrigerated. Solutions for injection can be stored frozen for 6 weeks.

108.41.1.2 ADMINISTRATION.

Can be given orally without regard to meals. Food delays absorption but does not affect its extent.

Dosage				
INDICATIONS (Dogs)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Skin, pyoderma	22	PO	8	14–28 ^a
Systemic, orthopedic infections	22	IV, IM, SC, PO	6–8	28 ^a

a Treatment duration varies, usually 5–7 days beyond resolution of infection by culture testing.

108.41.1.3 ADDITIONAL DOSAGES.

Respiratory infections, [Table 88-8](#).

108.41.1.4 DISPENSING INFORMATION.

Keep reconstituted oral suspension in refrigerator, discard unused portions after 2 weeks.

108.42 CHLORAMPHENICOL

108.42.1 CLASS.

Acetamide.

108.42.2 ACTION.

Bacterostatic; binds to 50s ribosomes of bacteria, inhibiting protein synthesis.

108.42.3 MORE INFORMATION.

See FLORFENICOL, see elsewhere THIAMFENICOL. See [Chapter 34](#), chloramphenicol; references: [Ch 34](#), ref. 289; [Ch 34](#), ref. 407.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.42.4 PHARMACOKINETICS.

GI absorption dependent on formulation. Crystalline salt is better, may cause salivation in cats but has good bioavailability with rapid absorption. Oral palmitate is better tolerated but gives poor systemic drug availability in anorectic cats (Ch 34, ref. 407). In dogs, drug availability with the palmitate is similar to tablets. The inactive palmitate is hydrolyzed in small intestine to release active absorbable drug. Sodium succinate ester can be given IV, SC, IM. Systemic availability is similar with each route, but IM injection is more painful. The succinate ester lacks antimicrobial activity but is hydrolyzed in liver, lung, and kidney to release active drug. It produces better bioavailability than chloramphenicol in aqueous suspensions or dissolved in organic solvents. Chloramphenicol is lipid soluble and distributed well to all tissues, including skeleton, prostate, CNS. Order of decreasing tissue concentrations is as follows: lymph node, spleen, pancreas, liver, kidney, lung, muscle, brain (Ch 34, ref. 407). Penetrates pleural, ascitic, and synovial fluids, saliva, milk, prostatic and amniotic fluids. Tissue concentrations often exceed those in plasma, but the drug is slower (3-4 hr) to penetrate the intact brain and CSF barriers. Compared with plasma, concentrations are 23% in aqueous and 77% in CSF (Ch 34, ref. 407). Concentrations are not altered appreciably by inflammation. Metabolized in liver by glucuronyl transferase; in dogs 90% of drug is metabolized and metabolites are excreted in urine. Only 5%-10% of a dose in adult dogs and 25% in cats and neonatal dogs is excreted unchanged in urine. Urine concentrations are 10-20 times blood concentrations and are therapeutic. Optimum activity at a urine pH of 7.5-8.0.

1226

1227

108.42.5 SPECTRUM.

Gram positive: *Streptococcus*, *Staphylococcus*. **Gram negative:** *Salmonella*, *Shigella*, *Escherichia*, *Proteus*, *Bordetella*. **Anaerobes:** *Clostridium*, *Fusobacterium*, *Bacteroides*. Resistance can develop during use. **Others:** *Chlamydia*, *Rickettsia*, *Mycoplasma*, *Ehrlichia*, *Leptospira*, *Borrelia*. **Most effective:** anaerobic infections, rickettsial infections. **Ineffective:** *Mycobacterium*, *Pseudomonas*, *Enterobacter*, *Serratia*, *Klebsiella* may be resistant or develop it during treatment.

108.42.6 INDICATIONS.

Cats: chronic rhinitis-sinusitis, pneumonia, pyothorax, periodontitis-gingivitis, bacterial enteritis, biliary infections, intraabdominal sepsis, lower urinary infection, hemotropic mycoplasmosis (hemobartonellosis), bordetellosis, rickettsiosis, anaerobic infections (abscesses). Dogs: tetracycline-resistant *Ehrlichia canis* infections without myelosuppression; respiratory, urinary, and soft tissue infections.

108.42.7 CONTRAINDICATIONS.

Pre-existing leukopenia or anemia; hepatic dysfunction requires reducing dose to lower risk of marrow suppression. Avoid in pregnancy, neonates, hepatic insufficiency, cats with renal failure. Avoid IV use in animals with cardiac failure because it depresses myocardium. Do not use in breeding animals because it may affect gonadal function. No reduction in dosage needed in dogs with mild renal insufficiency, but a 10% reduction is recommended in uremia as a result of protein catabolic effects of the drug.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.42.8 ADVERSE REACTIONS.

Protein synthesis inhibitor; theoretically, might delay wound healing or immunoglobulin synthesis. High plasma concentrations can be toxic for prenatal or neonatal animals owing to immature hepatic metabolism. Inhibits ferrochelatase, an enzyme in hemoglobin synthesis, resulting in reversible nonregenerative anemia. Reversible myelosuppression affecting the maturation of granulocytes occurs in dogs and cats. This should be differentiated from severe, often fatal irreversible idiosyncratic pancytopenia that occurs in some people (Ch 34, ref. 289). Dogs: with >2-3 weeks of treatment at >175 mg/kg/day may develop depression, anorexia; at >225 mg/kg/day, myelosuppression, reticulocytopenia. No morphologic bone marrow effects are found in treated dogs. Erythropoietic response is suppressed at therapeutic dosages in dogs with pre-existing or concurrent blood loss when therapy commences. Regeneration occurs when therapy is discontinued. Cats: at 25-40 mg/kg/day for 3 weeks or 120 mg/kg/day for 1 week develop depression, dehydration, anorexia, weight loss, diarrhea, vomiting, myelotoxicity. Reversible erythroid maturation arrest, vacuolation of marrow elements, and pancytopenia occur.

108.42.9 INTERACTIONS.

Avoid prescribing it with other drugs metabolized in the liver, especially to cats. Inhibits cytochrome P-450 activity and resultant hepatic biotransformation of drugs, which may potentiate by prolonging action of pentobarbital, phenobarbital, primidone, warfarin, salicylates, inhalation anesthetics, diphenylhydantoin, digoxin (Ch 34, ref. 174). Action of cyclophosphamide is inhibited because its metabolites are active. Effect on P-450 activity has even been noted with topical ophthalmic preparations. Does not alter the effects or duration of ketamine-xylazine anesthesia. Prolongs propofol anesthesia in dogs (Ch 34, ref. 233; 278). Decreases effectiveness of iron, B₁₂ aminoglycosides, penicillins. Rifampin and phenobarbital decrease the effectiveness of chloramphenicol. Oral coadministration of calcium lactate, kaolin-pectin, aluminum hydroxide preparations may increase bioavailability. May cause a spurious positive test result for glucose using glucose oxidase strips.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules	250 mg, 500 mg	<i>Chloromycetin</i> (Parke-Davis) ^a
	Oral liquid (palmitate)	50 mg/ml	<i>Chloromycetin</i> Palmitate (Parke-Davis) ^a
	Powder for injection (sodium succinate)	1-g, 10-g vials (100 mg/ml)	<i>Chloromycetin</i>
Veterinary	Oral tablets, film coated	100 mg, 250 mg, 500 mg, 1g	<i>Amphicol</i> (Butler) ^a , generic (Phoenix)
	Capsules	100 mg, 250 mg, 500 mg	<i>Chloromycetin</i> , generic (many) ^a

^a No longer available in US

108.42.10 INTERNATIONAL PREPARATIONS.

Aquamycetin, Biophenicol, Chemicetina, Chlorcol, Cloranfe, Dispaphenicol, Globenicol, Fenicol, Hortfenicol, Kemicetin, Septicol, Sificetina, Troymycetin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.42.11 HANDLING.

Oral palmitate suspension, tablets, capsules should be stored at room temperature away from light. Stable for several years at room temperature. The sodium succinate powder should be kept at controlled room temperatures. Once reconstituted, is stable for 1 mo at room temperature or 6 mo if frozen.

108.42.12 ADMINISTRATION.

Oral administration is generally satisfactory. Sodium succinate can be given IV, IM, SC, although pain or irritation may result at extravascular sites. SC or IM for fractious, unconscious animals or animals with GI disturbance; IV for high rapid levels in severe systemic infections. If no response to therapy in 3-5 days, reconsider diagnosis and treatment. Should recheck CBC for myelotoxicity at 1-week and 2-week intervals in cats and dogs, respectively.

1227

1228

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Urinary, rickettsial, localized soft tissue infections	25–50 mg/kg	PO	8	7
Systemic infection	50 mg/kg	IV, IM, SC, PO	6–8	3–5
Severe bacteremia, sepsis	50 mg/kg	IV, IM, SC	4–6	3
Cats				
Urinary, localized soft tissue infections	50 mg/cat	PO	12	14
Systemic infections	25–50 mg/kg	IV, IM, SC, PO	12	≤14
Bacteremia, sepsis	50 mg/cat	IV, IM, SC, PO	6–8	≤5

108.42.13 ADDITIONAL DOSAGES.

Canine distemper, [Table 3-5](#); ehrlichiosis, [Table 28-4](#); Rocky Mountain spotted fever, [Table 29-4](#); streptococcal infections, [Table 35-2](#); enteric bacterial infections, [Table 39-2](#); anaerobic infections, [Table 41-12](#); Lyme borreliosis, [Table 45-5](#); plague, [Table 47-1](#); actinomycosis, [Table 49-2](#); feline abscesses, [Table 52-3](#); musculoskeletal infections, [Table 86-4](#); bacteremia, [Table 87-6](#); respiratory disease, [Table 88-8](#); oral infections, [Table 89-4](#); colitis, [Table 89-19](#); intraabdominal infections, [Table 89-21](#); hepatobiliary infections, [Table 90-5](#); urinary infections, [Table 91-10](#); CNS infections, [Table 92-5](#).

108.42.14 DISPENSING INFORMATION.

This drug is potentially toxic to people. Wear latex gloves when handling and administering to pets. Return animal every 2 weeks for hematologic testing. Can be administered with food. Tablets or capsules may be bitter if crushed. Shake suspensions well before use.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.42. **CIPROFLOXACIN HYDROCHLORIDE**

108.43.1. **CLASS.**

Fluoroquinolone.

108.43.2. **ACTION.**

Bactericidal; interferes with DNA gyrase and synthesis of bacterial DNA.

108.43.3. **MORE INFORMATION.**

See ENROFLOXACIN; [Chapter 34](#), quinolones, [Table 34-11](#).

108.43.4. **PHARMACOKINETICS.**

See also ENROFLOXACIN. More variable and slower absorption than enrofloxacin. Well absorbed in dogs (70%) after PO administration. Absorption was lower in cats ([Ch 34](#), ref. 4); however, the drug was given in gelatin capsules. Food may delay rate but not degree of absorption. Approximately 40%-50% excreted unchanged in urine. Urinary metabolites have lower antibacterial activity. Wide tissue distribution. Concentrations in genital tissues of both sexes are high. Present in active form in saliva, nasal and bronchial secretions, sputum, skin blister fluid, lymph, peritoneal fluid, bile and prostatic secretions. Lower concentrations in lung, skin, fat, muscle, cartilage, bone. In people, concentrations in CSF are 40%-90% of serum with inflammation and less than 10% if uninflamed. Concentrations in aqueous humor are 4%-25% of serum, with low concentrations in vitreous.

108.43.5. **SPECTRUM.**

See also ENROFLOXACIN. **Gram positive:** *Staphylococcus* (including methicillin-resistant strains), most *Streptococcus* are moderately susceptible. **Gram negative:** *Escherichia*, *Klebsiella*, *Enterobacter*, *Citrobacter*, *Salmonella*, *Campylobacter*, *Brucella*, *Pasteurella*, some *Pseudomonas* develop resistance. **Anaerobes:** most are resistant. **Others:** *Mycoplasma*, *Leptospira*, *Borrelia*, *Chlamydia*, *Mycobacterium tuberculosis*, some opportunistic mycobacteria, but not *Mycobacterium avium-intracellulare* complex. Increased activity and spectrum may occur in combined therapy with metronidazole, clindamycin, β -lactam drugs, or aminoglycosides. **More effective:** gram-negative bacteria. **Ineffective:** *Enterococcus*, *Actinomyces*, *Nocardia*, *Ehrlichia*, obligate anaerobes, *M. avium-intracellulare* complex.

108.43.6. **INDICATIONS.**

See also ENROFLOXACIN. Complicated or chronic urinary tract infections or prostatitis caused by *Escherichia*, *Klebsiella*, *Enterobacter*, *Serratia*, *Proteus*, *Citrobacter*, *Pseudomonas*, *Staphylococcus*. Infectious diarrhea caused by pathogenic gram-negative bacteria such as enterotoxigenic *Escherichia*, *Campylobacter*, and *Salmonella*. Lower respiratory, skin, bone, and joint infections with very susceptible organisms. Gram-negative bacterial meningitis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.43.7 CONTRAINDICATIONS.

See also ENROFLOXACIN. In reduced renal function, there is slight prolongation of ciprofloxacin elimination: reduce dose (once daily) in renal failure. Owing to arthropathy, should not be used in growing animals or in pregnant or lactating animals. Avoid in animals with previously documented adverse reaction.

108.43.8 ADVERSE REACTIONS.

See also ENROFLOXACIN. Nausea, anorexia, vomiting, diarrhea are most frequent side effects. Malaise and inappetence occurs in cats. May cause CNS stimulation with tremors or seizures in predisposed animals. Permanent cartilage damage and lameness develop in growing animals. Dermal hypersensitivity reactions have occurred. High overdosages in dogs have resulted in nephrotoxicity from crystal deposition in kidneys (especially alkaline urine), cataracts, reduced spermatogenesis. These have not been seen with therapeutic dosages. Tendon ruptures have been observed in people. This drug is the most likely quinolone to cause hepatic necrosis and inflammation (Ch 34, ref. 394).

108.43.9 INTERACTIONS.

Concurrent use with theophylline results in elevated theophylline concentrations and increased risk of CNS stimulation.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Film coated oral tablets	250 mg, 500 mg, 750 mg	<i>Cipro</i> (Miles-Bayer)
	Parenteral (IV) solution	200 mg, 400 mg	<i>Cipro</i>

1228

108.43.10 INTERNATIONAL PREPARATIONS.

Baycip, Belmacina, Catex, Ceprimax, Ciflox, Ciloxan, Ciprobay, Ciproxin, Cunesin, Flociprin, Quipro.

1229

108.43.11 HANDLING.

Add parenteral solution of 0.9% NaCl or 5% dextrose. Stable for 14 days if refrigerated, but protect from light. Do not mix with clindamycin or clavulanate. Can be formulated for smaller tablet size by compounding pharmacies.

108.43.12 ADMINISTRATION.

For IV, dilute in saline before administration and give slowly over 1 hr using large veins. Orally, food slows or reduces absorption of the drug. Preferred dosing is 2 hr after meal. Concurrent administration of antacids containing magnesium or aluminum hydroxide may reduce bioavailability to 90%. Sucralfate given within 2 hr of oral dosing similarly reduces absorption.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS (Dogs)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Urinarytract infections	10	PO	24	7–14
Skin, local soft tissue infections	10–15	PO	24	7–14
Bone, and systemic infections, bacteremia and more resistant pathogens (e.g., <i>Enterobacter</i>)	20	PO	24	7–14
<i>Pseudomonas otitis externa</i> ^a				
a Ch 85, ref. 42				

108.43.13 ADDITIONAL DOSAGES.

Gram-negative bacterial infections, [Table 37-3](#); musculoskeletal infections, [Table 86-4](#); bacteremia and endocarditis, [Table 87-6](#). In people, *Pseudomonas* meningitis was successfully treated with high dose IV ciprofloxacin every 8 hr for 1 week ([Ch 34](#), ref. 221).

108.43.14 DISPENSING INFORMATION.

Administer at least 1 hr before or 2 hr after meals and do not give concurrently with antacids or sucralfate.

108.44.1 CLARITHROMYCIN

108.44.1 CLASS.

Macrolide, methylerythromycin derivative.

108.44.2 ACTION.

Bacteriostatic; inhibits bacterial RNA-dependent protein synthesis by binding to 50s subunit of ribosome.

108.44.3 MORE INFORMATION.

See AZITHROMYCIN; [Chapter 34](#), Macrolides.

108.44.4 PHARMACOKINETICS.

Best absorbed macrolide with or without ingesta (55% bioavailable) because stable in gastric acid. Better absorption and tissue penetration than erythromycin with prolonged elimination half-life. Concentrated in and transported by phagocytes. Lipophilic and distributed widely throughout the body. High concentration reached in sputum, lung, tonsil, nasal sinus, stomach, uterus, ovary, cervix, and prostate. Accumulates in pulmonary tissue. Penetrates and concentrates intracellularly in macrophages and neutrophils, facilitating killing of intracellular pathogens. Does not penetrate well into CNS. Metabolized in liver by hydroxylation and

Infectious Diseases of the Dog and Cat, 3rd Edition

methylation, forming a very biologically active hydroxymetabolite and inactive demethylated compound, which are excreted predominantly in the bile. Metabolites are excreted in urine. From 20%-40% of dose may appear in urine as unchanged drug, depending on the formulation (tablets or powder, respectively).

108.44.5 SPECTRUM.

See ERYTHROMYCIN for gram-positive and gram-negative aerobic bacteria. **Anaerobes:** *Bacteroides*, *Clostridium*, *Peptococcus*, and *Propionibacterium*. Best activity against gram-positive aerobes and anaerobes. **Others:** opportunistic mycobacteria, *M. avium-intracellulare complex (MAC)*, *Borrelia*, *Bartonella*, *Toxoplasma*, *Chlamydia*. **More effective:** than erythromycin against *Streptococcus*, *Staphylococcus*, *Campylobacter*, *Helicobacter*, and obligate anaerobes.

108.44.6 INDICATIONS.

Lower respiratory tract and skin infections, enteropathogenic bacterial infections, nasal sinusitis, *Toxoplasma* (combined with pyrimethamine), many cutaneous opportunistic mycobacterial infections, including those caused by MAC (recommend combining with other effective agents). Used in Lyme borreliosis and gastric helicobacteriosis. A substitute for erythromycin with less GI irritation, lower dose but higher cost.

108.44.7 CONTRAINDICATIONS.

Previous erythromycin hypersensitivity. Reduce dose for renal or severe hepatic failure. Active urinary metabolite will not be produced with hepatic dysfunction. Avoid in pregnancy; has adverse effects on fetal development in experimental animals.

108.44.8 ADVERSE REACTIONS.

Nausea, diarrhea, abdominal pain, cholestatic hepatitis, increased liver enzymes, thrombocytopenia, rare eosinophilia, allergic skin reactions. Should hepatic enzyme elevations occur, use lower dosage range. May be less likely than erythromycin to cause GI disturbances.

108.44.9 INTERACTIONS.

See ERYTHROMYCIN; interferes with metabolism of drugs by cytochrome P-450 system. May inhibit benzodiazepine or digoxin metabolism.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Tablets	250 mg, 500 mg	<i>Biaxin</i> (Abbott), <i>Klacid</i> (many countries)
	Granules for oral suspension	125 mg/5 ml, 250 mg/5 ml	<i>Biaxin</i>

1229

108.44.10 INTERNATIONAL PREPARATIONS.

1230

Biclar, *Cyllind*, *Klacid*, *Klaciped*, *Klariced*, *Macladin*, *Mavid*, *Veclam*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.44.11 HANDLING.

Do not refrigerate suspension because it develops a bitter taste; keep at room temperature and use within 14 days.

108.44.12 ADMINISTRATION.

Can be given with or without fasting, but food delays absorption.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Dogs</i>	5–10	PO	12	prn
<i>Cats</i>	7.5	PO	12	prn

108.44.13 ADDITIONAL DOSAGES.

Helicobacteriosis, [Table 39-6](#); mycobacterial infections, [Tables 50-4](#), [50-6](#), [50-7](#), and [50-9](#).

108.44.14 DISPENSING INFORMATION.

Can be given with food. Shake suspension before administration. May cause diarrhea or vomiting.

108.45 CLINDAMYCIN

108.45.1 CLASS.

Lincosamide; semisynthetic derivative of lincomycin.

108.45.2 ACTION.

Bacteriostatic and antiprotozoal activity; binds to 50s subunit of bacterial and protozoal ribosome inhibiting protein synthesis. Potentiates opsonization and phagocytosis.

108.45.3 MORE INFORMATION.

See LINCOMYCIN; [Chapter 34](#), Lincosamides; references: [Ch 34](#), ref. 47; 150; 156; [Ch 71](#), ref. 34.

108.45.4 PHARMACOKINETICS.

After oral administration, GI absorption approached 90%. For oral suspension, palmitate ester is hydrolyzed to active base while aqueous drops are readily absorbed. Absorption is delayed but not prevented by food. Better absorbed than lincomycin. Widely distributed to most tissues, including skin, muscle, bone, body fluids (pleural, peritoneal, synovial) to therapeutic levels. Active transport into phagocytic cells and abscess fluids, killing susceptible intracellular bacteria. Lowest levels reached are in intact CNS and CSF. Levels in inflamed

Infectious Diseases of the Dog and Cat, 3rd Edition

meninges are 40% of blood concentration. Crosses placenta and enters milk. Hepatic metabolism to active and inactive moieties with excretion in bile, feces, urine. Prolonged enterohepatic circulation and excretion in stool for up to 2 weeks after last dose. It is predominantly (80%-90%) excreted in bile with 10%-20% renally excreted. Dogs and cats with periodontitis, treated with 11 mg/kg once daily for 5 days, had mean concentrations of 8.18 µg/g in dogs (range, 3.16 to 24.08 µg/g) and 17.43 µg/g in cats (range, 2.45 to 51.60 µg/g) (Ch 34, ref. 438).

108.45.5 SPECTRUM.

Gram positive: Aerobic cocci, including *Streptococcus* (not enterococci) and more susceptible *Staphylococcus*, *Nocardia*, and few *Corynebacterium*. **Gram negative:** *Campylobacter*, *Helicobacter*. **Anaerobes:** *Peptostreptococcus*, *Peptococcus*, *Actinomyces*, *Propionibacterium*, *Eubacterium*, *Clostridium* (except *C. difficile*), *Bacteroides*, *Fusobacterium*. **Others:** *Chlamydia*; protozoa *Toxoplasma*, *Neospora*, *Babesia*, *Pneumocystis*. **Ineffective:** most gram-negative aerobic bacteria, *Mycobacterium*, and *Mycoplasma*. Whenever resistance to lincomycin or erythromycin exists. Bacterial resistance may develop during treatment and usually also involves lincomycin.

108.45.6 INDICATIONS.

Bacteria: For gram-positive aerobic and in anaerobic infections. Intraabdominal or GI abscesses and infections (perforating ulcers, penetrating injuries, biliary infections, ischemic bowel, colitis, hepatic or biliary abscesses, soft tissue or subcutaneous abscesses, pelvic genital infections, or prostatitis caused by anaerobes, chronic sinusitis or otitis, bacterial pharyngitis, stomatitis, bite wounds, dental infections, periodontal disease, dental plaque prevention); for oral, dental, or upper respiratory tract procedures, pleuropulmonary infections (pyothorax, aspiration pneumonia, pleuritis, pulmonary abscesses). Skin and soft tissue infections (staphylococcal pyoderma); osteomyelitis; diskospondylitis; prophylaxis for head, neck, and open bowel surgery (for the latter, combine with aminoglycosides); endocarditis prophylaxis (after amoxicillin and erythromycin), streptococcal or staphylococcal septicemia. Very effective in treating anaerobic infections and could be preferred over chloramphenicol or metronidazole because of less toxicity. Usually combined with an aminoglycoside or quinolone to treat gram-negative aerobic bacterial infections. Clindamycin resistance has been increasing in recent years. It is most common among anaerobes in the *Bacteroides fragilis* group and among anaerobes, *C. difficile* is the most resistant to this drug (Ch 41, ref. 26a). **Protozoa:** Toxoplasmosis and neosporosis: can be used in combination with pyrimethamine. Systemic toxoplasmosis in dogs and cats and enteroepithelial toxoplasmosis in cats. Pneumocystosis: combined with primaquine. Babesiosis: combined with quinine.

108.45.7 CONTRAINDICATIONS.

Bacterial resistance to lincomycin. Reduce dose with hepatic dysfunction and biliary obstruction from any cause. Reduce dose with severe renal failure. Safety in reproductively active animals or pregnancy is uncertain.

108.45.8 ADVERSE REACTIONS.

GI signs; generally less vomiting than with lincomycin, transient diarrhea when dose is reduced or temporarily discontinued. Pseudomembranous colitis, documented for other species, not a substantiated complication in dogs and cats. Local or systemic or dermal hypersensitivity reactions occur rarely. Local pain and sterile abscesses can form after IM and phlebitis after IV. Oral clindamycin may cause lip smacking and

Infectious Diseases of the Dog and Cat, 3rd Edition

hypersalivation in some cats. Anorexia, vomiting, diarrhea owing to GI irritation can be overcome by parenteral rather than PO use and dosage reductions. May cause diarrhea in pups or kittens of dams receiving therapy. Can produce neuromuscular blockade. May cause leukopenia or increased serum hepatic enzyme activity. Cardiac arrhythmias may develop with bolus infusions of undiluted drug. 1230 1231

108.45.9 INTERACTIONS.

Neuromuscular blockade compounded by other similar-acting agents such as aminoglycosides. Erythromycin and chloramphenicol interfere with the action of clindamycin in vivo. Do not use with macrolides.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral suspension (palmitate)	15 mg/ml	<i>Cleocin</i> (Pharmacia & Upjohn)
	Solution for injection (phosphate)	150 mg/ml	<i>Cleocin</i>
	Oral capsules	75 mg, 150 mg, 300 mg	<i>Cleocin</i>
Veterinary	Oral capsules	25 mg, 75 mg, 150 mg	<i>Antirobe</i> (Pharmacia & Upjohn)
	Oral solution (hydrochloride)	25 mg/ml	<i>Antirobe Aquadrops</i>

108.45.10 INTERNATIONAL PREPARATIONS.

Clindatech, Dalacin.

108.45.11 HANDLING.

Parenteral phosphate solution can be stored at room temperature, compatible with most isotonic IV solutions. Contains no preservatives, and if refrigerated, crystals will form that dissolve on rewarming. Oral hydrochloride is stable at room temperature for extended periods. Once reconstituted, palmitate stable for 2 weeks at room temperature but congeals if refrigerated. Parenteral solution of 300-900 mg diluted in 20 ml of 10% dextrose solution, is stable in frozen storage for 30 days. Parenteral solution is incompatible in infusions with aminophylline, calcium gluconate, ceftriaxone, barbiturates, ampicillin.

108.45.12 ADMINISTRATION.

Oral preparations can be given with food, which does not modify the normal absorption of drug. For IV use, always dilute or administer parenteral solution in 0.9% sodium chloride, 5% dextrose, or lactated Ringer's. IV preparation can be added to solutions containing aminoglycosides (some), penicillins, cephalosporins, glucocorticoids, potassium chloride, sodium bicarbonate. Each dose can be given IV over 4-6 hr or slow IV bolus over 20-min period. Never give greater than 15 mg/min. Pain at IM or SC injection site. The SC route using a clindamycin hydrochloride parenteral solution was superior to the IM route in terms of local tolerance and serum drug level (Ch 34, ref. 216). Manufacturer recommends a treatment interval of 5-28 days. Monitor hepatic, renal function, and hematologic test results during prolonged (≥ 30 day) therapy.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Staphylococcal pyoderma	10–11	SC, PO	24 ^a	7–28
Anaerobic wounds, abscesses, dental infections, stomatitis	5–11	IV, SC, PO	12	7–28
Dental prophylaxis, reduce plaque and pockets	5	PO	12	5–8 ^b
Neosporosis, toxoplasmosis	5–20	IV, SC, PO	12	15
Neosporosis	13.5	PO	8	21
Staphylococcal osteomyelitis	11	PO	12	28–42
Anaerobic osteomyelitis	11	PO	8	28–42
Systemic, bacteremia	3–10	IV, SC, PO	8	prn
Cats				
Skin and soft tissue infections	11–24	PO, SC	24	7–28
Skin and soft tissue infections, stomatitis	5–11	PO, SC	12	7–28
Enteropathogenic toxoplasmosis	25–50	PO	24	7–14
Systemic toxoplasmosis	8–16	PO, SC	8	14–28
	12.5–25	PO, SC	12	14–28

a [Ch 85](#), ref. 13. Has also been used at 5.5 ([Ch 85](#), ref. 83). At this dosage level is only moderately effective, so higher levels 10 mg/kg every 12 hr has been more effective against resistant staphylococcal pyoderma ([Ch 85](#), ref. 63).

b [Ch 34](#), ref. 274; 405.

108.45.12 ADDITIONAL DOSAGES.

FIV stomatitis, [Table 14-6](#); endotoxemia, [Table 38-6](#); *Clostridium perfringens* diarrhea, [Table 39-10](#); anaerobic infections; [Table 41-12](#); tetanus, [Table 43-2](#); actinomycosis, [Table 49-2](#); feline abscesses, [Table 52-3](#); pneumocystosis, [Table 68-2](#); hepatozoon, [Table 74-2](#); babesiosis, [Table 77-3](#); toxoplasmosis, [Table 80-3](#); neosporosis, [Table 80-7](#); musculoskeletal infections, [Table 86-4](#); oral infections, [Table 89-4](#); intraabdominal infections, [Table 89-21](#); hepatobiliary infections, [Table 90-5](#); local use for ocular infections, [Table 93-4](#).

108.45.14 DISPENSING INFORMATION.

Shake oral suspension before each administration. Give liquid or capsules with small amount of food if vomiting occurs; otherwise give on an empty stomach. Cats may salivate when treated with PO preparations. Report any persistent or bloody vomiting or diarrhea to the veterinarian.

1231

Infectious Diseases of the Dog and Cat, 3rd Edition

1232

108.46. CLOFAZIMINE

108.46.1 CLASS.

Iminophenazine dye.

108.46.2 ACTION.

Antimycobacterial; binds preferentially to mycobacterial DNA. Some antiprotozoal and antifungal activity.

108.46.3 MORE INFORMATION.

See [Chapters 34](#) and [50](#); reference: [Ch 34](#), ref. 189.

108.46.4 PHARMACOKINETICS.

Good absorption (45%-60%) from GI tract. Highly lipophilic, taken up in adipose and mononuclear phagocytes. Retained in tissues for long periods and can be excreted via bile into feces for months. Small amounts present in other body secretions.

108.46.5 SPECTRUM.

Mycobacterium avium-intracellulare complex (MAC), opportunistic rapid-growing mycobacteria. Weak activity against *Mycobacterium leprae*. Resistance rarely develops during treatment.

108.46.6 INDICATIONS.

MAC infections, leprosy, opportunistic mycobacteriosis. Combination therapy with other drugs (see [Chapter 50](#)) overcomes resistance and increases efficacy in treating mycobacteriosis. Combined with dapsone to treat leprosy. On a limited basis has been used to treat human leishmaniasis and topical mycoses. Has anti-inflammatory activity. Has some antileishmanial activity.

108.46.7 CONTRAINDICATIONS.

During pregnancy can cause fetotoxicity and should be avoided in pre-existing gastrointestinal illness. Consider doxycycline or quinolones as alternatives.

108.46.8 ADVERSE REACTIONS.

GI pain resulting from crystalline deposits of drug in viscera (nausea, vomiting, abdominal pain). Pitting corneal lesions may develop. Reduce or discontinue drug use if signs occur. Skin and body fluid discoloration (pink to brown) especially when exposed to sunlight (photosensitivity). CNS signs, high serum hepatic transaminases.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.46.9 INTERACTIONS.

Interactions with dapsone are uncertain but combined therapy may be necessary.

AVAILABILITY ^a	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral capsules	50 mg, 100 mg	Lamprene (Geigy)

- a Drug availability is becoming limited for general use in many countries. See [Tables 50-4, 50-6, and 50-9](#). The “off label” use of clofazimine for other than leprosy is discouraged by the World Health Organization and Norvaritis. See www.fda.gov/cder/drug/shortages/lamprene_Doctor_ltr.pdf.

108.46.10 INTERNATIONAL PREPARATIONS.

Lampren.

108.46.11 HANDLING.

Store at room temperature in moisture-proof containers. Capsules contain micronized drug in an oil-wax base, making it difficult to give partial amounts. Clofazimine ‘capsules’ (which contain 50 mg of the dye) can be cut into halves using a scalpel blade while wearing disposable gloves and the 2 portions placed into gelatin capsules to facilitate dosing.

108.46.12 ADMINISTRATION.

When given with food, absorption improved.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (Weeks)
Dogs	4–8 mg/kg	PO	24	4
Cats	8 mg/kg	PO	24	4
	50 mg/cat	PO	24	4

108.46.13 ADDITIONAL DOSAGES.

Mycobacterial infections, [Tables 50-4](#) and [50-6](#).

108.46.14 DISPENSING INFORMATION.

Administer with meals. Medicine may turn animal's skin pink and its excretions a brownish-black color.

108.47 CLOTRIMAZOLE

108.47.1 CLASS.

Imidazole-antifungal.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.47.2 ACTION.

Fungistatic; inhibits ergosterol formation in fungal cell wall.

108.47.3 MORE INFORMATION.

See ENILCONAZOLE; Topical Antifungal Therapy, [Chapter 57](#), Aspergillosis, [Chapter 64](#), and Candidiasis, [Chapter 65](#), and [Tables 57-4](#), [58-7](#), [64-3](#), and references [Ch 64](#), ref. 29; [Ch 57](#), ref. 34; 133.

108.47.4 PHARMACOKINETICS.

Minimally (3%) not absorbed when used topically in mucosa and 0.5% through intact skin. Any absorbed is metabolized and excreted in bile with low concentrations of active drug and predominantly metabolites appearing in urine.

108.47.5 SPECTRUM.

Dermatophytes, yeasts (*Candida*, *Malassezia*), and *Aspergillus*.

108.47.6 INDICATIONS.

Topically used to treat dermatophytosis, yeast-induced otitis externa, and nasal aspergillosis. Used as an intravesicular flush to treat refractory *Candida* urinary infections.

108.47.7 CONTRAINDICATIONS.

Previous hypersensitivity, avoid ocular contact.

108.47.8 ADVERSE REACTIONS.

Irritating, burning sensation, erythema, nasal discharge when used in nasal passages. Use of commercial preparations containing propylene glycol or isopropyl alcohol may cause severe airway obstruction. Clotrimazole may prolong barbiturate anesthesia.

1232

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Topical solution 1% (also cream, lotion)	10 ml, 30 ml	<i>Lotrimin</i> (Schering-Plough Animal Health), <i>Mycelex</i> (Miles)
	Vaginal tablets	100 mg, 500 mg	<i>Lotrimin</i>

1233

108.47.9 INTERNATIONAL PREPARATIONS.

Antifungol, *Candibene*, *Canesten*, *Trimysten*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.47.10 HANDLING.

Flush for nasal aspergillosis: crush 1 g (two 500-mg tablets) of clotrimazole. Add to 100 ml of polyethylene glycol 400 (PEG-400) and stir on a hot plate until mixed. Keep suspension warm until used.

108.47.11 ADMINISTRATION.

Intranasal: surgically place indwelling tubes in nasal passage and frontal sinuses, or alternatively (noninvasively) anesthetize animal and flush retrograde in nostrils. The surgical invasive technique has shown better clinical response than the noninvasive method. For more details on tube placements, see procedure under ENILCONAZOLE and in [Chapter 64](#). The 1% clotrimazole is sufficiently viscous to pass through the tubes yet remain in the passages. Two 60-ml dose syringes containing the drug are attached to tubes. Initially 30 ml of the solution is flushed into each cavity. Then the remainder is flushed slowly over 60 min while the animal remains anesthetized (see [Figure 64-5](#)). **Topical:** apply to dermatophyte lesions twice daily for 3 to 4 weeks.

Bladder infusion: In a dog, the 1% topical solution was infused via ultrasonographically-guided cystocentesis with no or minimal sedation, every other day for three treatments, then one last treatment 2 weeks after the first infusion. Ultrasound observation minimized the chance of extraluminal infusion. Bladder volume is estimated and approximately the same volume of clotrimazole is infused. If the bladder volume is ≥ 30 ml, then an amount is removed so that a maximum of 30 ml remains. Infusion is done slowly through a 22-gauge 1.5 inch needle attached to a stopcock and catheter extension tube. After the needle is removed the animal is monitored for 1 hr, the solution often remains in the bladder at least 5 min before it is voided by urination. ([Ch 57](#), ref. 34) In a cat, the infusion was performed once weekly for 3 treatments ([Ch 57](#), ref. 133).

108.47.12 ADDITIONAL DOSAGES.

See [Chapter 64](#) and [Tables 85-6](#) and [85-8](#) for topical usages and formulations.

108.48 CLOXACILLIN

108.48.1 CLASS.

Isoxazolyl penicillin.

108.48.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.48.3 MORE INFORMATION.

See DICLOXACILLIN, OXACILLIN; [Chapter 34](#), Penicillins; [Table 34-1](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.48.4 PHARMACOKINETICS.

Only partially absorbed (40%-50%) from the GI tract after PO administration, and food reduces this further. Distributed to most tissues and body fluids with the exception of CNS and CSF. Metabolized by the liver to active and inactive moieties, predominantly excreted in the urine and minor amounts in bile and feces.

108.48.5 SPECTRUM.

Staphylococcus, including β -lactamase producers, other gram-positive aerobic cocci, some gram-positive anaerobes.

108.48.6 INDICATIONS.

Staphylococcal infections, especially pyoderma in dogs.

108.48.7 CONTRAINDICATIONS.

Hypersensitivity, hepatotoxicity.

108.48.8 ADVERSE REACTIONS.

See OXACILLIN.

108.48.9 INTERACTIONS.

See OXACILLIN.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules (as sodium)	250 mg, 500 mg	<i>Cloxapen</i> (SmithKline Beecham), <i>Tegopen</i> (Bristol), generic (various)
	Oral powder (as sodium)	125 mg/5 ml	<i>Tegopen</i>

108.48.10 INTERNATIONAL PREPARATIONS.

Alclox, *Anaclosil*, *Bactopen*, *Cloxyphen*, *Ekvacillin*, *Orbenin*, *Rivoclox*.

108.48.11 HANDLING.

Store oral powder and capsules at room temperature. Reconstituted oral solution is stable for 14 days if refrigerated, 3 days at room temperature.

108.48.12 ADMINISTRATION.

Give without food.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Localized soft tissue infections, staphylococcal pyoderma, diskospondylitis, osteomyelitis	10–15	PO	6	14–84
Systemic infection, bacteremia	20–40	PO	6–8	7–14

108.48.13 ADDITIONAL DOSAGES.

Musculoskeletal infections, [Table 86-4](#).

108.48.14 DISPENSING INFORMATION.

Give 1 hr before or 2 hr after feeding.

1233

108.48 DAPSONE

1234

108.49.1 CLASS.

Sulfone, 4-4'-diaminodiphenylsulfone.

108.49.2 ACTION.

Antimycobacterial, antiprotozoal. Analog of para-aminobenzoic acid, acts as folic acid synthesis inhibitor. Inhibits dihydropteroate synthetase.

108.49.3 MORE INFORMATION.

See [Chapter 34](#), Antituberculous Drugs, and [Chapter 50](#).

108.49.4 PHARMACOKINETICS.

Soluble at acidic gastric pH; however concomitantly administered alkalinizing drugs may paradoxically increase absorption. Well absorbed (70%-80%) from GI tract after PO administration. Enters all body tissues and fluids, being retained in skin, muscle, liver, and kidney. Achieves steady state after 1 week. Metabolized in liver and undergoes enterohepatic circulation. Metabolites are excreted in urine for an extended period after drug is stopped.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.49.5 SPECTRUM.

Mycobacterium leprae, *M. lepraemurium*, *Leishmania*, *Pneumocystis*.

108.49.6 INDICATIONS.

Leprosy, leishmaniasis, *Pneumocystis* pneumonia. Has been used to prevent systemic toxoplasmosis in immunosuppressed people. Recommended in combination with trimethoprim for prophylaxis in pneumocystosis (Ch 68, ref. 29). Has some anti-inflammatory activity at therapeutic dosages.

108.49.7 APPROVED USES.

Humans: leprosy and dermatitis herpetiformis.

108.49.8 CONTRAINDICATIONS.

Previous hypersensitivity, anemia, pregnancy, lactation. Reduce dosage in renal failure.

108.49.9 ADVERSE REACTIONS.

Dermatologic eruption, vomiting, diarrhea, anorexia, sulfone syndrome (dose-related hemolytic anemia, resulting from methemoglobinemia; especially with glucose-6-phosphate dehydrogenase deficiency), CNS signs, motor weakness, myelotoxicity with agranulocytosis, carcinogenic.

108.49.10 INTERACTIONS.

Toxicity of dapsone and folate antagonists is increased when used in combination perhaps because of increased concentrations. Rifampin accelerates metabolism and removal of dapsone. Increased levels of both drugs occur when coadministered with trimethoprim. Dapsone should be combined with rifampin or clofazimine or another drug to treat mycobacterial infections and avoid resistance. It should be combined with pyrimethamine or trimethoprim to treat or prevent *Pneumocystis* pneumonia (Ch 68, ref. 29).

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral tablets	25 mg, 100 mg	<i>Dapsone</i> (Jacobus)

108.49.11 INTERNATIONAL PREPARATIONS.

Aulosulfon, *Disulone*, *Isoprodian*, *Maloprim*.

108.49.12 HANDLING.

Tablets should be stored at room temperature away from light.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.49.13 ADMINISTRATION.

An oral suspension can be prepared by grinding tablets, putting in a sweet syrup, and adjusting pH to <5. Stable for 2 weeks if refrigerated. A proprietary liquid form is available (Jacobus) for investigational use.

Dosage				
INDICATIONS (MYCOBACTERIOSIS) ^a	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Initial	1.1	PO	6	Until remission
Maintenance	0.3	PO	8–12	After recovery
Cats				
	8.0	PO	24	6 weeks
^a Dose for pneumocystosis has not been determined for dogs or cats.				

108.49.14 ADDITIONAL DOSAGES.

None.

108.49.15 DISPENSING INFORMATION.

Avoid prolonged exposure of treated animals to sunlight because photosensitivity may develop.

108.50 DECOQUINATE

108.50.1 CLASS.

4-hydroxyquinolone

108.50.2 ACTION.

Antiprotozoal. Coccidiostatic drug. Interferes with life cycle of Apicomplexa protozoans. It acts by inhibiting electron transport in the parasite mitochondria, thus interfering with the development of sporozoite stages. Arrests development of *Hepatozoon* merozoites after release from meronts.

108.50.3 MORE INFORMATION.

See [Chapter 71](#), Antiprotozoal Drugs, and [Chapter 74](#) (Hepatozoonosis); Reference [Ch 71](#), ref. 54.

108.50.4 PHARMACOKINETICS.

Not available.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.50.5 SPECTRUM.

Active against *Hepatozoon* spp, *Sarcocystis* spp, *Toxoplasma gondii*, *Neospora caninum*.

108.50.6 INDICATIONS.

For the treatment of *Hepatozoon americanum* infection in dogs.

108.50.7 APPROVED USES.

For use in coccidiosis affecting food-producing animals. Available is a powdered feed additive. Comes as a tan to brown powder composed of drug mixed with corn meal, soybean oil and lecithin.

1234

108.50.8 CONTRAINDICATIONS.

Vomiting or anorexia, since given as a food additive.

1235

108.50.9 ADVERSE REACTIONS.

The compound has been studied by the manufacturer in a variety of food-producing domestic animals. It has a wide margin of safety. Multiple studies in dogs including two year toxicity studies have shown no adverse effects on body functions including reproduction. No toxic effects were observed in dogs given 15 or 1000 mg/kg for 13 weeks; or 200 µg/g or 1000 µg/g in the diet for 2 yrs.

108.50.10 INTERACTIONS.

None known, given with a variety of folate synthesis antagonists and clindamycin as combined therapy for Hepatozoonosis (see [Chapter 74](#)).

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Cattle, Sheep, Goats, Broiler Chickens	Powder 6%	27.2gm active compound/lb	Deccox (Alpharma)

108.50.11 INTERNATIONAL PREPARATIONS.

Same worldwide.

108.50.12 HANDLING.

Powder is stable in the dry form at ambient temperature (25°C) with a 48-mo expiration. Powder is hygroscopic and should be stored in airtight containers.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.50.13 ADMINISTRATION.

Oral powder is mixed with food. Drug therapy must be given continuously on a daily basis to inhibit development of the protozoans. During treatment, organisms have been found to persist for up to 18 mo or more in some cases. It is likely that the infection is never eliminated in treated dogs.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Hepatozoonosis	10–20	PO	12	365 to 730 ^a
Hepatozoonosis	50	PO	24	730

a Given initially with trimethoprim-sulfonamide, clindamycin and pyrimethamine for 14 days (see [Table 74-2](#)). Then decoquinatate is continued alone. These three drugs are reinstituted if animal relapses. At the end of the treatment period, a muscle biopsy should be examined and if the parasite is eliminated, then therapy can be discontinued.

108.50.14 ADDITIONAL DOSAGES.

Could be used at a shorter interval in dogs to control coccidiosis as in food-producing animals; however, not approved for this use.

108.50.15 DISPENSING INFORMATION.

Mix measured amount of powder granules to food and twice each day.

108.51 DICLAZURIL

108.51.1 CLASS.

Benzeneacetonitrile.

108.51.2 ACTION.

Antiprotozoal, anticoccidial (coccidiostat).

108.51.3 MORE INFORMATION.

[Chapter 71](#). See also similar drugs, TOLTAZURIL and PONAURIL.

108.51.4 SPECTRUM.

Coccidia, *Hepatozoon*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.51.5 INDICATIONS.

Coccidiosis. Has been used extralabel to treat *Sarcocystis neurona* infection in horses.

108.51.6 APPROVED USES.

Coccidiosis in broiler chickens as a feed additive.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Powder 0.5% (5g/kg)	20kg bag	Vecoxan, Clinicox (Janssen ^a)

a Supplier in some countries is Pharmacia Upjohn or Schering Canada.

Dosage

INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Coccidiosis	25	PO	24	1

108.51.7 ADDITIONAL DOSAGES.

Coccidiosis, [Table 81-2](#). Reference [Ch 71](#), ref. 52.

1235

108.52 DICLOXACILLIN

1236

108.52.1 CLASS.

Isoxazolyl penicillin.

108.52.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.52.3 MORE INFORMATION.

See OXACILLIN, CLOXACILLIN; [Chapter 34](#) and [Table 34-1](#).

108.52.4 PHARMACOKINETICS.

Similar in dogs and cats ([Ch 34](#), ref. 95) Following IM dosing, concentrations >4 µg/ml in serum for at least 8 hr. IV levels peak higher but remain lower through duration of elimination. Peak levels and time duration is lower with PO administration. Partially absorbed (35%-70%) from GI tract after PO administration, which is reduced by ingesta. Well distributed to tissues and body fluids with exception of CNS and CSF. This relates to high degree of plasma protein binding (90%) in dogs.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.52.5 SPECTRUM.

Staphylococcus, including β -lactamase producers, other gram-positive aerobic cocci, some gram-positive anaerobes.

108.52.6 INDICATIONS.

Staphylococcal infections, pyoderma.

108.52.7 CONTRAINDICATIONS.

See OXACILLIN.

108.52.8 ADVERSE REACTIONS.

See OXACILLIN.

108.52.9 INTERACTIONS.

See OXACILLIN.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)

	Oral powder for suspension (as sodium)	125 mg/5 ml	<i>Pathocil</i> , <i>Tegopen</i>

108.52.10 INTERNATIONAL PREPARATIONS.

Diclocil, *Dicloxan*, *Diclocillin*, *Dynapen*, *Novapen*.

108.52.11 HANDLING.

Store capsules and powder at controlled room temperature. Once reconstituted, oral solution is stable for 14 days when refrigerated, 7 days at room temperature.

108.52.12 ADMINISTRATION.

Food interferes with absorption.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Localized soft tissue or skin infections caused by susceptible (non- β -lactamase producers) bacteria	25	PO	6	14–84
Problematic (resistant) staphylococci, systemic infections	25	IM, IV	6–8	prn

108.52.13 ADDITIONAL DOSAGES.

None.

108.52.14 DISPENSING INFORMATION.

Give at least 1 hr before or 2 hr after feeding. Store oral suspension in refrigerator.

108.53 DIETHYLCARBAMAZINE: SEE IMMUNOMODULATORS, [Chapter 2](#).

108.54 DIFLOXACIN

108.54.1 CLASS.

Fluoroquinolone.

108.54.2 ACTION.

Bactericidal, inhibits bacterial DNA gyrase.

108.54.3 MORE INFORMATION.

See ENROFLOXACIN, MARBOFLOXACIN, ORBIFLOXACIN; [Chapter 34](#); [Table 34-11](#).

108.54.4 PHARMACOKINETICS.

Bioavailability exceeds 80%. Active drug comprises 90% of plasma levels following oral or IV administration. Low plasma protein binding of 46% to 52%. Readily diffuses into tissues. Lipophilic with most (80%) elimination in biliary tract as glucuronide and only 5% excreted in urine. Undergoes enterohepatic circulation. Does not accumulate when a 24-hr interval of administration is used.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.54.5 BODY FLUID/TISSUE DISTRIBUTION IN DOGS.

After a single dose of 10 mg/kg PO (expressed as µg/ml or µg/g).

a Based on percent of dose with urine output at 50 ml/kg/day.

108.54.6 SPECTRUM.

Gram positive: *Staphylococcus intermedius*. **Gram negative:** *Escherichia*, *Pasteurella*, *Enterobacter*, *Pseudomonas*, *Proteus*, *Klebsiella*. **Anaerobes:** Not effective. **Others:** *Mycoplasma*, *Chlamydia*, *Rickettsia*, some opportunistic mycobacteria. **Most Effective:** Anaerobic and facultative gram-negative organisms. **Intermediate Effective:** *Proteus* spp, *Staphylococcus* spp, *Streptococcus canis*, other streptococci. **Ineffective:** *Enterococcus*, *Actinomyces*, *Nocardia*, *M. avium-intracellulare*, *Leptospira*, *Ehrlichia*, and obligate anaerobes.

108.54.7 INDICATIONS.

Skin, soft tissue, and acute uncomplicated urinary infections. Effective against many gram negative bacteria such as *E. coli* and *Staphylococcus* spp. Alternative to aminoglycosides in presence of renal failure or when oral therapy is desired. See also ENROFLOXACIN.

108.54.8 APPROVED USES.

Skin, soft tissue, and urinary infections in dogs.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.54.9 CONTRAINDICATIONS.

Not for growing dogs or dogs with a history of seizures. Not for use in pregnant or lactating bitches or male stud dogs. See also ENROFLOXACIN.

108.54.10 ADVERSE REACTIONS.

Generally self limiting, anorexia, vomiting, diarrhea, and anal irritation. See also ENROFLOXACIN. Transient erythema/edema on the facial area, diarrhea, decreased appetite have been seen, especially at higher than therapeutic dosages in dogs.

108.54.11 INTERACTIONS.

See ENROFLOXACIN. Compounds (e.g. sucralfate, antacids) containing divalent and trivalent cations may interfere with the absorption of these drugs from the GI tract.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary (dogs)	Oral tablets (as hydrochloride)	11.4 mg, 45.4 mg, 136 mg (USA) 15, 50, 150 mg (Europe)	<i>Dicural</i> (Fort Dodge)
	Solution	50 mg/ml (Europe)	

108.54.12 HANDLING.

Store tablets between 15–25°C away from moisture.

108.54.13 ADMINISTRATION.

See ENROFLOXACIN.

Dosage				
INDICATIONS	DOSE(mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Skin and urinary infections	5	PO	24	Maximum 21 days ^a
a Give for 2 to 3 days beyond resolution of clinical signs to a maximum of 30 days.				

108.54.14 ADDITIONAL DOSAGES.

None.

108.54.15 DISPENSING INFORMATION.

See ENROFLOXACIN.

1237

Infectious Diseases of the Dog and Cat, 3rd Edition

1238

108.55.5 DIIDOXYHYDROXYQUIN

(See IODOQUINOL)

108.55.1 CLASS.

8-hydroxyquinoline.

108.55.2 ACTION.

Antiprotozoal.

108.55.3 MORE INFORMATION.

See IODOQUINOL.

108.56.1 DIMINAZENE ACETURATE

108.56.1 CLASS.

Aromatic diamidine.

108.56.2 ACTION.

See PENTAMIDINE.

108.56.3 MORE INFORMATION.

See PENTAMIDINE, IMIDOCARB, AMICARBALIDE; [Chapter 71](#) and [Table 71-1](#); references: [Ch 71](#), ref. 19; 53; 68; 69; 71; 72; 62.

108.56.4 PHARMACOKINETICS.

Not well absorbed orally. Rapid uptake after IV or IM administration, distributed extensively in tissues. Some hepatic metabolism with gradual urinary excretion of metabolites and active drug. Residues may persist for weeks in liver and kidneys, with lower amounts in GI tract, lungs, muscle, brain, fat, milk ([Ch 71](#), ref. 69).

108.56.5 SPECTRUM.

African *Trypanosoma*, *Babesia*, *Leishmania*, *Hepatozoon*, *Cytauxzoon*; some resistance may develop with repeated use.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.56.6 INDICATIONS.

African trypanosomiasis, babesiosis, cytauxzoonosis.

108.56.7 APPROVED USES.

African trypanosomiasis in cattle.

108.56.8 CONTRAINDICATIONS.

Pre-existing cardiomyopathy or heart failure.

108.56.9 ADVERSE REACTIONS.

Vomiting may occur. Less likely to produce acute anaphylaxis than other drugs in this class. Dosages up to 12 mg/kg are more effective in eliminating the organism but are more toxic. In general doses >10 mg/kg should be avoided. Like other diamidines may produce CNS signs, including behavioral changes, nystagmus, ataxia, extensor rigidity, opisthotonus, sometimes death. Although signs have been attributed to parasympathomimetic signs related to cholinesterase inhibition, this was not documented in treated dogs with babesiosis (Ch 71, ref. 62). Acute hemorrhagic gastroenteritis and cardiomyopathy have been reported. Delayed onset (1 week later) of CNS signs may relate to intracerebral killing of *Babesia*. Cats become anorectic, febrile, and depressed after initial treatment for *Cytauxzoon*. Hypotension occurs during treatment of canine babesiosis; however it does not develop as a direct effect of the drug in healthy dogs (Ch 71, ref. 40).

108.56.10 INTERACTIONS.

For *T. congolense*, best response when combined with the experimental drug, difluoromethylornithine (DFMO), Hoechst Marion Roussel, Cincinnati, Ohio, (513)-948-7003 (Ch 71, ref. 68). Synergism against trypanosomes has also been observed with suramin. To prevent adverse reactions, antihistamines or nonsteroidal anti-inflammatory drugs (respectively, mepyramine maleate or piroxicam) have been used (Ch 71, ref. 72).

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Parenteral injection	Diluted to 70 mg/ml	<i>Berenil</i> (Bayer); not available in U.S.

108.56.11 INTERNATIONAL PREPARATIONS.

Azidine, Ganaseg, Ganasegur, Veriben.

108.56.12 HANDLING.

To ensure stability, should be kept refrigerated in sealed glass light-proof containers. At room temperature, solution is stable for at least 10-15 days. Lyophilized powder has an extended shelf-life for months at room temperature.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.56.12 ADMINISTRATION.

For *Babesia*, more effective treatment to eliminate resistant infections has been achieved by 3.5 mg/kg diminazene followed in 24 hr by 5 mg/kg imidocarb (Ch 71, ref. 71). Trypanosomes may disappear from the blood within 24 hr of treatment, but hematologic changes take at least 3 weeks to correct. CBC should be performed weekly. May have to repeat as needed if parasitemia recurs. Some suggest one or two additional daily treatments for resistant infections, but toxicity increases. Has been used topically to treat cutaneous leishmaniasis. Cats become more depressed, febrile, and anorectic after one injection presumably related to parasite death. A second injection is given after these signs subside. Inflammatory reactions in muscles or skin, causing lameness or dermatitis, respectively, can be prevented by deep IM injection in lumbar muscles.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
African trypanosomiasis (<i>T. brucei brucei</i> , <i>T. congolense</i>)	7.0	IM	24	1
Babesiosis				
<i>Babesiacanis</i>	3.5–5.0	IM, SC	24	1
<i>Babesiagibsoni</i>	7.5–10	IM, SC	24	1
Cats				
Cytauxzoonosis	2.0	IM, SC	96	^a

^a A second dose is given at an interval of 72–96 hr after the first injection or when adverse signs of the first injection subside (Ch 76, ref. 14).

1238

108.56.14 ADDITIONAL DOSAGES.

1239

African trypanosomiasis, Table 72-1; cytauxzoonosis, Table 76-1, babesiosis, Table 77-3.

108.57 DOXYCYCLINE

108.57.1 CLASS.

Tetracycline.

108.57.2 ACTION.

Bacteriostatic; inhibits bacterial protein synthesis by binding 3 ribosomal units.

108.57.3 MORE INFORMATION.

MINOCYCLINE; TETRACYCLINE; Chapter 34; Table 34-7; references: Ch 34, ref. 309; 332.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.57.4 PHARMACOKINETICS.

In presence of food, 93% absorption of PO dose; blood concentration after PO dose is equivalent to IV dose. More lipid soluble (five times) than tetracycline, allowing better GI absorption and good penetration into most tissues and body fluids, including difficult areas such as prostate, female reproductive tract, eye, CNS, lung, sputum, bile. Persists in respiratory and prostatic secretions. Crosses placenta to accumulate in fetal bone, teeth and enters milk. Penetrates well into nasal sinuses. Extensively bound to plasma proteins (>90%) as compared to other tetracyclines, giving it half-life of 10 hr in dogs. Long half-life for a tetracycline, making once- or twice-daily dosing feasible. Primary elimination into digestive tract by nonbiliary secretion as inactive compounds with up to 90% eliminated in feces. Therefore, can be given without concern in animals with renal failure. Has some biliary elimination with enterohepatic circulation. Approximately 20% appears in urine via glomerular filtration. Higher plasma protein binding in cats makes it less well distributed, and plasma concentrations are approximately twice those of dogs given the same dose ([Ch 34](#), ref. 310).

108.57.5 SPECTRUM.

Gram positive: few *Streptococcus*, few *Staphylococcus*, *Nocardia*, *Listeria*, *Bacillus*. **Gram negative:** *Bartonella*, *Brucella*, *Francisella*, *Pasteurella*, *Campylobacter*, *Helicobacter*, *Yersinia*, *Enterobacter*, *Klebsiella*, *Bordetella*. **Anaerobes:** *Clostridium*, *Fusobacterium*, *Actinomyces*. **Others:** *Haemobartonella*, *Chlamydia*, *Mycoplasma*, *Rickettsiae* (*Coxiella*, *Rickettsia*, *Ehrlichia*), *Spirochetes* (*Leptospira*, *Borrelia*), opportunistic rapid-growing mycobacteria, *M. avium-intracellulare* complex, *Entamoeba*, *Balantidium*, *Coccidia*, *Toxoplasma*. **More effective:** *Borrelia*, *Rickettsia*, *Leptospira*. **Ineffective:** *Proteus*, *Enterobacter*, *Klebsiella*, *Escherichia*, *Pseudomonas*. Gram-negative bacteria frequently develop resistance. Cross-resistance between other tetracyclines occurs.

108.57.6 INDICATIONS.

Acute urinary infections, chronic prostatitis, respiratory tract infections, nasal and sinus infections, periodontal disease, rickettsial diseases, borreliosis, chlamydial and mycoplasma infections, hemotropic mycoplasmosis (hemobartonellosis), tularemia, actinomycosis, nocardiosis, mycobacteriosis, canine ehrlichiosis, borreliosis, Rocky Mountain spotted fever, leptospirosis, bartonellosis, intestinal amebiasis. Combined with aminoglycosides in treatment of brucellosis. In leptospirosis, has been used to clear the carrier state. Reduces severity of articular cartilage breakdown in various animal models of noninfectious arthritis ([Ch 34](#), ref. 42; 184), which questions the assumption that all doxycycline-responsive polyarthritis is infectious. Has been used in conjunction with niacinamide to treat immune mediated dermatoses such as pyogranulomatous dermatitis or pemphigus. It has been effective in treating lymphocytic/plasmacytic pododermatitis in cats.

108.57.7 CONTRAINDICATIONS.

Pregnancy, (embryotoxic). Minimal dose adjustment needed with hepatic or renal failure. Unlike other tetracyclines, doxycycline does not accumulate in renal failure in dogs because it diffuses passively into the intestinal lumen ([Ch 34](#), ref. 310). Therefore, it is the best tetracycline for use in an azotemic animal. Less of a problem with dental staining so can be used in younger (<6-mo old animals).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.57.8 ADVERSE REACTIONS.

Esophageal irritation and strictures (Ch 34, ref. 126a; 249; 254). Vomiting and GI irritation, especially from esophagitis, can be reduced by administering with food. Esophagitis and esophageal ulcers that form can be reduced by giving liquids or food after dosing and not giving to recumbent animals. May relate to formulation because capsules are more irritating than tablets or enteric coated preparations. The monohydrate salt is less acidic and ulcerogenic than the hydrochloride or hyclate formulations. Gastroenteritis can develop, especially in cats, but this drug is better tolerated than other tetracyclines in this species, causing less fever, anorexia, and vomiting compared with other tetracyclines. Because of more complete absorption, microfloral alterations and diarrhea are less frequent with other tetracyclines. Hypotension or vomiting may be observed with rapid IV infusion of doxycycline hyclate. Photosensitivity and skin eruptions may develop. Teeth and bone deposition and discoloration occur in young, but of all tetracyclines, doxycycline is least likely to have this effect (Ch 34, ref. 101). Diarrhea from enteric microbial alterations is less common than with tetracycline, presumably because of the better enteric absorption and lower dosage needed with doxycycline. Hepatotoxicity can occur in dogs and cats after oral or parenteral therapy. Dramatic increases in serum alanine transaminase and alkaline phosphatase are noted. Thrombocytopenia, neutropenia, and eosinophilia have been observed in people, and neutropenia has been observed in dogs.

108.57.9 INTERACTIONS.

GI absorption reduced by divalent and trivalent cations as found in iron preparations, aluminum hydroxide gels, sodium bicarbonate, bismuth subsalicylate, calcium, and magnesium salts. Having a high lipid solubility, it has less affinity for calcium binding as do other tetracyclines. Ingesta has relatively little effect on GI absorption. Half-life of anticonvulsants (phenobarbital, diphenylhydantoin) may be reduced, and these drugs reduce doxycycline serum concentrations. Rifampin may also increase clearance, lowering doxycycline efficacy. Interferes with activity of aminoglycosides, cephalosporins, penicillins. Renal failure can develop owing to calcium oxalate nephrolithiasis after methoxyflurane anesthesia.

1239

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules or tablets (hyclate)	50 mg, 100 mg	<i>Doxychel</i> (Rachelle), <i>Vibramycin</i> (Pfizer), generic (various)
	Oral syrup (calcium)	50 mg/5 ml	<i>Vibramycin</i>

a Not available in USA.

108.57.10 INTERNATIONAL PREPARATIONS.

Abadox, *Biocyclin*, *Cyclidox*, *Diolan*, *Doxina*, *Doxydyn*, *Doxyhexal*, *Doxymycine*, *Dumoxin*, *Gewacyclin*, *Helvedoclyn*, *Ronaxan*, *Rudocycline*, *Unacil*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.57.11 HANDLING.

Parenteral hyclate solution is reconstituted with sterile water. Compatible when diluted to 1 mg/ml in 0.9% NaCl, 5% dextrose, Ringer's, and lactated Ringer's. Solutions of infusion fluids are generally stable for at least 12 hr at room temperature to 72 hr if refrigerated. Incompatible with solutions containing lidocaine, penicillin G, and piperacillin-tazobactam. Store tablets and capsules at room temperature in airtight light-proof containers. After reconstitution, the PO suspension is stable at room temperature for 2 weeks. Oral gel should be stored in refrigerator (2–8°C).

108.57.12 ADMINISTRATION.

Parenteral: This is the only tetracycline recommended for IV use, because it is less likely to cause thrombophlebitis or hepatic toxicity. For IV use, give as slow infusion over at least 1 hr in diluted form. Do not give IM or SC. **Oral:** Oral fluids, given at the time of medication, will propel the tablets or capsules into the stomach and reduce the effects of esophageal irritation and ulceration (Ch 34, ref. 415). Tablets or capsules can be crushed or opened and mixed with food. Must avoid liquids containing polyvalent cations, which affect absorption. If gastric irritation occurs, give medication with food or milk, because the latter does not affect absorption of doxycycline as much as with other tetracyclines. **Topical:** Teeth should be scaled prior to application. The product is applied under sedation or anesthesia. It is mixed and applied with a canula 1-2 mm below the gingival margin of each tooth. See package insert for complete directions.

Dosage				
INDICATIONS ^a	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Antiarthritic effect	3–4 mg/kg	PO	24	7–10 ^b
General use for infection	3–5 mg/kg	PO	12	7–14
Soft tissue, urinary	4.4–11 mg/kg	PO, IV	12	7–14
Acute <i>E. canis</i> infection	5 mg/kg	PO	12	14
Acute <i>E. canis</i> infection	10 mg/kg	PO	24	16 ^c
Chronic <i>E. canis</i> infection	10 mg/kg	PO	24	30–42 ^d
Cats^e				
Hemotropic mycoplasmosis	5–10 mg/kg	PO	24	14 ^f
Bartonellosis	50 mg/cat	PO	12	14–28
Systemic infection, bacteremia	5–11 mg/kg	PO, IV	12	prn
Ehrlichiosis or Anaplasmosis	5–10 mg/kg	PO	12	21

a For topical use, see under Administration.

b Ch 34, ref. 42; 184.

c Dogs treated with acute monocytic ehrlichiosis were cleared as tested by PCR of splenic aspirates (Ch 34, ref. 152c)

d 34:Ch 34, ref. 153; 152c.

Infectious Diseases of the Dog and Cat, 3rd Edition

- e Because of esophageal irritation from doxycycline, the dosage should be rounded up so that whole capsules or tablets are given, especially to cats.
- f Effective in reducing quantitative blood PCR gene copy level of *Mycoplasma haemofelis* in treated cats (Ch 34, ref. 365a).

108.57.13 ADDITIONAL DOSAGES.

Canine infectious tracheobronchitis, Table 6-1; salmon poisoning, Table 27-2; ehrlichiosis, Table 28-4; Rocky Mountain spotted fever, Table 29-4; hemotropic mycoplasmosis, Table 31-3; canine brucellosis, Table 40-2; leptospirosis, Table 44-7; Lyme borreliosis, Table 45-5; mycobacterial infections, Tables 50-4, 50-7, and 50-9; feline abscesses, Table 52-3; feline bartonellosis, Table 54-3; hepatozoonosis, Table 74-2; babesiosis, Table 77-3; musculoskeletal infections, Tables 86-3 and 86-4; respiratory infections, Table 88-8; hepatobiliary disease, Table 90-5.

108.57.14 DISPENSING INFORMATION.

May be given with food if necessary, especially to help reduce vomiting. Do not give with antacids, dairy products (less of a problem), iron supplements. To avoid esophageal irritation, tablets or capsules should not be broken or crushed and water should be given immediately after (by syringe if necessary) to flush the drug into the stomach.

1240

108.58 DROTRECOGIN ALFA (RECOMBINANT HUMAN ACTIVATED PROTEIN C, RHAPC)

1241

108.58.1 CLASS.

Glycoprotein. Analog of native protein C synthesized and secreted by genetically altered human cells. Activated by thrombin in vitro.

108.58.2 ACTION.

Inhibits coagulation, increases fibrinolysis, inhibits synthesis of tumor necrosis factor which has also been incriminated in the pathogenesis of sepsis.

108.58.3 MORE INFORMATION.

Chapter 38, Endotoxemia.

108.58.4 PHARMACOKINETICS.

In people, reaches a steady state 2 hr after starting an infusion. Is inactivated by plasma protease inhibitors. Drug cannot be detected after infusion is discontinued.

108.58.5 INDICATIONS.

Adjunctive treatment of severe sepsis manifested by organ dysfunction.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.58.6 APPROVED USES.

People for treatment of septic shock.

108.58.7 CONTRAINDICATIONS.

Patients with active or recent bleeding tendencies or with a risk of bleeding from trauma. Must be avoided where CNS lesions are present that may predispose to bleeding in neural parenchyma.

108.58.8 ADVERSE REACTIONS.

GI and intraabdominal bleeding most frequent. Hemorrhage can occur in any other organ.

108.58.9 INTERACTIONS.

Bleeding in people was not increased when low-dose SC heparin was used concurrently as prophylaxis for hypercoagulable states. Antibodies to human protein might be expected to develop with repeated use and these might interfere with subsequent effectiveness or produce allergic reactions.

AVAILABILITY	TYPE	SIZE	PREPARATION (COMPANY)
Human	Lyophilized for reconstitution	5- and 20-mg vials	<i>Xigris</i> (Lilly)

108.58.10 HANDLING.

Once reconstituted, should be used within 12 hr.

108.58.11 ADMINISTRATION.

Given as a continuous IV infusion. No change in dose or rate is needed for hepatic or renal failure. Infusion should be discontinued at least 2 hr prior to surgery or invasive procedures. Can be restarted 12 hr after major surgery or immediately after minor procedures is hemostasis is achieved.

INDICATIONS (NEUTROPENIA)	DOSE ^a (mg/kg/hr)	ROUTE	INTERVAL (hr)	DURATION (hr)
<i>Dogs and Cats</i>				
Severe sepsis	24	IV	Continuous	96
^a Human dosage regimen.				

108.58.12 ADDITIONAL DOSAGES.

Doses for dogs and cats have not been established.

108.58.13 DISPENSING INFORMATION.

For use in hospitalized patients; coagulation parameters should be monitored during use.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.59.1 **ENDOTOXIN ANTISERA**

108.59.1 **CLASS.**

Immunoglobulin.

108.59.2 **ACTION.**

Neutralizes gram-negative endotoxin.

108.59.3 **MORE INFORMATION.**

[Chapters 8, 38, and 100](#); references: [Ch 100](#), ref. 122; 429.

108.59.4 **PHARMACOKINETICS.**

Enters systemic circulation at time of infusion.

108.59.5 **SPECTRUM.**

Salmonella typhimurium endotoxin antiserum of equine origin.

108.59.6 **INDICATIONS.**

Canine or feline parvoviral diarrhea with signs of bacterial sepsis, gram-negative bacterial infections with endotoxemia.

108.59.7 **APPROVED USES.**

Gram-negative endotoxemia.

108.59.8 **CONTRAINDICATIONS.**

Younger than 8 weeks of age, use only once.

108.59.9 **ADVERSE REACTIONS.**

Anaphylactic reactions likely after repeated administration. If anaphylactoid reaction occurs, administer epinephrine. A second administration is not indicated because the course of illness is limited.

108.59.10 **INTERACTIONS.**

For adjunctive therapy, see [Table 38-8](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.59.11 INDICATIONS.

Canine or feline endotoxemia or parvoviral infections with associated endotoxemia.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Equine-origin antisera	50-ml bottles	SEPTI-serum (Immvac)

1241

108.59.12 HANDLING.

If refrigerated, 36-mo shelf-life. Use or dispose of entire contents once opened.

1242

108.59.13 ADMINISTRATION.

Warm refrigerated solution to room (or preferably body) temperature before use. Given IV, diluted 1 : 1 with sterile isotonic saline or lactated Ringer's. Give only once over at least a 30-min period.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Dogs and Cats</i>	4–8 mg/kg	IV	Once	1

108.59.14 ADDITIONAL DOSAGES.

None.

108.60.1 ENILCONAZOLE

108.60.1 CLASS.

Triazole (a.k.a., imazalil, ISO 1750).

108.60.2 ACTION.

Antifungal. See also KETOCONAZOLE.

108.60.3 MORE INFORMATION.

See [Chapters 57](#) and [65](#); [Table 57-4](#); reference: [Ch 57](#), ref. 118.

108.60.4 PHARMACOKINETICS.

Not absorbed from the GI tract after PO administration. Only used topically and not absorbed, even where epithelium is damaged. Creates a vapor phase at the site of local application that may add residual activity.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.60.5 SPECTRUM.

Microsporum, Trichophyton, Aspergillus, Malassezia.

108.60.6 INDICATIONS.

Topical for dermatophytosis in dogs and for IN installation in dogs with nasal aspergillosis. Extralabel use with emulsion in treating feline dermatophytosis. For canine nasal aspergillosis, its use in daily nasal flushes via surgically implanted tubes for 14 days is effective.

108.60.7 APPROVED USES.

Dermatophytosis in dogs.

108.60.8 CONTRAINDICATIONS.

Not recommended for use in cats owing to potential toxicity; however topical use for dermatophytosis in diluted formulations has been effective at the emulsion concentration of 0.2%.

108.60.9 ADVERSE REACTIONS.

Systemic reactions in cats. Oral ingestion during administration can cause salivation, inappetence, weight loss, increased hepatic enzymes and idiopathic. However, with topical use, in one study, whole-body application twice weekly for 8 weeks in cats with dermatophytosis failed to reveal any adverse reactions (Ch 57, ref. 26). In another study, Persian cats treated topically with 0.2% solution every 3 days for a total of 8 treatments were monitored for 180 days. (Ch 57, ref. 56). Hypersalivation, idiopathic muscle weakness, and elevated serum ALT were noted. The cats improved clinically and became culture negative by day 28. By day 180 some of the cats developed lesions again and all were culture positive. In general, the solution was effective and well tolerated; however, other measures would be needed to prevent reinfections. The undiluted solution is irritating. However, when it is mixed with water as a diluted emulsion it is nonirritating to the skin or eyes or mucosae. With intranasal solution in conscious dogs with surgically implanted tubes, drooling, sneezing, head shaking may occur for 10-15 min with each flush.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Topical solution (for ringworm in cattle, horses, and dogs)	100 mg/ml (10%)	<i>Imaverol</i> (Janssen);
	Disinfectant solution (for poultry hatcheries)	750 ml bottle (13.8%)	<i>Clinifarm EC, Clinifarm SG</i> (Schering-Plough)

108.60.10 HANDLING.

Wear protective rubber gloves when working with solutions. For topical use on skin, the concentrated solution is diluted 1 : 50 with lukewarm water to produce 0.2% (2 mg/ml) emulsion. Higher concentrations diluted 1 : 10 (10 mg/ml) to a strength of 1%, or greater, are used for nasal lavage. Prepare emulsion immediately prior to use. Do not discharge any into streams or untreated water supplies. Store at room temperature protected from light for stability up to 5 yrs.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.60.1 ADMINISTRATION.

Dermatophytosis and dermatomycosis: remove crusts on diseased skin. As *Clinifarm EC* solution, dilutions of 50 : 1 with water to produce emulsion have been applied as a sponge dip for topical treatment of dermatophytosis, or cutaneous infections with *Malassezia* or *Candida* (Ch 57, ref. 27). For best results, shave long-haired dogs. Unless cats are long-haired with generalized lesions, clip only around visible lesions since shaving spreads fungus and abrades remaining skin. Burn all hair removed. Apply diluted emulsion 3-day intervals for four treatments. Cats can be treated without shaving but by brushing the emulsion through their haircoat. **Environmental control of dermatophytes:** A smoke generator (5 g enilconazole for 50 cubic meter room) or an emulsifiable concentrate (15% solution which is diluted 1 : 100 in tap water) can be used to smoke or spray respectively. **Aspergillosis surgical tube placement method:** under anesthesia, holes are drilled in the frontal sinuses and tubes inserted. Combine with turbinectomy initially or later if disease recurs. After anesthetic recovery, infuse 7-10 mg/kg of 10% solution (of *Imaverol*), diluted 50 : 50 with sterile water, through tubes twice daily for 10-14 days. **Nonsurgical method:** see Chapter 64 for tube placement. Various techniques have been described. In general, the dog, under general anesthesia, has its nasal passage lavaged with saline, and debris is removed, sometimes via endoscopy. The Foley catheters are positioned in the nasal passages or sinuses, sometimes via endoscopy. The nares and oropharynx are occluded to prevent leakage. The volume, which usually approaches 60-75 ml per nostril for larger breeds, is infused over 1 hr, while the animal is repositioned to bathe all nasal and sinus areas, before anesthetic recovery. **Results of nonsurgical method:** The nonsurgical method has been effective using clotrimazole in polyethylene glycol base (see Clotrimazole). However, treatment failure and mucosal irritation was observed with enilconazole when 1 : 10 diluted Imaverol solution, creating a 1% emulsion (10 mg/ml), was used as a one-hour nasal lavage as a single application under anesthesia (57:Bray et al 1998). These same animals responded to subsequent daily infusion of the same solution via implanted tubes. In a second study (Ch 64, ref. 163), dogs were treated with a nasal lavage under anesthesia using 1% or 2% enilconazole emulsion (*Imaverol*) with reported success. Dogs having 2% emulsion lavage, followed by subsequent treatment with oral ketoconazole (10 mg/kg every 12 hr for 4-6 weeks), had a better response to treatment. In this study, tubes were endoscopically placed up dorsally in the frontal sinuses. In a third study (Ch 57, ref. 90), dogs were treated by topic intranasal lavage under a single anesthetic procedure using commercial grade enilconazole (*Clinifarm-EC*) diluted to 5% concentration (50 mg/ml) with sterile water. The tubes were placed endoscopically into the caudal nasal passage and the dogs were positioned in dorsal and then ventral recumbency during a 1-hr contact period of intranasal infusion. To minimize mucosal contact with this more concentrated enilconazole solution, cotton plugs were placed in the nares, gauze squares were packed around the endotracheal tube in the oropharynx, and accessible mucosal areas were coated with petrolatum.

1242

1243

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Nasal aspergillosis (<i>Imaverol</i>)	10 mg/kg (50:50 diluted)	Topically via indwelling tubes	12	7-14
Dermatomycosis (<i>Clinifarm EC</i>)	Volume varies (50:1 diluted)	Topically via dip, sponge bath or brushing	72-96	21-42 ^a

^a Minimum 21 days for *Malassezia* and 28-42 days for dermatophytes.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.60.12 ADDITIONAL DOSAGES.

Dermatophytosis, [Table 58-7](#).

108.60.13 DISPENSING INFORMATION.

Nasal flush: With indwelling tubes, dilute dispensed solution volume for each dose 50 : 50 with provided water immediately prior to use, and infuse via syringe. **Emulsion:** For dip, emulsion is stable for 4-6 weeks once diluted, if it is protected from light. Manufacturer recommends preparation of a fresh dilution with each use.

108.61 ENROFLOXACIN

108.61.1 CLASS.

Fluoroquinolone.

108.61.2 ACTION.

Bactericidal; inhibits bacterial DNA gyrase.

108.61.3 MORE INFORMATION.

See CIPROFLOXACIN, DIFLOXACIN, IBAFLOXACIN, MARBOFLOXACIN, ORBIFLOXACIN; [Chapter 34](#); [Table 34-11](#); references: [Ch 34](#), ref. 3; 14; 15.

108.61.4 PHARMACOKINETICS.

This concentration-dependent antimicrobial is well absorbed (80%-100%) from GI tract. Widely distributed in body tissues, including skeleton, CNS, CSF. Highest concentrations in liver, bile, kidney, genital tissues and secretions, urine ([Ch 34](#), ref. 390). Penetrates and concentrates in macrophages, neutrophils. Carried to sites of inflammation and surrounding tissues and fluids. Concentrations in bone, lungs, prostate, kidneys are sufficient to affect aerobic and facultative gram-negative bacteria. Higher than serum concentrations in saliva, genital, nasal, and bronchial secretions. Adequate concentrations in CNS and CSF are only reached at higher doses or with inflamed meninges. Ciprofloxacin, the major metabolite of enrofloxacin, achieves prostatic concentrations 30 times that in blood ([Ch 34](#), ref. 14). Ciprofloxacin also accumulates in leukocytes along with enrofloxacin. Leukocytes likely carry these drugs to sites of infection where the drug may be released after the cells die, or affect intracellular pathogens that survive phagocytosis. Compared with ciprofloxacin, tissue enrofloxacin concentrations are often higher than in blood owing to less protein binding, high tissue penetration, extended serum half-life. Concentrations in skin exceed those in blood after several days of therapy and may be suitable to treat dermal staphylococcal isolates ([Ch 34](#), ref. 353). Concentrations in inflamed skin (superficial and deep pyoderma) are greater than in healthy skin ([Ch 34](#), ref. 93; 91). Predominate route of excretion in dogs is biliary (70%) via glucuronidation with subsequent enterohepatic circulation. The remainder (30%-40%) is excreted in the urine, with up to 50% unchanged ([Ch 34](#), ref. 194). The remainder is metabolized to less active compounds and to active ciprofloxacin with biliary (fecal) and

Infectious Diseases of the Dog and Cat, 3rd Edition

renal excretion (Ch 34, ref. 208). The amount of ciprofloxacin produced by metabolic elimination varies between and within animal species. Distribution in the body: enrofloxacin penetrates into all canine and feline tissues and body fluids. Concentrations of drug equal to or greater than the minimal inhibitory concentration (MIC) for many pathogens (see following table) are reached in most tissues by 2 hr after dosing at 2.5 mg/kg and are maintained for 8-12 hr after dosing. Particularly high levels of enrofloxacin are found in urine. A summary of the body fluid–tissue drug levels at 2-12 hr after oral dosing at 2.5 mg/kg and at 1-hr or greater intervals after 5 mg/kg is given in following table. High dose (20 mg/kg) IV data is also given for the dog. The drug levels are higher than indicated after multiple dosing as accumulation occurs.

- a This data does not take into account the amount of the active metabolite ciprofloxacin, which comprises an additional amount of antimicrobial activity. Data provided by product insert for enrofloxacin and references [Ch 34](#), ref. 262; 308; 250; 194; 38; 93; 91; 157.

108.61.5 SPECTRUM.

Gram positive: *Staphylococcus*, variable *Streptococcus*. **Gram negative:** *Brucella*, *Pasteurella*, *Escherichia*, *Aeromonas*, *Proteus*, *Shigella*, *Salmonella*, and other enteropathogens such as *Campylobacter*, *Yersinia*, and some *Pseudomonas*. In vivo resistance noted with *Clostridium* spp., *Bacteroides* spp. **Others:** *Mycoplasma*, *Chlamydia*, *Rickettsia*, *Haemobartonella*, some slow-growing, opportunistic mycobacteria (see [Chapter 50](#)). **More effective:** aerobic and facultative gram-negative organisms. **Ineffective:** *Enterococcus*, *Actinomyces*, *Nocardia*, *Mycobacterium avium-intracellulare* complex, *Leptospira*, *Ehrlichia*, and obligate anaerobes. Resistance can develop by chromosomal mutation, although plasmid-mediated resistance does not occur. Resistance is more common with some organisms such as *Pseudomonas aeruginosa*, *Escherichia coli* and *Staphylococcus aureus*. An increase in the number of enrofloxacin-resistant *E. coli* urinary tract infections has been observed in dogs ([Ch 34](#), ref. 76).

1244

108.61.6 INDICATIONS.

Complicated or recurrent urinary tract infections caused by more resistant gram-negative bacteria; prostatitis. Good alternative to aminoglycosides in presence of renal dysfunction. Respiratory infections from resistant gram-negative bacteria (often nosocomial). Osteomyelitis and joint infections because quinolones have good penetration and safety for long-term use in gram-negative infections. With staphylococcal osteomyelitis, additions of rifampin may assist. Complicated SC infections caused by *Staphylococcus*, gram negatives, or opportunistic mycobacteria. Always use in combination for treating brucellosis. For severe otitis externa caused by *Pseudomonas*. For enteropathogenic bacterial gastroenteritis (e.g., salmonellosis or campylobacteriosis; see [Chapter 39](#)) ([Ch 34](#), ref. 324). GI infections caused by gram-negative bacteria, urinary tract infections, respiratory tract infections, infections of skin, eyes, and joints ([Ch 34](#), ref. 324) and canine bacterial pyoderma ([Ch 34](#), ref. 176; 293). Beneficial responses have been found in dogs treated with histiocytic ulcerative colitis ([Ch 89](#), ref. 131). Can be used topically (see Handling) for resistant gram-negative otitis externa to avoid aminoglycoside toxicity. Fluoroquinolones in combination have been shown to improve in vivo efficacy of some antifungal azoles.

1245

108.61.7 CONTRAINDICATIONS.

During a rapid growth period, young animals should not receive the drug because of the potential of cartilaginous injury. Avoid in small- and medium-breed dogs (>8 mo), large breeds (<12 mo), and giant breeds (<18 mo), and cats younger than 8 weeks. Some reduction in dosage is advised for marked renal failure, but hepatic elimination should compensate in minor renal dysfunction. Caution is advised with quinolones in pregnant animals, although side effects are not documented. Dosages of 15 mg/kg to males and to females of various stages of gestation and during lactation had no adverse effects. Animals being treated must always be adequately hydrated. Use cautiously in animals with seizure histories.

108.61.8 ADVERSE REACTIONS.

Vomiting when IM solution is given IV. Intravascular hemolysis has been observed in some cats given parenteral solution IM or undiluted parenteral solution IV. Diarrhea and depression are occasionally seen in

Infectious Diseases of the Dog and Cat, 3rd Edition

dogs (Ch 34, ref. 209), especially with higher dosages. Neurotoxicity or seizures at very high (supratherapeutic) IV dosages or with rapid IV infusion. In animals with seizure history, causes increase in the frequency and intensity of seizures in phenobarbital-treated dogs (Ch 34, ref. 390). Cats receiving 50 mg/kg have had neurologic signs, and some dogs receiving 10 mg/kg enrofloxacin have had seizures. Enrofloxacin, as other quinolones, has the potential to produce retinotoxicity as evidenced by mydriasis, blindness, increased tapetal hyperreflectivity and attenuated retinal vasculature. Cats receiving higher than 5 mg/kg/day or treated with parenteral drug at these levels may develop irreversible damage to their photoreceptor cells (Ch 34, ref. 420). Nonsteroidal antiinflammatory drugs (e.g., fenbufen) may accentuate this problem. Occasional anorexia, vomiting, or diarrhea, especially with higher dosages. Cartilaginous damage to weight-bearing joints of immature growing dogs and cats. IM and SC injections are painful. Focal alopecia may occur over sites of SC injection. Efficacy in treating urinary tract infections can be enhanced by raising the urine pH with bicarbonate, but this may favor nephrotoxicity from renal tubular crystalluria. Because of the potential for renal dysfunction with overdosages, hydration should be maintained. Dogs given 5 mg/kg enrofloxacin IM for 14 days developed increased MCV and serum activity of AST, and increased bilirubin and sodium concentrations (Ch 34, ref. 378). Decreases were observed in serum potassium, bicarbonate, and blood pH and a resultant metabolic acidosis. Generally these biochemical changes were mild. Streptococcal superinfection with necrotizing fasciitis has been observed in dogs receiving prior treatment with enrofloxacin (see Chapter 35). Very high supratherapeutic doses (125 mg/kg PO) have been given to dogs and cats in early toxicity studies. Animals showed vomiting, anorexia, depression, locomotor difficulties, and death. For additional information concerning adverse reactions to quinolones, see section on their toxicity, Chapter 34.

108.61.9 INTERACTIONS.

Additive antibacterial effects with doxycycline, minocycline, or aminoglycosides for brucellosis. For nocardiosis, leprosy or opportunistic mycobacteriosis, it may be synergistic with doxycycline, dapsone or clofazimine. The coadministration of clindamycin or amoxicillin with quinolones results in increased serum bactericidal activity against gram-positive bacteria. Use of metronidazole, b-lactams, aminoglycosides, or clindamycin may extend the antimicrobial spectrum while not affecting the pharmacokinetics of quinolones (Ch 34, ref. 31). Reduced GI absorption caused by preparations containing polyvalent cations (Al, Mg, Ca, Fe, Zn). Antacids containing these and sucralate given within 24 hr can interfere with absorption (Ch 34, ref. 295). Concurrent cimetidine can delay quinolone elimination. May interfere with theophylline elimination, producing CNS stimulation. Enrofloxacin may reduce serum levels of anticonvulsants such as phenytoin. Nephrotoxic effect of cyclosporine may be increased when co-administered with enrofloxacin. May potentiate effects of vitamin K antagonist rodenticides. The effectiveness of quinolones on some bacteria may be reduced by microbial protein-synthesis inhibitors such as chloramphenicol, nitrofurans, rifampin, and erythromycin. Enrofloxacin and digoxin do not alter either drug's metabolism when coadministered to dogs (Ch 34, ref. 279). Antineoplastic agents may reduce serum concentrations of enrofloxacin. Enrofloxacin interferes with some glucose test measurements, resulting in underestimated concentrations of urine glucose. Caution must be used when using urine as a basis for monitoring diabetic dogs (Ch 34, ref. 306c).

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Tablets	5.7 mg, 22.7 mg, 68 mg, 136 mg	Baytril (Bayer)
	Chewable (Taste®) Tablets	mg	
	Parenteral solution for IM use	22.7 mg/ml	Baytril

Infectious Diseases of the Dog and Cat, 3rd Edition

108.61.10 HANDLING.

Parenteral solution and oral tablets should be stored away from direct sunlight, at room temperature, and never frozen. For topical otic preparation, take one 22.7-mg tablet and crush it with a mortar and pestle. Add powder to petrolatum and mix well with tongue depressor. Place mixture in syringe and administer in ear canals at least once daily. Person administering drug should avoid contact with hands and skin. If contact with eyes occurs, they should be rinsed with copious amounts of water. Skin should be cleansed with soap and water. Alternatively, a 3 mg/ml topical solution can be prepared by taking 4 ml of 20 mg/ml enrofloxacin injection solution and mixing it with 24 ml of sterile normal saline. This solution is stored in a dropper bottle at room temperature (Ch 85, ref. 42).

1245

1246

108.61.1 ADMINISTRATION.

Never crush nonchewable tablets because the active ingredient is bitter. Always pill animals using this preparation. With chewables, these may be hand fed or mixed in food. Allow 4-6 hr prior to, and at least 2 hr after, quinolone administration when giving antacid, multivalent cation-containing preparations, or sucralfate. Ingesta may delay absorption slightly, but may prevent vomiting that occasionally occurs. Preferably, administer on empty stomach. The manufacturer's suggested maximum duration of treatment was 10 days; however, this has been extended to 30 days. An IV preparation is not available; however, some have given the IM solution IV. Dilute 1 part parenteral solution to 3 to 9 parts sterile water or normal saline before IV infusion and give it over 10-30 min. May precipitate in alkaline or balanced electrolyte solutions. Can give in combination with doxycycline, minocyclines, aminoglycosides, or rifampin to improve efficacy in treating certain persistent intracellular bacterial infections.

Dosage				
INFECTION WITH SUSCEPTIBLE ORGANISMS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
INDICATIONS/SITE (FOR SPECIES)				
Urinary, respiratory, soft tissue infections (<i>cats</i>) ^a	5 mg/kg	PO	24	7-14
Mycoplasma haemofelis infection (<i>cats</i>)	5-10 mg/kg	PO	24	14 ^b
Skin, urinary infections (<i>dogs</i>)	2.5-5 mg/kg	PO	12	7-14
Deep pyodermas, complicated urinary (<i>dogs</i>)	5 mg/kg	PO	24	7-14 ^c
Lower respiratory infections (<i>dogs</i>)	5-10 mg/kg	PO	24	7-84
Prostate infections	5 mg/kg	PO	12	7-14
Histiocytic ulcerative colitis (<i>dogs</i>)	5 mg/kg	PO	12	21-90 ^d
Hemotropic mycoplasmosis (<i>dogs</i>)	5 mg/kg	PO, IM	12	7-14
Systemic, orthopedic infections (<i>dogs</i>)	5-11 mg/kg	PO, IM, IV, SC	12	10
<i>Pseudomonas</i> in soft tissues (<i>dogs</i>)	11 mg/kg	PO, IM, SC	12	7-14 ^e
	20 mg/kg	PO, IM, SC	12	prn ^f
Bacteremia, sepsis (<i>dogs</i>)	11 mg/kg	PO, IM, IV, SC	12	prn

a Due to potential retinotoxicity, the manufacturer recommends this maximum daily dose of 5 mg/kg.

b Dose of 10 mg/kg was more effective than 5 mg/kg and similar in efficacy to doxycycline; care must be taken if drug is used for this infection because this higher than recommended dosage has the risk of causing retinotoxicity (Ch 34, ref. 105; 365a).

Infectious Diseases of the Dog and Cat, 3rd Edition

- c 10 to 12 weeks of therapy is required in pyoderma, especially in German shepherds ([Ch 34](#), ref. 178).
- d [Ch 34](#), ref. 131.
- e Up to 12 weeks with malignant otitis externa caused by *Pseudomonas*. Dosage from [Ch 85](#), ref. 121.
- f [Ch 85](#), ref. 42.

108.61.12 FLEXIBLE DOSAGES.

Enrofloxacin was originally licensed for use in the United States at a dose of 2.5-5.0 mg/kg, given every 12 hr. Now it has been approved with professional label flexible dosage ranges for up to 24-hr intervals, based upon knowledge of the drug pharmacodynamics, its achievable concentrations at the site of infection, properties of the infecting organism, and host factors. The 24-hr dosage range is 5-20 mg/kg and a rough guideline is presented in the preceding table. The low end of the dosage regimen is generally sufficient for infections caused by susceptible organisms in tissues or fluids where sufficient concentrations can be effectively reached. The high end should only be used to treat highly resistant organisms ($MIC \geq 2 \mu\text{g/ml}$) or those such as *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Escherichia coli* which have shown tendencies to develop resistance. In general the achievable concentration in the desired tissue or body fluid should be at least 2 to 8 times the MIC_{90} of the offending pathogen. The recommendations for maximum length of use of this drug have been extended to 30 days.

108.61.13 ADDITIONAL DOSAGES.

Rocky Mountain spotted fever, [Table 29-4](#); gram-negative infections, [Table 37-3](#); endotoxemia, [Table 38-6](#); enteric pathogenic bacteria, [Table 39-2](#); mycobacteria, [Tables 50-4](#) and [50-9](#); cytauxzoonosis, [Table 76-1](#); canine pyoderma, [Table 85-3](#); musculoskeletal infections, [Table 86-4](#); bacteremia, endocarditis, [Table 87-6](#); respiratory disease, [Table 88-8](#); oral infections, [Table 89-4](#); gastrointestinal infections, [Table 89-16](#); intraabdominal infections, [Table 89-21](#); hepatobiliary infections, [Table 90-5](#); urinary infections, [Table 91-10](#). This drug accumulates in animals with decreased renal or hepatic function; therefore a reduction in dosage may be necessary.

108.61.14 DISPENSING INFORMATION.

Give medication without feeding, unless vomiting occurs. Never give antacids or GI protectants within 2 hr of medication. Always be certain pet has plenty of fresh water to drink.

1246

108.62 ERTAPENEM

1247

108.62.1 CLASS.

Ertapenem is a β -lactam of the carbapenem group. As with meropenem, another newer carbapenem of this group, it does not require cilastatin coadministration.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.62.2 ACTION.

Bactericidal; ertapenem inhibits synthesis of bacterial cell wall peptidoglycan. As other carbapenems, this drug is relatively resistant to hydrolysis by β -lactamases.

108.62.3 MORE INFORMATION.

See [Chapter 34](#).

108.62.4 PHARMACOKINETICS.

Poorly absorbed from GI tract, but good systemic availability if given parenterally. It is highly protein bound and as a result has a longer half life in serum in people compared to imipenem and meropenem. This allows for once a day dosing. In people, it is partly metabolized by the liver; however, 80% is excreted by the kidney with 38% as unchanged drug. Approximately 10% appears in the feces.

108.62.5 SPECTRUM.

Narrower spectrum than other members of this class, see Imipenem. Resistant to most bacterial β -lactamases. In vitro, ertapenem is more active against anaerobes, and is more active than imipenem against Enterobacteriaceae. It has similar activity as do the other carbapenems against gram-positive organisms; however, it has little or no activity against *Pseudomonas aeruginosa* or *Acinetobacter* spp. Methicillin-resistant staphylococci and enterococci, and β -lactamase-resistant streptococci are usually resistant to ertapenem.

108.62.6 INDICATIONS.

For treatment of organisms resistant to other antibiotics and for mixed infections that require a broad spectrum including anaerobes. For treatment of intraabdominal, skin and soft tissue, lower respiratory, urinary, and pelvic infections. See Imipenem for more specific indications.

108.62.7 APPROVED USES.

Serious and multiple-resistant bacterial infections when a single agent is needed.

108.62.8 CONTRAINDICATIONS.

The dosage should be reduced in renal failure. Dosage adjustments are not likely with hepatic impairment. Cross-hypersensitivity to other β -lactams. No complications have been observed in human or animal pregnancy; however, only clear indications should permit its use during this period.

108.62.9 ADVERSE REACTIONS.

Diarrhea, vomiting, increased hepatic aminotransferase activities, and thrombophlebitis. Allergic reactions to vehicle, treat as anaphylaxis. All β -lactams can cause seizures if underlying brain disease or if overdosed related to body size and renal function. As with other β -lactams, monitor renal, hepatic, and hematopoietic

Infectious Diseases of the Dog and Cat, 3rd Edition

systems during treatment. Neutropenia was consistently observed in treated rats; however, studies in rabbits and monkeys were inconclusive. The IM product contains lidocaine hydrochloride, which is contraindicated with known hypersensitivity, with shock, or heart block.

108.62.10 INTERACTIONS.

Antagonistic interaction may reduce effectiveness of this drug coadministered with other β -lactam drugs. Addition of aminoglycosides or trimethoprim- sulfonamide may be synergistic against certain organisms.

Same.

108.62.12 HANDLING.

Supplied as a powder, soluble in water and 0.9% NaCl. Never store powder above 25°C For IM use, the drug is reconstituted with 3.2 ml of 1% lidocaine HCl (without epinephrine). This should never be given IV. For IV injection, the powder is added to 10 ml 0.9% NaCl or bacteriostatic water for injection. The drug should not be mixed with other medications and dextrose-containing solutions should never be used as diluents.

Reconstituted solutions can be used within 6 hr at 25°C or 24 hr at 5°C. Solutions should be used within 4 hr after removal from refrigeration and never frozen.

108.62.13 ADMINISTRATION.

For IM, use a 21-gauge needle and deep injection. Aspirate before injection to avoid inadvertent IV administration.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
(Human) ^a				
Bacteremia/sepsis	1g	IV, IM	24	prn
a This is a dose for adult people; no studies are available for other age or for gender, and none exist for dogs or cats.				

108.62.14 ADDITIONAL DOSAGES.

None.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.63.1 ERYTHROMYCIN

108.63.1 CLASS.

Macrolide.

108.63.2 ACTION.

Bacteriostatic; binds to 50s ribosomes of bacteria-inhibiting protein synthesis.

108.63.3 MORE INFORMATION.

AZITHROMYCIN, CLARITHROMYCIN, ROXITHROMYCIN; [Chapter 34](#), Macrolides; [Table 34-8](#).

108.63.4 PHARMACOKINETICS.

Several oral formulations exist. The degree of absorption from the GI tract depends on the formulation, gastric pH, presence of ingesta (see [Table 34-8](#)). Erythromycin is absorbed in the proximal small intestine and must withstand effects of gastric acid. Estolate and ethylsuccinate compounds resist degradation in the stomach and release free base for absorption in duodenum. Estolate is better absorbed than ethylsuccinate. Enteric-coated tablets required for free base and stearate formulations to prevent gastric acid inactivation. Unlike estolate and ethylsuccinate esters, absorption of the base and stearate are reduced by ingesta. Absorption of coated base tablets is less affected by food than stearate. Enteric-coated pellets are better absorbed than tablets. Well distributed to most body tissues, especially skin and respiratory tract, enters pleural and ascitic fluids, respiratory secretions but only the inflamed meninges. Enters the prostate and concentrates in leukocytes. Primarily eliminated by hepatic metabolism and biliary excretion. Does not achieve high enough levels in urine for likely therapeutic efficacy (4% of oral and 15% of parenteral dose). Bioavailability is lower by SC (40%) than IM (65%) routes.

1247

1248

108.63.5 SPECTRUM.

Gram positive: *Staphylococcus*, *Streptococcus*, *Corynebacterium*, *Listeria*, *Erysipelothrix*, *Bacillus*. Predominantly for gram-positive infections. **Gram negative:** *Pasteurella*, *Campylobacter*, *Bordetella*, *Legionella*. Not for most gram-negative infections. Cross-resistance can occur with other macrolides and lincosamides. **Anaerobes:** *Fusobacterium*, *Clostridium* (limited activity). **Others:** *Chlamydia*, *Mycoplasma* (susceptibility varies), *Borrelia*, *Leptospira*; protozoa, e.g., amebae. **More effective:** *Campylobacter*, *Legionella*, *Mycoplasma*. **Ineffective:** most Enterobacteriaceae.

108.63.6 INDICATIONS.

Gram-positive infections involving the GI tract, skin, respiratory tract, soft tissue infections as an alternative to β -lactams (e.g., penicillins, first- generation cephalosporins) when hypersensitivity exists. Campylobacteriosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.63.7 CONTRAINDICATIONS.

Previous hypersensitivity, preexisting hepatic dysfunction, reduce dose in severe liver diseases, minimal dosage adjustment in renal failure.

108.63.8 ADVERSE REACTIONS.

Vomiting—specific cholinergic effect. Abdominal discomfort or GI irritability—anorexia, vomiting, diarrhea. Can occur with parenteral preparations because of excretion in the bile. Thrombophlebitis with IV; pain on IM injection; rare ototoxicity; and hepatotoxicity (cholestatic hepatitis). The latter syndrome can be reduced in frequency of occurrence by shorter treatment regimens.

108.63.9 INTERACTIONS.

Chloramphenicol and lincosamides (lincomycin, clindamycin) have similar action and should not be used in combination. Increases cyclosporin concentrations with resultant nephrotoxicity. Increases blood digoxin, methylprednisolone, theophylline concentrations, and other hepatic metabolized drugs as a result of cytochrome P-450 interactions.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Base oral tablets, enteric coated	250 mg, 333 mg, 500 mg	<i>E-mycin</i> (Pharmacia & Upjohn), <i>Ilotycin</i> (Dista)
	Estolate oral tablets	500 mg	<i>Ilosone</i> (Dista)
	Oral capsules, chewable tablets	125 mg, 250 mg	<i>Ilosone</i>
	Oral suspension	125 mg/5 ml, 250 mg/5 ml	<i>Ilosone</i>
	Stearate oral tablets, enteric coated	250 mg, 500 mg	<i>Erpar</i> (Parke-Davis), <i>Erythril</i> (E.R. Squibb), generic (various)
	Ethylsuccinate		
	Oral tablets	200 mg (125 mg base), 400 mg (250 mg base)	E.E.S generic (various), <i>E-MycinE</i> (Pharmacia & Upjohn)
	Oral suspension or powder for suspension	100 mg/5 ml, 62.5 mg/5 ml, 200 mg/5 ml (125 mg/5 ml base), 400 (250 mg/5 ml base)	<i>Eryped</i> (Abbott), <i>Pediamycin</i> (Ross)
	Glucaptate IV solution	250 mg, 500 mg, 1g	<i>IlotycinGlucaptate</i> (Dista)
	Lactobionate IV infusion	500 mg, 1g	<i>ErythrocinLactobionate-IV</i> (Abbott)
Veterinary	Polyethylene injectable solution	100 mg/ml, 200 mg/ml	<i>Erythro</i> (Sanofi) <i>Erythromycin-200</i> (RXV)

108.63.10 INTERNATIONAL PREPARATIONS.

Abboticine, Aknemycin, Betamycin, Cusimicina, Doranol, Eboren, Erycinum, Erythromid, Erytran, Erytrocina, Meromycin, Primacine, Stiemycin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.63.1.1 HANDLING.

Lactobionate is stable at room temperature in dry form. Parenteral solutions are stable at room temperature. Cold temperature may cause solidification, which can be reversed by immersion in warm water for 15-20 min. Once reconstituted the lactobionate is stable for 24 hr and 2 weeks, and the gluceptate for 24 hr and 1 week, at room and refrigerated temperatures, respectively. Erythromycin solutions are more unstable at acid pH (4.0-6.0). Oral suspensions (estolate, ethylsuccinate) should be refrigerated and generally have 14-day stability.

108.63.1.2 ADMINISTRATION.

Given PO, administer on an empty stomach (base and stearate forms) unless GI upset occurs, then take with food. Estolate, ethylsuccinate, and enteric-coated forms can be taken with food. Capsules containing enteric-coated pellets *ERYC* (Parke-Davis) can be opened and sprinkled on food. Ethylsuccinate is nonirritating, tasteless, and suitable as a PO preparation for puppies and kittens. Dilute IV solutions given over 20-60 min. Give slowly IV by intermittent or continuous infusion using concentrations diluted to 1 to 5 mg/ml. IV route is preferred for very ill animals or those with GI signs. If given IM, must be deep into large muscles. IM preparations contain lidocaine. Should not be given SC or IP.

1248

1249

Dosage

INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Localized, soft tissue infections	15-25	PO	12	7-10
Localized, soft tissue infections	10-15	PO	8	7-10
Systemic, bacteremia infections	22	PO, IV	8	prn

108.63.1.3 ADDITIONAL DOSAGES.

Streptococcal infections, [Table 35-2](#); *Rhodococcus* infection, [Table 35-7](#); enteric bacterial infections, [Table 39-2](#); actinomycosis, [Table 49-2](#); nocardiosis, [Table 49-3](#); canine pyoderma, [Table 85-3](#); gastrointestinal infections, [Table 89-16](#).

108.63.1.4 DISPENSING INFORMATION.

May cause GI irritation and resultant vomiting and diarrhea. If so, give first few doses with food to reduce irritation but then give to fasted animal.

108.64.1 ERYTHROPOIETIN (rHuEPO, EPO)

108.64.1 CLASS.

Cytokine. Synthetic human recombinant protein.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.64.2 ACTION.

This substance naturally produced by the kidney and activated by the liver, stimulates erythroid progenitors in bone marrow. Increases blood hematocrit in clinically healthy or anemic animals, predominantly with an anemia caused by renal failure. It also stimulates megakaryopoiesis and thrombopoiesis. The effect may take 2-8 weeks.

108.64.3 MORE INFORMATION.

[Chapters 2](#) and [58](#) references: [Ch 2](#), ref. 37; 37a; 124a.

108.64.4 PHARMACOKINETICS.

The drug must be given parenterally as it is not absorbed after oral administration. Its pharmacokinetic data is uncertain; however, elimination is prolonged in people with chronic renal failure. As a human recombinant product, anti-EPO antibodies may develop in 25%-30% of treated animals after use for 6 mo to 1 yr. These antibodies bind to native EPO and recombinant EPO nullifying their actions resulting in non regenerative anemia. Antibodies usually disappear after discontinuation of treatment. The drug may cross the placenta and adversely affect the fetus.

108.64.5 INDICATIONS.

For anemia of chronic renal failure. This drug has been used in FIV- or FeLV-infected cats in an attempt to stimulate production of erythrocytes; however, its effects in this regard have generally been disappointing. See [Chapter 2](#) for details on studies involving this drug.

108.64.6 APPROVED USES.

People for treatment of anemia associated with chronic renal failure.

108.64.7 CONTRAINDICATIONS.

Pregnancy. Development of refractory anemia while being treated with this drug suggests development of antibodies. Under such conditions, a bone marrow examination will reveal suppressed erythropoiesis compared to myelogenesis and the drug should be discontinued.

108.64.8 ADVERSE REACTIONS.

Systemic hypertension, seizures and iron depletion occur and result from increased erythrocyte mass.

108.64.9 INTERACTIONS.

May have compounding of effects if given concurrently with androgenic hormones.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZE	PREPARATION (COMPANY)
Human	Solution for injection	2000–40,000 units in 1- to 2-ml vials	<i>Epogen</i> (Amgen) <i>Procrit</i> (Ortho Biotech)

108.64.10 HANDLING.

The solution for injection is stored at refrigerator (4°C) temperature. The vial should not be frozen or exposed to sunlight. Sodium chloride, citrate buffers, and albumin are added to the solution for stability which is 2 yrs with proper storage.

108.64.11 ADMINISTRATION.

The drug is given SC on a 3 times weekly basis until the hematocrit is achieved and then dosages are adjusted as needed on a not less than 3-week interval to allow time for dosage adjustments to have effects. The hematocrit and blood pressure must be monitored on a continual basis to avoid anemia or hypertension as potential side-effects. Iron supplementation should be adequate to maintain levels needed for regeneration. If beneficial effects are not noticed after the first month of instituting this therapy then it may not be effective. If the hematocrit increases but later decreases, then formation of antibodies can be suspected. In this case treatment should be discontinued. A bone marrow examination will help to determine if iron stores are adequate and the proportion of progenitor cells.

INDICATIONS (NEUTROPENIA)	DOSE (Units/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Dogs and Cats</i> Anemia in infections	100	SC	48 ^a	prn ^b
a Three times weekly at a dose ranging from 50–150 Units/kg.				
b Treat until desired hematocrit is reached, then as needed.				

1249

108.64.12 ADDITIONAL DOSAGES.

FIV infection, [Table 14-6](#).

1250

108.64.13 DISPENSING INFORMATION.

Animal should return for monitoring, initially at least weekly, with a complete blood count.

108.65 ETHAMBUTOL

108.65.1 CLASS.

Synthetic antimycobacterial.

108.65.2 ACTION.

Inhibits intracellular metabolism of mycobacterial cells.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.65.3 MORE INFORMATION.

See Tuberculosis, [Chapter 50](#); [Table 50-4](#).

108.65.4 PHARMACOKINETICS.

Readily absorbed from GI tract and 80% bioavailable, unaffected by food. Diffuses into tissues and fluids, including the CSF, with inflamed meninges. A lower percentage is metabolized by liver, and some is excreted in feces; most is excreted in urine as unchanged drug and metabolites.

108.65.5 SPECTRUM.

Mycobacterium tuberculosis, *M. bovis*, *M. avium-intracellulare* complex (MAC).

108.65.6 INDICATIONS.

Tuberculosis caused by *M. tuberculosis* or *M. bovis* in combination with other antimycobacterial drugs.

108.65.7 CONTRAINDICATIONS.

Reduce dose by extending interval of dose administration in renal insufficiency. Has caused teratogenesis in laboratory animals during pregnancy.

108.65.8 ADVERSE REACTIONS.

In people, reduced visual acuity from optic neuritis; anorexia, vomiting, abdominal pain, CNS signs, and thrombocytopenia.

108.65.9 INTERACTIONS.

Often combined with isoniazid, rifampin, pyrazinamide, or aminoglycosides for tuberculosis. For MAC infections, may be given in combination with fluoroquinolones, azithromycin or clarithromycin, aminoglycosides, rifampin, or clofazimine.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral tablets	100 mg, 400 mg	<i>Myambutol</i> (Lederle)

108.65.10 INTERNATIONAL PREPARATIONS.

Afimocil, *Cidanbutol*, *Dexambutol*, *Etapiam*, *Servambutol*.

108.65.11 HANDLING.

Keep in airtight containers at controlled room temperature, protected from moisture, heat, and light. Can mix with water and heat to 49°C for 10 min to dissolve and then put in suspension, which can be refrigerated for 1 week.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.65.12 ADMINISTRATION.

Aluminum-containing compounds reduce absorption. Administering with food reduces GI irritation. Use only in combination with other antimycobacterial drugs.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (mo)
Dogs	15	PO	24	3–6
	25	PO	72	3–6 ^a

^a Long-term suppressive therapy may be needed.

108.65.13 ADDITIONAL DOSAGES.

Tuberculosis, [Table 50-4](#).

108.65.14 DISPENSING INFORMATION.

This medicine can be given with food.

108.66 FEBANTEL (combined with PRAZIQUANTEL and PYRANTEL PAMOATE)

108.66.1 CLASS.

Pro-benzimidazole.

108.66.2 ACTION.

Anthelmintic, antiprotozoal. Binds to tubulin subunit and interferes with microtubule formation. Only the febantel and its metabolite, fenbendazole, are effective against *Giardia*.

108.66.3 MORE INFORMATION.

[Chapter 71](#); [Table 71-1](#); Reference: [Ch 71](#), ref. 6; 70.

108.66.4 PHARMACOKINETICS.

Rapidly absorbed after oral administration and metabolized into fenbendazole, oxfendazole, and 8 other metabolites. These are predominantly excreted in the bile.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.66.5 SPECTRUM.

Giardia; in addition, combination is effective against *Toxocara canis*, *Toxascaris leonina*, *Ancylostoma caninum*, *Uncinaria stenocephala*, *Trichuris vulpis*, *Taenia pisiformis*, *Echinococcus granulosus*, *E. multilocularis*, and *Dipylidium caninum*.

108.66.6 INDICATIONS.

Helminths, *Giardia*.

108.66.7 APPROVED USES.

For control of ascarids (*Toxocara canis*, *Toxascaris leonina*), hookworms (*Ancylostoma caninum*, *Uncinaria stenocephala*), whipworms (*Trichuris vulpis*), and tapeworms (*Taenia pisiformis*, *Echinococcus granulosus*, *E. multilocularis*, *Dipylidium caninum*) in dogs.

108.66.8 CONTRAINDICATIONS.

Not for pregnant or lactating bitches. Praziquantel should not be given to pups <4 weeks, or kittens <6 weeks, of age.

1250

108.66.9 ADVERSE REACTIONS.

Unusual at label dose since has a wide margin of safety. When given 5 times the label dose for 3 consecutive days, salivation, anorexia, vomiting, and soft stool are noted (Ch 71, ref. 6).

1251

108.66.10 INTERACTIONS.

Synergistic activity with these drugs in combination.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Dog	Oral tablets	68 mg praziquantel	<i>Drontal-Plus</i> (Bayer)
		68 mg pyrantel pamoate	
		340.2 mg febantel	

108.66.11 HANDLING.

Product should be stored in airtight containers at controlled (15–30°C) temperature.

108.66.12 ADMINISTRATION.

Give with food to increase the bioavailability. At the time the last dose is given, the dogs should be bathed and moved from runs to cages to decrease the risk of reinfection (Ch 71, ref. 70).

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS	DOSE (mg/kg) ^a	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Helminths, <i>Giardia</i>	26.8–35.2	PO	24	3–5
Helminths	10–25	PO	24	3
Cats				
Helminths, <i>Giardia</i>	10 ^b	PO	24	3

a Dosed on basis of febantel, other drugs are at a fixed range in tablets.

b Two small dog tablets are given to each cat.

108.66.13 ADDITIONAL DOSAGES.

None.

108.66.14 DISPENSING INFORMATION.

Place amount indicated in mouth and encourage patient to drink fluids and swallow.

108.67 FENBENDAZOLE

108.67.1 CLASS.

Benzimidazole.

108.67.2 ACTION.

Anthelmintic, antiprotozoal.

108.67.3 MORE INFORMATION.

[Chapter 71](#); [Table 71-1](#); Reference: [Ch 71](#), ref. 9; 60; 82; 100.

108.67.4 PHARMACOKINETICS.

Minimal amount absorbed following oral administration, and any absorbed drug is rapidly metabolized. Increasing the dose to up to 80 mg/kg in dogs did not significantly increase the amount of drug absorbed. Administration with food, irrespective of fat content, increases its bioavailability. A majority of the drug is excreted unchanged in the feces, and minimal amounts (<1%) of the administered dose appear in the urine.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.67.5 SPECTRUM.

Giardia; in addition to approved uses, it is effective against various intestinal helminths and *Capillaria aerophila*, *Filaroides hirthi*, and *Paragonimus kellicotti*. The nematocidal label dosage is effective for treating *Giardia* in dogs (Ch 71, ref. 100).

108.67.6 INDICATIONS.

Helminths, *Giardia*. Because of low toxicity, this is the preferred drug for treatment of giardiasis. Infection was more difficult to clear in cats co-infected with *Cryptosporidium* (Ch 71, ref. 41).

108.67.7 APPROVED USES.

For control of ascarids (*Toxocara canis*, *Toxascaris leonina*), hookworms (*Ancylostoma caninum*, *Uncinaria stenocephala*), whipworms (*Trichuris vulpis*), and tapeworms (*Taenia pisiformis*) in dogs.

108.67.8 CONTRAINDICATIONS.

Unknown. Has been safe when administered to cats and pregnant animals.

108.67.9 ADVERSE REACTIONS.

Unusual; vomiting occurs uncommonly when given with food. Other drugs of this class have been reported to cause hepatotoxicity. With large burdens of helminths, allergic reactions to dying tissue forms may be noted. Cats have been given dosages of 250 mg/kg for 9 days, which is five times the level and three times the recommended duration of treatment, with no side effects (Ch 71, ref. 82). Although less common than with albendazole use, fenbendazole administration (50 mg/kg PO every 12 hr, for 11 days) was associated with pancytopenia in a dog (Ch 71, ref. 23a). The pancytopenia gradually resolved by 15 days after discontinuation of therapy.

108.67.10 INTERACTIONS.

Myelotoxicity was reported with coadministration of trimethoprim-sulfonamide in one dog (Ch 71, ref. 97a). It was reversible after treatment was discontinued.

1251

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Dog	Oral granules 22.2%, packets or jar	1-g, 2-g, 4-g, 1-lb jar	Panacur (Hoechst Marion Roussel)
Horse	Oral granules 22.2%, packets	5.2-g	Panacur
	Paste 10%	25-g syringe	Panacur
Cattle and horse	Oral Paste 10%	92-g syringe	Panacur
	Oral suspension 10%	1 liter	Panacur
Cattle	Oral paste 10%	290-g syringe	Panacur
	Oral suspension 10%	1 gallon	Panacur

1252

Infectious Diseases of the Dog and Cat, 3rd Edition

108.67.11 HANDLING.

Product should be stored away from moisture at a controlled (15–30°C) temperature.

108.67.12 ADMINISTRATION.

For a dose of 50 mg/kg, use 1 g of packet granules for each 10 lb of body weight. Mix the correct amount of granules with a small amount of the usual diet. If dry food is fed, add water to facilitate mixing with the drug. To be effective, the drug must be administered for a minimum of 3 days. Treatment for more resistant protozoa or helminths continues for up to 14 days.

Dosage				
INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Helminths, <i>Giardia</i>	50	PO	24	3–5

108.67.13 ADDITIONAL DOSAGES.

Giardiasis, [Table 78-3](#).

108.67.14 DISPENSING INFORMATION.

Place amount indicated on canned pet food or moistened dry food. Make sure all the drug is taken by withholding other food until it is eaten.

108.68 FILGRASTIM (GRANULOCYTE COLONY-STIMULATING OR HEMATOPOIETIC GROWTH FACTOR, G-CSF)

108.68.1 CLASS.

Cytokine.

108.68.2 ACTION.

Stimulates myeloid progenitors in bone marrow. Increases blood neutrophil counts in clinically healthy or neutropenic animals. May also reduce production of inflammatory mediators, such as IL-1, TNF- α , and IFN- γ , which may be beneficial in preventing too severe an inflammatory reaction. In vitro, pretreatment of neutrophils with G-CSF and/or IFN- γ can attenuate the inhibitory effect of glucocorticoids on neutrophil-induced hyphal damage.

108.68.3 MORE INFORMATION.

[Chapters 2](#) and [58](#) and [100](#); references: [Ch 2](#), ref. 37; 37a; 125.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.68.4 PHARMACOKINETICS.

Human recombinant product, increases blood neutrophil counts in various animals. In dogs and cats, short-term increases in neutrophil counts are followed by neutropenia with continued use owing to development of neutralizing antibodies to this heterologous protein. Neutrophilia occurs by day 7 and reaches maximal levels from 10-14 days of treatment. Short-term increases are followed by neutropenia (between 10 days-7 weeks) with continued use owing to development of neutralizing antibodies to this heterologous product.

108.68.5 INDICATIONS.

To stimulate production and function of neutrophils and monocytes. In dogs, for short-term use in treating neutropenia from whole body irradiation, parvovirus and *Ehrlichia* infections, myelosuppressive drugs. Potential uses in cats are leukopenias associated with FeLV, myeloproliferative disease, lymphoid tumors, aplastic anemias. Best for short-term (≤ 21 days) use for treatment of neutropenia caused by infectious agents, chemotherapy, or total body irradiation. Has been recommended for neutropenia caused by toxins (e.g., cancer chemotherapeutics, estrogens, chloramphenicol, trimethoprim-sulfonamides) or infections (e.g., ehrlichiosis, parvoviral infections). Studies have shown that effect in parvoviral infections of dogs is minimal as high levels are already circulating. Similar studies in cats with parvovirus have not been rewarding. See [Chapter 2](#) for details on studies involving this drug.

108.68.6 APPROVED USES.

People for neutropenia associated with HIV infection, cancer and antiviral chemotherapy, and transplantation.

108.68.7 CONTRAINDICATIONS.

Treatment for longer than 3 weeks ([Ch 2](#), ref. 3). Enhanced expression of FIV by infected lymphocytes in cats; therefore not recommended for treatment of this disease.

108.68.8 ADVERSE REACTIONS.

Bone discomfort or splenomegaly, allergic reactions ([Ch 2](#), ref. 3). After 10 days to 7 weeks of therapy, persistent antibodies develop against endogenous canine or feline G-CSF, resulting in rebound neutropenia.

108.68.9 INTERACTIONS.

Artifactual increased serum lactic dehydrogenase and ALP from bone isoenzyme in people.

AVAILABILITY	TYPE	SIZE	PREPARATION (COMPANY)
Human	Solution for injection	300 mg/ml in 1-ml vial	<i>Neupogen</i> (Amgen)

1252

108.68.10 HANDLING.

Stock solution can be diluted with sterile physiologic buffered saline and bovine serum albumin. The final dilution is 100 $\mu\text{g/ml}$, which is stored at 4°C. The vial should not be frozen or exposed to sunlight.

1253

Infectious Diseases of the Dog and Cat, 3rd Edition

Incompatible in solution with amphotericin B, some cephalosporins, clindamycin, furosemide, methylprednisolone sodium succinate, metronidazole, and piperacillin.

108.68.1 ADMINISTRATION.

Can be given SC or IV. Should give along with supportive care such as concurrent blood transfusions for concurrent anemia or thrombocytopenia or antibiotics for leukopenia. For IV use, may be further diluted to 5 to 15 µg/ml with addition of 5% dextrose. Albumin is added (12 mg/ml) to prevent absorption to plastics. Infusion rate IV should be over at least 15 min. Should not be given earlier than 24 hr after cytotoxic chemotherapy or 24 hr before. Bone pain can be alleviated by concurrent administration of nonsteroidal antiinflammatory drugs. SC injection should be spaced out at different sites for each injection and may be more effective than IV use.

INDICATIONS (NEUTROPENIA)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Dogs and Cats</i>				
Acute viral infections	5	SC	24	3–5
Chronic viral infections	5	SC	24	≤21

108.68.12 ADDITIONAL DOSAGES.

FIV infection, [Table 14-6](#).

108.68.13 DISPENSING INFORMATION.

Animal should return for monitoring at least twice weekly with a complete blood count. Since antibodies develop within 14–21 days, the drug is discontinued prior to this time.

108.69 FLORFENICOL

108.69.1 CLASS.

Acetamide.

108.69.2 ACTION.

Binds to 50s ribosome of bacteria-inhibiting protein synthesis.

108.69.3 MORE INFORMATION.

See CHLORAMPHENICOL; [Chapter 34](#).

108.69.4 PHARMACOKINETICS.

Similar to chloramphenicol. In dogs PO and IM bioavailability is good; however, absorption is inconsistent by SC route. In cats well absorbed by PO, IM routes ([Ch 34](#), ref. 291a).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.69.5 SPECTRUM.

See CHLORAMPHENICOL.

108.69.6 INDICATIONS.

See CHLORAMPHENICOL.

108.69.7 CONTRAINDICATIONS.

Pregnancy.

108.69.8 ADVERSE REACTIONS.

Chemical modification of this drug has alleviated the myelotoxic effect, although toxicity studies are not available for dogs and cats. Also not associated with human myelotoxicity. Can be locally irritating to animals when administered or to mucosae of sensitive people inadvertently contacting the drug.

108.69.9 INTERACTIONS.

See CHLORAMPHENICOL.

108.69.10 INDICATIONS.

Systemic bacterial or rickettsial infections when potential myelotoxicity in animals or people is to be avoided. MIC concentrations of 1.0-8.0 for pathogens from dogs and cats.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary (cattle)	Parenteral solution 300 mg/ml	100, 250, 500 ml	Nuflor (Schering-Plough Animal Health)

108.69.11 HANDLING.

Can be stored between 2–30°C, although refrigeration is not necessary. Color is pale yellow and does not affect patency.

108.69.12 ADMINISTRATION.

Can be given IM or SC; the former may cause pain and irritation.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Systemic infections	20	IM	8	3–5
Cats				
Systemic infections	22	IM, PO ^a	12	3–5
a Oral product is not available, however solution given orally was well absorbed by experimental cats.				

108.69.12 ADDITIONAL DOSAGES.

Canine distemper, [Table 3-5](#).

1253

108.70.1 FLUCONAZOLE

1254

108.70.1 CLASS.

Bis-triazole.

108.70.2 ACTION.

Antifungal; inhibits sterol and cytochrome P-450 synthesis. Higher affinity for fungal enzyme than ketoconazole or itraconazole.

108.70.3 MORE INFORMATION.

See KETOCONAZOLE, ITRACONAZOLE; [Chapter 57](#); [Table 57-1](#); references: [Ch 57](#), ref. 21; 50; 62.

108.70.4 PHARMACOKINETICS.

Low molecular weight and high water solubility results in high bioavailability (>90% systemic availability) after IV or PO administration. GI absorption is unaffected by food intake or changes in gastric acidity caused by cimetidine or antacids containing magnesium or aluminum ([Ch 57](#), ref. 135). In people, reaches effective tissue concentrations by 5–10 doses, which is 5–10 days with once-daily dosing or by 2 days if loading with twice the recommended dose is used the first day. Not extensively bound, so penetrates all body cavities and tissues, including eye and CNS. Sites having concentrations equal to or exceeding those in blood are skin, urine, skin blister fluids, body cavities, nails, saliva, sputum, reproductive tissues. Elimination half-life in cats after 50 mg was 25 hours ([Ch 57](#), ref. 137). Penetration into CSF is 50%–90% of plasma levels independent of inflammation. Not extensively metabolized; therefore primarily eliminated (80%) by renal excretion of active drug ([Ch 57](#), ref. 21; 62).

108.70.5 SPECTRUM.

Excellent for yeast forms such as *Cryptococcus*, *Candida*, *Blastomyces*, *Histoplasma*, *Coccidioides*, *Malassezia*; variable efficacy against filamentous fungi such as *Aspergillus*, dermatophytes.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.70.6 INDICATIONS.

Systemic fungal infections involving difficult-to-reach tissues (e.g., CNS). Blastomycosis, coccidioidomycosis, histoplasmosis, cryptococcosis, especially for cryptococcal infections of the brain, spinal cord, or eye (57:O'Toole et al 2003). Nasal aspergillosis. Higher doses, if tolerated, may improve therapeutic efficacy. Excellent for fungal urinary tract infections such as caused by *Candida* or *Torulopsis*.

108.70.7 APPROVED USES.

Human: for treatment of esophageal candidiasis and maintenance therapy of cryptococcal meningitis and for treatment failures of candidiasis.

108.70.8 CONTRAINDICATIONS.

Reduce dose in renal failure; avoid in pregnancy.

108.70.9 ADVERSE REACTIONS.

See also KETOCONAZOLE. Can cause vomiting, diarrhea, abdominal discomfort. Dermal eruptions, hepatotoxicity (elevated transaminases, cholestasis, hepatitis, hepatic failure). Hepatotoxicity is much less frequent than with ketoconazole or itraconazole. Does not suppress adrenal or sex hormones like ketoconazole. Alopecia, dry skin and mucosae, and dizziness have been reported only in people.

108.70.10 INTERACTIONS.

Cimetidine interferes with absorption. Fluconazole increases concentrations of thiazide diuretics, rifampin, cyclosporine, glipizide, antihistamines, diphenylhydantoin, and theophylline. Potentiates bleeding caused by anticoagulant rodenticides.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	50 mg, 100 mg, 150 mg, 200 mg	<i>Diflucan</i> (Pfizer)
	Oral capsule	150 mg	<i>Diflucan</i>
	Powder for oral suspension	10 mg/ml, 40 mg/ml reconstituted	<i>Diflucan</i>
	Parenteral injection	2 mg/ml	<i>Diflucan</i>

108.70.11 INTERNATIONAL PREPARATIONS.

Biozolene, Elazor, Fungata, Lavisa, Loitin, Triflucan.

108.70.12 HANDLING.

Keep tablets at controlled room temperature in airtight containers. PO suspension: store powder at room temperature and dilute in distilled water; shake before using. Store reconstituted suspension between refrigerated and room temperature up to 2 weeks. Parenteral injection should be stored at room or refrigerator temperature. Do not add anything or freeze.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.70.13 ADMINISTRATION.

Give twice calculated daily dose for the first day of treatment. Give for 2-3 days if rapidly advancing or severe disseminated mycosis. IV solution should be given over 1-2 hr. Often treat neurologic or ocular cryptococcosis for at least 12 weeks or for 2 weeks after CSF examination shows resolution of inflammation and antigen test results on serum and CSF are negative. The best therapeutic response in CNS cryptococcosis of cats is with the 200 mg/cat/day dosages (Ch 57, ref. 21). Because of high oral bioavailability, dosages for parenteral administration do not differ.

1254

1255

Dosage					
INDICATIONS		DOSE	ROUTE	INTERVAL (hr)	DURATION (days) ^a
Dogs					
Cryptococcosis, candidiasis, systemic mycoses, nasal aspergillosis	2.5–5 mg/kg	PO, IV	12–24	56–84	
Meningitis	5.0–8.0 mg/kg	PO, IV	12	56–84	
	8.0–12 mg/kg	PO, IV	24	56–84	
Cats					
Nasal or dermal cryptococcosis ^b	5 mg/kg	PO	12–24	^c	
	10 mg/kg	PO	24	^c	
CNS, intraocular or multisystemic infection	50 mg/cat	PO	24	^c	
CNS, intraocular, or multisystemic cryptococcosis ^b	50–100 mg/cat	PO, IV	12	^c	
Both					
Urinary candidiasis	5–10 mg/kg	PO	24	21–42	
Urinary <i>Candida glabrata</i> infection	12	PO	24	21–42	

- a For most infections, treatment duration is a minimum of 42–56 days; however cats with cryptococcosis require minimum treatment duration of 120–180 days to prevent relapse. Animals should be monitored with serologic antigen detection methods to determine treatment efficacy.
- b For most infections in cats, 50 mg/cat per day achieves adequate therapeutic levels (Ch 57, ref. 137).
- c Treatment should continue until antigen testing results of blood or CSF (with CNS disease) are negative. This is usually at least 2 mo beyond clinical resolution and a mean time of approximately 8 mo.

108.70.14 ADDITIONAL DOSAGES.

Blastomycosis, Table 59-1; cryptococcosis, Table 61-5; coccidioidomycosis, Table 62-3; nasal aspergillosis, Table 64-1; candidiasis, Table 65-4; trichosporonosis, Table 66-1.

108.70.15 DISPENSING INFORMATION.

This medication can be given with food.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.71.1 FLUCYTOSINE

108.71.1 CLASS.

Fluorinated pyrimidine.

108.71.2 ACTION.

Antifungal; converted by specific enzyme in fungal cells to metabolites like 5-fluorouracil that interfere with fungal thymidylate synthase and resultant DNA and RNA synthesis.

108.71.3 MORE INFORMATION.

See [Chapter 57](#); [Table 57-1](#).

108.71.4 PHARMACOKINETICS.

Well absorbed from GI tract and widely distributed in tissues and body fluids, including joints, peritoneal fluid, and aqueous humor. CSF concentration is 70%-90% that in serum. Only 4% absorbed drug being metabolized, 80%-90% is excreted unchanged in urine.

108.71.5 SPECTRUM.

Candida, *Cryptococcus*. Some effect against *Aspergillus*. Always used in combination with amphotericin B. Resistance may develop during treatment. **Ineffective:** filamentous fungi and dermatophytes.

108.71.6 INDICATIONS.

Serious (disseminated) infections with *Candida* or *Cryptococcus* such as sepsis, endocarditis, meningitis.

108.71.7 APPROVED USES.

In combination therapy for systemic yeast infections.

108.71.8 CONTRAINDICATIONS.

Reduce dose or avoid in renal failure. Avoid with pre-existing myelosuppression, pregnancy, or in neonates.

108.71.9 ADVERSE REACTIONS.

Myelosuppression (leukopenia, thrombocytopenia), teratogenic in laboratory animals. Renal failure, crystalluria, dermal eruptions, vomiting, diarrhea, abdominal pain, hepatotoxicity (cholestatic hepatitis, icterus and increased liver enzymes), CNS signs. Converted by GI flora to 5-fluorouracil, which can be toxic when absorbed producing myelosuppression or enterocolitis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.71.10 INTERACTIONS.

Synergistic with amphotericin B, but renal toxicity of both drugs is enhanced.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral capsules	250 mg, 500 mg	Ancobon (Roche)

108.71.11 INTERNATIONAL PREPARATIONS.

Ancobon, Ancotil.

108.71.12 HANDLING.

Store capsules in airtight, light-proof containers at controlled room temperature.

108.71.13 ADMINISTRATION.

Food may slow but not reduce drug absorption after PO administration. Repeatedly monitor hemogram, renal and hepatic test results every 2 weeks during treatment. Assess renal function at least twice a week if amphotericin B is also used.

1255

Dosage				
INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Cryptococcosis,	25–50	PO	6	42
candidiasis ^a	50–65	PO	8	42
Cryptococcosis ^a	50	PO	6	42

1256

^a Must give in combination with a polyene or azole antifungal drug.

108.71.14 ADDITIONAL DOSAGES.

Cryptococcosis, [Table 61-5](#); CNS infections, [Table 92-5](#).

108.71.15 DISPENSING INFORMATION.

Monitor animal for any GI signs or bruising tendencies.

108.72 FOSCARNET SODIUM (PHOSPHONOFORMATE)

108.72.1 CLASS.

Pyrophosphate analog.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.72.2 ACTION.

Antiviral; inhibits replication of all known herpesviruses. Inhibits virus-specific DNA and RNA polymerases and reverse transcriptases at concentrations that do not affect those in cells. Prevents pyrophosphate exchange in virus to a much greater degree than mammalian cells. Activity against retroviruses is by binding to reverse transcriptase in a non-competitive and reversible manner distinct from other antivirals and it does not require phosphorylation to be active.

108.72.3 MORE INFORMATION.

See Foscarnet, [Chapter 2](#); [Table 2-1](#); references: [Ch 2](#), ref. 127; 146.

108.72.4 PHARMACOKINETICS.

PO bioavailability 35% in cats, 10% in dogs. A derivative (thiofoscarnet) has higher PO bioavailability ([Ch 2](#), ref. 143). IV route produces higher concentrations and is preferred for systemic therapy. At physiologic pH, it is ionized and has limited cellular penetration. Penetrates CSF (40% of blood concentration) with some accumulation in bone from where it is eliminated slowly, especially in younger cats ([Ch 2](#), ref. 147). Drug undergoes little metabolism and is excreted mainly unchanged in urine. Clearance from plasma in young cats is quicker than in older cats ([Ch 2](#), ref. 146; 147).

108.72.5 SPECTRUM.

DNA viruses and RNA viruses, including retroviruses. Most effective against herpesviruses.

108.72.6 INDICATIONS.

Herpesvirus infections, retroviral infections. Acyclovir-resistant herpesvirus infections.

108.72.7 APPROVED USES.

Human: cytomegalovirus retinitis in AIDS patients.

108.72.8 CONTRAINDICATIONS.

Renal failure. Use caution in pregnant and lactating animals owing to potential for fetotoxicity and damage to bones and teeth of young animals.

108.72.9 ADVERSE REACTIONS.

Nephrotoxicity; must monitor renal function during therapy. Renal dysfunction is evident in most people after 2 weeks of therapy. Maintenance of adequate hydration, diuresis, and discontinuation of the drug facilitate reversal of nephrotoxicity. Chelates divalent cations such as calcium, so that hypocalcemia, hyperphosphatemia or hypophosphatemia, hypomagnesemia, and hypokalemia may develop. Ulceration of the

Infectious Diseases of the Dog and Cat, 3rd Edition

genital epithelium may occur with urine contamination. Anemia and granulocytopenia may develop. Young cats given high dosages develop widened growth plates, increased osteoid, mineralization failure.

108.72.10 INTERACTIONS.

With concurrent pentamidine, may exacerbate hypocalcemia. Renal toxicity increased with concurrent use of amphotericin B or aminoglycosides. Cannot use with other nephrotoxic drugs such as ganciclovir because of additive effect.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Injectable solution	24 mg/ml in 500-ml and 250-ml bottles for IV infusion	Foscavir (Astra)

108.72.11 INTERNATIONAL PREPARATIONS.

Triapten, Virudin.

108.72.12 HANDLING.

Store at room temperature (15–30°C) and not frozen. Should use only if bottle and seal are intact.

108.72.13 ADMINISTRATION.

Given IV by continuous infusion because of short half-life. Weakness or paresthesias may occur during infusion. Do not infuse as a bolus. This will increase the risk of toxicity. IV maximum rate of infusion of 1 mg/kg/min. Experimentally, has been given PO to dogs and cats (Ch 2, ref. 127; 146).

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs	20–30	IV, PO	8	prn
Cats				
Retroviral infection	13.3	IV	8	prn

1256

108.72.14 ADDITIONAL DOSAGES.

None.

108.72.15 DISPENSING INFORMATION.

This drug can cause oral irritation when given by mouth. Report any decrease in appetite or signs of oral bleeding to your veterinarian.

1257

Infectious Diseases of the Dog and Cat, 3rd Edition

108.73.1 FUMAGILLIN

108.73.1 CLASS.

Alicyclic antibiotic derived from *Aspergillus fumigatus*.

108.73.2 ACTION.

Inhibitor of endothelial cell proliferation and angiogenesis. It may inhibit methionine aminopeptidase 2.

108.73.3 MORE INFORMATION.

See [Table 71-1](#); Microsporidiosis, [Chapter 75 \(Ch 75\)](#), ref. 42a).

108.73.4 PHARMACOKINETICS.

Not well absorbed from epithelial surfaces such as the gut and extraocular tissues.

108.73.5 SPECTRUM.

Entamoeba and microsporidia such as *Encephalitozoon* and *Enterocytozoon bieneusi*. Has been used to treat infections with a closely related organism, *Nosema*, in honey bees.

108.73.6 INDICATIONS.

Intestinal amebiasis. Microsporidial diarrhea or dissemination. Applied topically to the conjunctiva in the treatment of microsporidial keratoconjunctivitis.

108.73.7 APPROVED USES.

Treatment of microsporidiosis in honeybees. Has been investigated for effects on angiogenesis in treatment of solid tumors in people. Once used to treat malaria.

108.73.8 CONTRAINDICATIONS.

Preexisting neutropenia or thrombocytopenia.

108.73.9 ADVERSE REACTIONS.

Myelosuppression (leukopenia, thrombocytopenia), nausea. The exceptional amount of side effects have made this medication less desirable for treatment of intestinal microsporidiosis in humans.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.73.10 INTERACTIONS.

Caution must be used with other myelosuppressive drugs.

AVAILABILITY ^a	TYPE	SIZES	PREPARATION (COMPANY)
Human Investigational	Oral capsules	20 mg	Sanofi-Synthelabo Labs
Human Investigational	Topical ocular solution as bicyclohexylammonium salt	70 µg/ml	Sanofi-Synthelabo Labs

a Available in the United States only through the manufacturer for research or investigational use, but not for human or drug use. Oral and topical formulations may have to be compounded by pharmacists.

108.73.11 INTERNATIONAL PREPARATIONS.

Fumagilina.

108.73.12 HANDLING.

Store capsules in airtight, light-proof containers at controlled room temperature.

108.73.13 ADMINISTRATION.

Food may slow but not reduce drug absorption after PO administration. Give separately from meals.

Dosage				
INDICATIONS (Humans)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Enterocytozoon ^a	20 mg total dose	PO	8	14

a Extrapolated from human dosages (Ch 75, ref. 42a).

108.73.14 ADDITIONAL DOSAGES.

None.

108.73.15 DISPENSING INFORMATION.

Take on an empty stomach.

108.74 FURAZOLIDONE

108.74.1 CLASS.

Nitrofurans.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.74.2 ACTION.

Antibacterial, antiprotozoal by unknown action; potentially interferes with carbohydrate metabolism of microorganism. Drug undergoes reductive activation in protozoa and killing correlates with reduced metabolites which damage cellular DNA.

108.74.3 MORE INFORMATION.

NITROFURANTOIN; [Chapter 34](#), Nitrofurans; [Table 34-9](#); Antiprotozoals, [Chapter 71](#); [Table 71-1](#).

108.74.4 PHARMACOKINETICS.

Small amounts are absorbed from GI tract, the majority is not absorbed and is active in the intestinal lumen. Absorbed fraction may be responsible for most of adverse reactions. Rapid tissue and hepatic metabolism of any absorbed drug. Colored metabolites are excreted in urine and major amount in feces.

108.74.5 SPECTRUM.

Gram positive: *Staphylococcus*. **Gram negative:** *Escherichia*, *Salmonella*, *Proteus*, *Aerobacter*, *Campylobacter*, and *Helicobacter*. **Protozoa:** *Giardia*, *Trichomonas*, *Coccidia*.

108.74.6 INDICATIONS.

Bacterial or protozoal enteritis caused by susceptible pathogens. Gastric helicobacteriosis.

108.74.7 APPROVED USES.

Humans: for bacterial and protozoal enteritis.

108.74.8 CONTRAINDICATIONS.

Prior sensitivity. Avoid in pregnant and lactating animals and neonates.

1257

108.74.9 ADVERSE REACTIONS.

1258

Vomiting, diarrhea, fever, dermatologic eruption, brown urine, hypoglycemia. Hemolysis in animals with glucose-6-phosphate dehydrogenase deficiency, or potentially in neonatal animals.

108.74.10 INTERACTIONS.

Increased vasopressor effects of sympathomimetic drugs.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral liquid	50 mg/15 ml	<i>Furoxone</i> (Procter and Gamble)
	Oral	tablets100 mg	<i>Furoxone</i>

Infectious Diseases of the Dog and Cat, 3rd Edition

108.74.11 INTERNATIONAL PREPARATIONS.

Nifuran.

108.74.12 HANDLING.

Store in airtight, light-proof containers at controlled room temperature. If exposed to light, liquids will darken.

108.74.13 ADMINISTRATION.

Oral suspension makes medication of cats convenient and dosing more accurate. Tablets can be crushed and added to corn syrup to improve palatability.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Human				
Adult giardiasis	100 mg/person	PO	6	7
Child giardiasis	1.25 mg/kg	PO	6	7–10
Dogs				
Coccidiosis	8–20 mg/kg	PO	24	7
Entamebiasis	2.2 mg/kg	PO	8	7
Cats				
Coccidiosis	8–20 mg/kg	PO	24	7
Giardiasis	4 mg/kg	PO	12	5–10
Amebiasis	2.2 mg/kg	PO	8	7

108.74.14 ADDITIONAL DOSAGES.

Giardiasis, [Table 78-3](#); coccidiosis, [Table 81-2](#).

108.74.15 DISPENSING INFORMATION.

Reduce feeding of tyramine-containing foods to your pet such as aged cheese and smoked or pickled meat while administering drug. This drug may cause gastrointestinal side effects in your pet and brown discoloration of urine.

108.75.1 FUSIDIC ACID

108.75.1 CLASS.

Antibiotic obtained from *Fusidium coccineum*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.75.2 ACTION.

Antibacterial, antiprotozoal by interfering with protein synthesis. Interferes with amino acid transfer from aminoacyl-sRNA to protein on the ribosomes. Effective against staphylococci and streptococci. May be bacteriostatic or bactericidal depending on the inoculum size. Bacterial cells stop dividing within 2 min of contact; however, nucleic acid synthesis continues for up to 2 hr thereafter. It is *only* effective against gram-positive bacteria. The poor activity against gram-negative bacteria and mammalian cells may relate to cell-wall permeability differences. With topical preparations, concentrations are adequate to treat other gram-positive organisms such as corynebacteria, *Neisseria*, clostridia, and *Bacteroides* species.

108.75.3 MORE INFORMATION.

NONE.

108.75.4 PHARMACOKINETICS.

Able to penetrate intact skin makes them effective in skin infections.

108.75.5 SPECTRUM.

Gram positive: *Staphylococcus*. Including β -lactamase resistant strains, and other gram positives. **Protozoa:** *Giardia*, *Plasmodium*.

108.75.6 INDICATIONS.

Bacterial dermatitis caused by susceptible pathogens.

108.75.7 APPROVED USES.

Bacterial dermatitis.

108.75.8 CONTRAINDICATIONS.

Sensitivity to fusidic acid and its salts or lanolin for topical product. Preexisting hepatic disease for parenteral use. No risk or dosage modification if renal dysfunction exists. No cross-resistance with other antibiotics in clinical use; however, bacteria can develop resistance to this drug in vitro and with clinical use.

108.75.9 ADVERSE REACTIONS.

In certain circumstances, may cause hypersensitivity. With topical use, if irritation or sensitization develop, discontinue therapy. May cause irritation if used near the eye because of conjunctival inflammation. With IV use, may get venospasm, thrombophlebitis, hemolysis, vomiting, icterus, hypocalcemia. Liver enzymes should be regularly monitored with prolonged therapy. Not recommended in pregnancy or lactation.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.75.10 INTERACTIONS.

Incompatible with amino acid solutions, acidic solutions or whole blood. Do not mix with aminoglycosides, cephalosporins, or penicillins.

1258

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Topical ointment or as an	Cream: 2% in tubes of 15 and 30gm.	<i>Fucidin</i> Ointment (Leo Pharma; Fusidic Acid)
	intertulle dressing	Intertulle: ointment-impregnated gauze	
	Oral tablets	250 mg	<i>Fucidin</i> Tablets
	Oral suspension	50 mg/ml	<i>Fucidin</i> Suspension
	IV Solution	580 mg sodium fusidate in 50 ml vial	<i>Fucidin</i> for Intravenous Infusion, <i>Sodium fusidate</i>

1259

108.75.11 HANDLING.

Store at room temperature (<25°C) and protect from light. Reconstitute the IV solution with the buffered diluent provided before diluting further. The diluent contains phosphate-citrate buffer which is essential for stability. IV solution contains no bacteriostat and must be used within 24 hr of preparation. Compatible with normal saline and 5% dextrose.

108.75.12 ADMINISTRATION.

Cream, apply topically to affected areas. **Oral preparations** (tablets and liquid), used to treat GI infections. **IV use**, intermittent infusion at a rate of 1-2 ml/min over 2-6 hr.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Human^a				
Gram-positive bacterial dermatitis	Small amount	Topically	8–12	7
	500 mg sodium fusidate ^b	PO	8	7–28
	738 mg fusidic acid suspension	PO	8	7–28
Systemic gram-positive infections	500 mg sodium fusidate ^b	IV	8	7–28

a No animal dosage available. This is a human dosage schedule.

b Equivalent to 480 mg fusidic acid. No doses are confirmed for dogs and cats. All doses listed are for humans. Due to incomplete absorption, the dose of the suspension is higher than other formulations. The dose has been increased to treat acute severe infections.

108.75.13 ADDITIONAL DOSAGES.

None.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.75.14 DISPENSING INFORMATION.

Apply to the affected area 2-3 times daily, for up to 7 days.

108.76 GANCICLOVIR (CYTOVENE; SYNTEX). SEE ACYCLOVIR AND [Chapter 2](#), ACYCLOVIR.

108.77 GENTAMICIN

108.77.1 CLASS.

Aminoglycoside.

108.77.2 ACTION.

Bactericidal; inhibits bacterial protein synthesis by binding to the 30s ribosomal subunit.

108.77.3 MORE INFORMATION.

AMIKACIN, KANAMYCIN, STREPTOMYCIN; [Chapter 34](#), Aminoglycosides; [Table 34-5](#); references [Ch 34](#), ref. 136; 137.

108.77.4 PHARMACOKINETICS.

Poor absorption from the GI tract after PO administration. IM absorption (>90%) is more predictable and rapid than SC. Distribution restricted into extracellular fluids (see AMIKACIN). Therapeutic concentrations achieved in some tissues, including lung, bone, and heart; also distributes in limited extent to bile, synovial, peritoneal, abscess, pleural fluids. Low levels in CNS, CSF, or eyes even with inflammation. Must inject intrathecally to achieve adequate concentrations in CSF. Accumulation in kidneys and inner ear may be responsible for intoxication. Small amounts excreted in bile, most excreted in urine as unchanged drug. Can cross placental barrier, which can be risk for fetus.

108.77.5 SPECTRUM.

Gram positive: *Corynebacterium*, some *Streptococcus*, *Staphylococcus*. **Gram negative:** *Escherichia*, *Pasteurella*, *Proteus*, some *Pseudomonas*, *Klebsiella*, *Serratia*, *Aerobacter*, *Citrobacter*, *Enterobacter*, *Salmonella*. No specific advantages over other aminoglycosides except possible synergy with penicillins against *Enterococcus*. **More effective:** gram-negative aerobes. **Ineffective:** obligate anaerobes, some resistance developing in strains of *Klebsiella*, *Escherichia*, and *Pseudomonas*.

108.77.6 INDICATIONS.

Synergism with β -lactams is documented in vivo. Use in combination with β -lactams for high-risk animals requiring treatment or prophylaxis of established bacteremia or potential bacteremia during urologic, genital, digestive manipulations, or surgery. With clindamycin for surgery on open fractures; with metronidazole before digestive surgery; with quinolones before endoscopic or radiologic urinary tract procedures.

Infectious Diseases of the Dog and Cat, 3rd Edition

Aminoglycosides are rarely recommended as single agents or for self-limiting infections when less toxic drugs are available. Genitourinary, respiratory, or skin and soft tissue infections caused by gram-negative bacilli; systemic infections (including bacteremia and endocarditis) caused by *Staphylococcus*; persistent fever in neutropenic animals. In serious infections caused by unknown organisms, usually combined with a penicillin or cephalosporin; combine with parenteral carbenicillin for serious infections caused by *Pseudomonas*. Can use in nebulization chambers (2.2 mg/kg) for aerosol treatment of bacterial pneumonia.

108.77.7 APPROVED USES.

Many, human and veterinary.

1259

108.77.8 CONTRAINDICATIONS.

1260

Avoid usage or greatly reduce dosage in renal failure; reduce dose in neonates. Can cause fetal intoxication during pregnancy. Nephrotoxicity is increased by dehydration, shock, renal failure, cardiac failure, hypotension, nonsteroidal anti-inflammatory (antiprostaglandin) drugs, metabolic acidosis, diuretics, calcium, or magnesium deficiencies. Should not be used in dogs that require hearing or balance for work or sport.

108.77.9 ADVERSE REACTIONS.

See also [Chapter 34](#), Aminoglycosides. Higher (> once daily) frequency and dosage is associated with nephrotoxicity and ototoxicity. Higher protein diets reduce nephrotoxicity in dogs ([Ch 34](#), ref. 136). More ototoxic than amikacin in cats. Topical lavage of open wounds or body cavities with parenteral formulation (50 mg/ml) can lead to significant absorption and nephrotoxicity ([Ch 34](#), ref. 251). Topical application of 3 mg/ml otic solution was not ototoxic in ear canals of dogs with intact or ruptured eardrums ([Ch 34](#), ref. 356). Often added at 3 mg/ml in tris-EDTA lavage solutions for *Pseudomonas* (see [Chapter 34](#), [Table 34-15](#)). Neuromuscular blockade can result after lavage of pleural or peritoneal cavities.

108.77.10 INTERACTIONS.

Increased nephrotoxicity when administered with some older parenteral first-generation cephalosporins, amphotericin B, osmotic (mannitol) or loop (furosemide) diuretics, vancomycin, or anesthesia with methoxyflurane or enflurane. Can potentiate paralysis by neuromuscular blockers (*d*-tubocurarine, pancuronium, atracurium). Increased ototoxicity with concurrent use of furosemide and with reduced renal function. Effectiveness of gentamicin is reduced with concurrent use of penicillin, ampicillin, or carbenicillin.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Injectable solution (sulfate)	40 mg/ml, 10 mg/ml	<i>Garamycin</i> , <i>Garamycin</i> Pediatric, (Schering-Plough Animal Health), generic (various)
	Intrathecal solution	2 mg/ml without no preservatives	<i>Garamycin</i> <i>Intrathecal</i>
Veterinary	Injectable solution (sulfate)	50 mg/ml (dogs and cats) 100 mg/ml (equine)	<i>Gentocin</i> (Schering-Plough Animal Health) <i>Gentocin</i>

Infectious Diseases of the Dog and Cat, 3rd Edition

108.77.11 INTERNATIONAL PREPARATIONS.

Akomicin, Biogen, Cidomycin, Dispagent, Gentalline, Gentamen, Gentax, Genticol, Gentogram, Geomycine, Martigenta, Refobacin, Sulmycin.

108.77.12 HANDLING.

Store at controlled room temperature and never refrigerate or freeze. Never mix aminoglycosides and β -lactams owing to inactivation in vitro but can be coadministered separately. For IV dose, can be diluted in 5% dextrose or 0.9% saline for infusion, or give as IV bolus.

108.77.13 ADMINISTRATION.

Can be administered IV or IM, but the former preferred for serious life-threatening bacteremia, animals in shock, those with reduced muscle mass, extensive skin lesions, or heart failure. If dosage frequency is increased to treat systemic infections, toxicity will be greater. Higher peak tissue levels are obtained by a greater dosage per administration (Ch 34, ref. 4). However, to prevent toxicity at higher dosages, the dosage interval must be reduced. For this reason, a 24-hr or longer interval is recommended. Treatment usually lasts for a maximum of 7-10 days. Renal function must be monitored wherever possible. Monitor urine for fixed specific gravity, casts, albumin, glucose or blood. Increasing the interval of administration to at least 24 hr will reduce toxicity. If toxicosis is noted, the drug should be stopped immediately and fluid and osmotic diuresis instituted. Appearance of nephrotoxicity may be delayed for 1-3 weeks after dosage is discontinued. Intrathecal dose is 2-4 mg total dose/day. After lumbar or cisternal puncture, remove 1 ml/10 kg CSF volume. Dilute the gentamicin with an equal volume of sterile saline or aspirated CSF (if clear) before infusing over 3-5 min.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Localized, urinary infections	2.2 ^a	2.2 IM, SC	24	7-10
Orthopedic and soft tissue infections	4.4-6.6	IV, IM, SC	24	<7 ^b
Bacteremia, sepsis ^c	6.6	IV, IM, SC	24	<7 ^b
Cats^d				
Urinary, soft tissue infections	2.2	IV, IM, SC	24	<7 ^b
Systemic, bacteremia	4.4	IV, IM, SC	24	<7 ^b

a Recommended to give 4.4 mg/kg for first dose to help establish tissue levels.

b Renal function must be closely monitored by urine sediment examination and serum urea nitrogen concentration.

c Once-daily administration of gentamicin for up to 5 days may provide adequate serum levels to treat most susceptible gram-negative infections with little or no nephrotoxicity in dogs (Ch 34, ref. 4).

d Maximum amount for obese cat is 2.5 mg/kg per dose (Ch 34, ref. 429).

1260

Infectious Diseases of the Dog and Cat, 3rd Edition

1261

108.77.14 ADDITIONAL DOSAGES.

Canine viral enteritis, [Table 8-1](#); feline panleukopenia, [Table 10-2](#); *Rhodococcus equi* infection, [Table 35-7](#); gram-negative infections, [Table 37-3](#); enteric bacterial infections, [Table 39-2](#); canine brucellosis, [Table 40-2](#); plague, [Table 47-1](#); opportunistic mycobacterial infection, [Table 50-9](#); dermatophilosis, [Table 51-1](#); otitis externa, [Table 85-6](#); musculoskeletal infections, [Tables 86-2](#) and [86-3](#); bacteremia, [Table 87-6](#); respiratory disease, [Table 88-8](#); oral infections, [Table 89-4](#); enteric infections, [Table 89-16](#); intraabdominal infections, [Table 89-21](#); hepatobiliary infections, [Table 90-5](#); local ocular infections, [Table 93-4](#).

108.77.15 DISPENSING INFORMATION.

Must be given SC; therefore, not advised for home administration. Monitoring for renal toxicity is also needed.

108.78 GRANULOCYTE COLONY-STIMULATING OR HEMATOPOIETIC GROWTH FACTOR (G-CSF; FILGRASTIM) SEE FILGRASTIM

108.79 GRANULOCYTE MACROPHAGE COLONY-STIMULATING OR HEMATOPOIETIC GROWTH FACTOR (GM-CSF; SARGRAMOSTIM) SEE SARGRAMSTIM

108.80 GRISEOFULVIN

108.80.1 CLASS.

Antifungal antibiotic derived from *Penicillium* sp.

108.80.2 ACTION.

Fungistatic; binds to keratin and inhibits fungal growth by disrupting mitosis.

108.80.3 MORE INFORMATION.

See [Chapter 57](#), Griseofulvin; [Table 57-1](#); reference: [Ch 57](#), ref. 95; 139.

108.80.4 PHARMACOKINETICS.

Variable absorption can be increased by feeding a high fat content meal. Ultramicrocrystalline size (<1 μm) is better absorbed (>95%) than microsize (4 μm) preparation (30%-75%) lowering the equivalent dosage. Concentrated in dermis and appendages. Becomes incorporated in newly formed keratinized epithelium. Metabolized in liver to inactive compounds that are excreted.

108.80.5 SPECTRUM.

Microsporium, *Trichophyton*. **Ineffective:** *Actinomyces*, *Nocardia*, *Aspergillus*, *Sporothrix*, *Blastomyces*, *Histoplasma*, *Cryptococcus*, *Coccidioides*, *Malassezia*, and *Candida*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.80.6 INDICATIONS.

“Ringworm,” dermatophytosis of hair, nails, and skin. Should not be used in cases that are self-limiting or adequately confined for topical therapies.

108.80.7 APPROVED USES.

Dermatophytosis in people and animals.

108.80.8 CONTRAINDICATIONS.

Hepatic dysfunction, pregnancy, anemia, leukopenia, or feline retroviral infections, especially with leukopenias.

108.80.9 ADVERSE REACTIONS.

Nausea, vomiting, diarrhea are most common. Systemic and dermal hypersensitivity (dermal edema and pruritus), hepatotoxicity. May be teratogenic and interferes with spermatogenesis. Myelotoxicity is idiosyncratic, uncommon, and independent of dosage, causing anemia, leukopenia, and/or thrombocytopenia. Neurotoxicity, usually associated with overdosage; ataxia and disorientation, cerebellar signs; may not resolve and may prove fatal (Ch 57, ref. 81). Teratogenic and can cause birth defects in pregnant animals. Given at 25 mg/kg daily for 30 days did not alter the viability, morphology, or motility of sperm in semen of male dogs (Ch 57, ref. 139).

108.80.10 INTERACTIONS.

Interferes with porphyrin metabolism. Reduces effectiveness of barbiturates and warfarin rodenticides. Phenobarbital or other anticonvulsants may reduce griseofulvin's effectiveness.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Microsize: oral tablets	250 mg, 500 mg	<i>Fulvicin-U/F</i> (Schering-Plough Animal Health), <i>Grisactin</i> (Wyeth Ayerst)
	Oral capsules	125 mg, 250 mg	<i>Grisactin</i>
	Oral suspension	125 mg/5 ml	<i>GrifulvinV</i> (Ortho), <i>Grisactin</i>
	Ultramicrosize: tablets	125 mg, 165 mg, 250 mg, 330 mg	<i>FulvicinP/G</i> , <i>GrisactinUltra</i> , <i>Gris-PEG</i> (Allergan Herbert)
Veterinary	Microsize: oral tablets	250 mg, 500 mg	<i>Fulvicin-U/F</i>
		125 mg	<i>Grisovin</i> (Schering-Plough Animal Health)

108.80.11 INTERNATIONAL PREPARATIONS.

Biogrisin, *Delmofulvina*, *Fulcin*, *Fulcine*, *Fungivin*, *Gricin*, *Griséfuline*, *Griseoderm*, *Griseomed*, *Griseostatin*, *Grisol*, *Grisovin*, *Grisovina*, *Lamoryl*, *Microcidal*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.80.12 HANDLING.

Store at controlled room temperature in airtight containers. Protect suspension from light.

108.80.13 ADMINISTRATION.

Therapy should continue until fungal cultures are negative or for at least 2 weeks after resolution of signs and for at least 5 mo for onychomycosis. Usually need 4-6 weeks of treatment because of drug incorporation into forming keratin. May combine with adjunctive topical therapy. Give tablet size most convenient by 1/4, 1/2, or whole-tablet increments. Give with a fatty meal or corn oil to enhance absorption and decrease GI irritation. Monitor CBC at least every 2 weeks during treatment.

108.80.14 DOSAGE.

The dose recommended by the manufacturer of the microsize veterinary formulation (11-22 mg/kg/day) is much less than currently recommended for use in dogs and cats because it does not account for the more rapid clearance of the drug in dogs and cats.

1261

1262

INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL(hr)	DURATION (days)
Dogs				
Dermatophytosis (microsized)	25	PO	12	42-56 ^a
Dermatophytosis (ultramicrosized)	5-10	PO	24	42 ^a
Cats				
Dermatophytosis (microsized)	50	PO	24	42-70
	25	PO	12	42-70
Dermatophytosis (ultramicrosized)	5-10	PO	24	42

^a May have to treat longer for *Trichophyton* than for *Microsporum*.

108.80.15 ADDITIONAL DOSAGES.

Dermatophytosis, [Table 58-5](#).

108.80.16 DISPENSING INFORMATION.

Return for CBC weekly or biweekly. Duration of therapy at least 6 weeks for skin infections and 5 mo for onychomycotic lesions. May take up to 2.5 mo for mycologic cure of skin infection in many cases ([Ch 57](#), ref. 95).

108.81 HETACILLIN

108.81.1 CLASS.

Penicillin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.81.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.81.3 MORE INFORMATION.

See also AMPICILLIN; [Chapter 34](#), Aminopenicillins; [Table 34-1](#).

108.81.4 PHARMACOKINETICS.

Hydrolyzed in the stomach to ampicillin. See AMPICILLIN.

108.81.5 SPECTRUM, INDICATIONS, CONTRAINDICATIONS, ADVERSE REACTIONS, AND INTERACTIONS.

See AMPICILLIN.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Oral tablets (potassium)	50 mg, 100 mg, 200 mg	<i>Hetacin-K</i> (Fort Dodge)

108.81.6 INTERNATIONAL PREPARATIONS.

Etaciland.

108.81.7 HANDLING AND ADMINISTRATION.

See AMPICILLIN.

Dosage					
INDICATIONS		DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs					
Urinary tract		11–22 mg/kg	PO	12	7–14
Systemic infections, difficult organism		22–44 mg/kg	PO	12	14
		11–22 mg/kg	PO	8	14
Cats					
Urinary infections		50 mg/cat	PO	12	7–14
Systemic infections		10–20 mg/kg	PO	8	7–14

108.81.8 ADDITIONAL DOSAGES.

None.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.81.9 DISPENSING INFORMATION.

Give 1 hr before or 2 hr after feeding.

108.82.1 IBAFLOXACIN

108.82.1 CLASS.

Fluoroquinolone.

108.82.2 ACTION.

Bactericidal; inhibits bacterial DNA gyrase. Main metabolite, 8-hydroxy-ibafloxacin is also antimicrobial.

108.82.3 MORE INFORMATION.

See ENROFLOXACIN; [Chapter 34](#); [Table 34-11](#).

108.82.4 PHARMACOKINETICS.

Rapidly absorbed from GI tract; plasma concentrations are maximal by 1-2 hr. The drug is 69%-81% bioavailable ([Ch 34](#), ref. 78b). Food positively increases absorption and bioavailability. Maximum concentration of 6 µ/ml at 15 mg/kg dosing. Widely distributed in tissues. Liver metabolizes a majority of the drug, and most found in the urine or feces or urine are metabolites. After multiple dosages, there is no dosage accumulation in dogs; however, moderate accumulation of drug can occur in cats. Following repeated oral administration to cats, increases in the drug and its less active metabolites were noted between days 1 and 10 of treatment ([Ch 34](#), ref. 78a). When administered to dogs at 75 mg/kg (5 times the recommended dose) for 90 days, it was well tolerated. However doses in a range of 15-75 mg/kg to cats for 30 days produced vomiting and hypersalivation.

1262

1263

108.82.5 SPECTRUM.

As for other quinolones. **Gram positive:** *Staphylococcus*. **Gram negative:** *Escherichia*, *Klebsiella*, *Pseudomonas*, *Proteus*, *Salmonella*, *Serratia*, *Shigella*, *Citrobacter*, *Enterobacter*, *Brucella*, *Pasteurella*. Anaerobes: less effective. Moderate activity against *Bordetella bronchiseptica*. Others: see ENROFLOXACIN. **More effective:** gram-negative aerobes and facultative anaerobes. **Low effectiveness:** *Pseudomonas* spp and streptococci **Ineffective:** obligate anaerobes. See also ENROFLOXACIN.

108.82.6 INDICATIONS.

For skin, urinary and respiratory infections. For skin infections such as pyoderma (deep or superficial), wounds or abscesses caused by susceptible strains of staphylococci, *E. coli* and *Proteus mirabilis*. For acute uncomplicated urinary tract infections caused by susceptible strains of staphylococci, *Proteus* spp. *Enterobacter* spp., *E. coli*, and *Klebsiella* spp. For Upper and lower respiratory infections caused by susceptible strains of staphylococci, *E. coli* and *Klebsiella* spp.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.82.7 APPROVED USES.

Dog, for treatment of pyoderma, wounds and abscesses caused by susceptible organisms. Unlike other veterinary quinolones, has been licensed for treatment up to 90 days. Cats, for dermal, soft tissue, and respiratory infections caused by susceptible organisms.

108.82.8 CONTRAINDICATIONS.

Not recommended for use in most dogs before 9 mo of age and up to 18 mo in large and giant breeds. The 7.5% gel should not be used in cats.

108.82.9 ADVERSE REACTIONS.

As with other quinolones, see ENROFLOXACIN. GI signs of diarrhea and vomiting.

108.82.10 INTERACTIONS.

See ENROFLOXACIN. Avoid concurrent administration of products containing multivalent cations which interfere with absorption. Avoid concurrent treatment with nitrofurans due to antagonism.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary (Dogs and cats)	Oral tablets	150 and 300 mg tablets; also	<i>Ibafin</i> (Intervet Inc., Intervet
	Double scored	30, 900 mg (USA)	Nederland B.V.)
	Gel for cats or dogs	3% or 7.5% (Europe)	<i>Ibafin</i> (Intervet Nederland B.V.)

108.82.11 HANDLING.

Store tablets in airtight, moisture-proof containers at room temperature below 25°C. Sold in blister packets.

108.82.12 ADMINISTRATION.

See ENROFLOXACIN. Has been approved for use in pregnant bitches.

Dosage					
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION ^a (days)	
Dogs					
Urinary, skin, soft tissue, respiratory infections	15 ^b	PO	24	10–21	
Cats					
Urinary, soft tissue	15 ^c	PO	24	10	

a Duration of treatment depends on nature and severity of infection. Ten-day course is often sufficient for self-limiting infections. Pyoderma often requires a minimum of 21 days.

b Ch 85, ref. 22; Ch 34, ref. 172a.

c Ch 34, ref. 78a.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.82.13 ADDITIONAL DOSAGES.

None.

108.82.14 DISPENSING INFORMATION.

Medicine should be given with food to help increase its absorption.

108.83 IDOXURIDINE (SEE [CHAPTER 2](#))

108.84 IMIDOCARB DIPROPIONATE

108.84.1 CLASS.

Aromatic diamidine.

108.84.2 ACTION.

Antiprotozoal. Interferes with nucleic acid metabolism.

108.84.3 MORE INFORMATION.

See DIMINAZENE, AMICARBALIDE, PHENAMIDINE, PENTAMIDINE; [Chapter 71](#); [Table 71-1](#); references: [Ch 71](#), ref. 42; 57; 71; [Ch 77](#), ref. 78.

108.84.4 PHARMACOKINETICS.

Slowly metabolized and excreted after IM injection. Persists for long periods in plasma and tissues and gradually eliminated. Protects dogs from infection for up to 5 weeks.

108.84.5 SPECTRUM.

Ehrlichia, *Babesia*. Some variation in species and strain susceptibility ([Ch 34](#), ref. 108a). Not effective against *E. platys* or *Mycoplasma haemofelis* ([Ch 34](#), ref. 427a). See [Table 77-3](#) for efficacy against *Babesia* species.

1263

1264

108.84.6 INDICATIONS.

Ehrlichiosis, babesiosis.

108.84.7 APPROVED USES.

Babesiosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.84.8 CONTRAINDICATIONS.

Use of organophosphates or cholinesterase-inhibiting drugs may increase toxicity. Reduce dose or avoid use with preexisting pulmonary impairment or renal or hepatic failure. Safety and efficacy have not been determined for puppies or for breeding, lactating, or pregnant dogs. Not recommended for IV use.

108.84.9 ADVERSE REACTIONS.

Pain swelling, abscess, or ulceration at injection site; periorbital edema, hypersalivation, nasal drip, shivering, lacrimation, diarrhea, vomiting, mental agitation, or depression. Posttreatment vomiting is one of the most consistent side effects. The less toxic dipropionate salt produces hypotension and signs similar to those of organophosphate intoxication when given IV (less with IM), but this reaction can be prevented by prior administration of atropine. Reversal with atropine is recommended. Occasional renal tubular necrosis develops. Dose range of 7-10 mg/kg has been tolerated by dogs but approached toxic levels. Doses of 10 mg/kg cause mild transient tachycardia, and higher dosages may cause premature ventricular tachycardia. Elevations of serum ALT and AST are observed proportional to dosages used as a result of hepatic necrosis. Hepatic vacuolization occurs at therapeutic IV dosage and consistent at overdosages of 20 mg/kg; massive fatal hepatic necrosis after very high (60 mg/kg) accidental overdosage (Ch 71, ref. 42). Inflammatory reactions in muscle or skin causing lameness or dermatitis, respectively, can be prevented by deep IM injection in lumbar muscle. Oncogenesis at high dosages in rats. To report adverse reaction in the U.S., call 1-800-224-5318.

108.84.10 INTERACTIONS.

For *Babesia*, synergistic with one injection of diminazene 24 hr later. Potentiates organophosphate toxicity as a result of inherent anticholinesterase activity. Should not be used simultaneously with exposure to cholinesterase-inhibiting substances.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Parenteral solution	12% solution multidose vial (120 mg/ml) in 10-ml sterile vials	<i>Forray-65</i> (Hoechst Marion Roussel), <i>Imizol</i> (Schering-Plough Animal Health) AgriVet

108.84.11 INTERNATIONAL PREPARATIONS.

Carbesia.

108.84.12 HANDLING.

Store between 2–25°C away from light.

108.84.13 ADMINISTRATION.

Follow CBC up to 12-20 weeks to monitor response to therapy.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage			
INDICATIONS	DOSE (mg/kg)	ROUTE	REPEAT INOCULATION (days)
Dogs			
Ehrlichiosis	5.0	IM, SC	14–21
	5.0	IM, SC	84
Babesiosis	5.0–6.6 ^a	IM, SC	14
	7.5	IM, SC	None
Cats			
Cytauxzoonosis	5.0	IM	7

^a Higher dose from product insert, Schering-Plough.

108.84.1 ADDITIONAL DOSAGES.

Ehrlichiosis, [Table 28-4](#); cytauxzoonosis, [Table 76-1](#); babesiosis, [Table 77-3](#).

108.85 IMIPENEM-CILASTATIN SODIUM

108.85.1 CLASS.

Imipenem is a β -lactam of the carbapenem group. It is used in a 1 : 1 ratio with cilastatin, an inhibitor of renal dehydropeptidase-1 that degrades cilastatin. Meropenem, a newer carbapenem, does not require cilastatin coadministration.

108.85.2 ACTION.

Bactericidal; imipenem inhibits synthesis of bacterial cell wall peptidoglycan.

108.85.3 MORE INFORMATION.

See [Chapter 34](#); [Table 34-1](#).

108.85.4 PHARMACOKINETICS.

Poorly absorbed from GI tract, but good systemic availability (75% of IV) after IM administration. Imipenem degradation by renal tubular enzyme is inhibited by cilastatin, which increases urine concentration of active drug and reduces potential nephrotoxicity from metabolites. Most of the drug is renally excreted. Penetrates all tissues and fluid compartments, including aqueous humor. Concentrations in CSF with inflamed and normal meninges are lower than in other tissues and body fluids, with the lowest levels in CSF, vitreous, placenta, milk. In pharmacokinetic studies in dogs, 5 mg/kg IV, IM, and SC had similar area-under-curve values. The MIC for *Escherichia coli* was exceeded for at least 4 hr. [Ch 34](#), ref. 18a.

1264

Infectious Diseases of the Dog and Cat, 3rd Edition

1265

108.85.5 SPECTRUM.

Very broad antibacterial activity. Resistant to most bacterial β -lactamases. **Gram positive:** *Staphylococcus*, some *Streptococcus*, including *S. viridans*, *Listeria*, *Nocardia*, some *Enterococcus* (not methicillin-resistant strains). **Gram negative:** most gram-negatives, *Escherichia*, *Klebsiella*, *Pseudomonas*, *Citrobacter*, *Enterobacter*, *Serratia*. Resistance to *Pseudomonas* can develop during use. **Anaerobes:** *Bacteroides*, *Fusobacterium*, *Peptostreptococcus*. **Others:** *Mycobacterium avium-intracellulare* complex. **More effective:** widest spectrum of any single antibacterial, little if any cross-resistance to penicillins or cephalosporins.

108.85.6 INDICATIONS.

Bowel ruptures, skin infections, abscesses, cellulitis, wounds, endometritis, lower respiratory tract infections. Single, mixed, and resistant gram-negative bacterial infections. Intraabdominal and genital infections caused by both gram-negative and anaerobic bacteria. May replace combined therapy with aminoglycoside or cephalosporin plus metronidazole or clindamycin. Good for lower respiratory tract infections, bacterial meningitis, bacteremia, sepsis caused by resistant organisms. IM route for less severe infections in soft tissue.

108.85.7 APPROVED USES.

Serious and multiple-resistant bacterial infections when a single agent is needed.

108.85.8 CONTRAINDICATIONS.

Severe or life-threatening infections, including bacterial sepsis, endocarditis, or shock. The dosage should be reduced in renal failure. Not determined whether safe for pregnant animals. Cross-hypersensitivity to penicillins.

108.85.9 ADVERSE REACTIONS.

Allergic reactions to vehicle, treat as anaphylaxis with epinephrine, oxygen, airway management, glucocorticoids. IV preparation may produce phlebitis, pain, erythema at injection site. In people, systemic signs during infusion have been nausea, diarrhea, vomiting, fever, hypotension, seizures, dizziness, urticaria. All β -lactams can cause seizures if underlying brain disease or if overdosed related to body size and renal function. Laboratory alterations include increased bilirubin, hepatic transaminases, hyponatremia, azotemia, thrombocytosis or thrombocytopenia, eosinophilia. The IM product contains lidocaine hydrochloride, which is contraindicated with known hypersensitivity, with shock, or heart block.

108.85.10 INTERACTIONS.

Antagonistic interaction may reduce effectiveness of this drug coadministered with other β -lactam drugs or chloramphenicol. Addition of aminoglycosides or trimethoprim-sulfonamide may be synergistic against certain organisms.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection as 1:1 combination with cilastatin	250 mg, 500 mg, in vials and bottles for IV 500 mg and 750 mg for IM (suspension)	<i>Primaxin</i> (Merck) <i>Primaxin I.M.</i>

108.85.11 INTERNATIONAL PREPARATIONS.

Tenacid, Tienam, Tracix, Zienam.

108.85.12 HANDLING.

Store powder at refrigerated or controlled room temperature. For IV, dilute contents into at least 100 ml of appropriate infusion solution (0.9% NaCl, 5% dextrose, sodium bicarbonate, mannitol [2.5-10%], and KCl [0.15%]). Maintains potency for 4-10 hr at room temperature 24-48 hr if refrigerated; the longer time periods are with 0.9% NaCl diluent. Never freeze. Give by intermittent IV infusion over 20-60 min. Do not mix with other drugs. For IM, solutions reconstitute with 1% lidocaine (without epinephrine); should be used within 1 hr.

108.85.13 ADMINISTRATION.

For IM, use a 21-gauge needle and deep injection. Aspirate before injection to avoid inadvertent IV administration. Absorption following SC and IM administration is comparable with IV and may be more convenient.

Dosage				
INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Tissue infections	3.0-7.5	IV, IM, SC	4-6	3-5
Sepsis, more resistant organism	5	IV	4 ^a	3-5

a Multidrug-resistant bacteria may require dosing every 2 hr to achieve and maintain therapeutic concentrations (Ch 34, ref. 18a).

108.85.14 ADDITIONAL DOSAGES.

Gram-negative bacterial infections, Table 37-3; endotoxemia, Table 38-6; nocardiosis, Table 49-3; bacteremia and endocarditis, Table 87-6; respiratory infections, Table 88-8; intraabdominal infections, Table 89-21.

1265

108.86 INTERFERON- α (IFN- α , HUMAN RECOMBINANT)

1266

108.86.1 CLASS.

Cytokine produced by recombinant means to match human protein. The 2a and 2b forms differ in the sequence of two amino acids and purification.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.86.2 ACTION.

Acts on terminal stages of virus production by preventing assembly and budding of mature virions, also immunomodulating influences.

108.86.3 MORE INFORMATION.

[Chapter 2](#); [Table 2-3](#); [Ch 2](#), ref. 25, 122, 169; [Appendix 8](#), ref. 3, 4, 7, 9. Previously known as leucocytic or lymphoblastoid interferon.

108.86.4 PHARMACOKINETICS.

Low-dose oral: (1-30 U) possibly stimulates oropharyngeal tonsils locally, not much absorbed systemically as destroyed by gastric acid. **High-dose parenteral:** SC (1.6×10^6 U/kg) resulted in plasma concentration measurable for 8 hr. Well absorbed after SC or IM injection. After IV injection, the drug is distributed primarily to liver and kidneys, with lesser amounts in thyroid, spleen, and GI mucosae. Filtered at renal glomerulus, catabolized by kidneys, and excreted in urine. At lower dosage concentrations of IFN- α (10^5 U/kg), the neutralizing antibody titers that develop (see later) were proportionally lower than those at the high dosages.

108.86.5 SPECTRUM.

Many viruses, immunostimulant.

108.86.6 INDICATIONS.

Oral: adjunct to alleviate clinical manifestations of ill FeLV—infected cats suffering from immunosuppressive (not neoplastic) effects of FeLV. It may prolong cat's well-being and associated survival time. Stimulates appetite. Does *not* affect viremia but may have some effect on virus-induced myelosuppression. Use only in ill FeLV-positive cats. Can be tried in cats with FIV or chronic upper respiratory tract disease or dogs with systemic mycotic infections as an adjunct to antifungal therapy. There has been subjective improvement in these situations but no controlled studies. **Parenteral:** may decrease retroviral viremia for limited periods. Use of recombinant human IFN parenterally can induce neutralizing antibody, which interferes with activity after several weeks. Cats receiving high doses (10^6 U/cat) for 21 days had neutralizing antibody titers develop and therapeutic refractoriness ([Ch 2](#), ref. 179; 180). Cats receiving high dose (10^6 U/cat) had reduced lymphocyte blastogenesis compared with those receiving 10^4 or 10^2 U/kg, which had enhanced lymphocyte activity ([Ch 2](#), ref. 171). Not routinely recommended for parenteral use in animals for these reasons. Low-dose oral is the preferred method of administration. Low doses (1-30 U/cat) given orally have been used in milder cases of noneffusive FIP, when it may help suppress disease progression ([Appendix 8](#), ref. 7). High doses ($>2 \times 10^4$ U/kg) given IM have been used as an immunomodulator in conjunction with glucocorticoids to treat effusive FIP ([Appendix 8](#), ref. 7). **Intralesional:** for viral papillomatosis in people; might be tried for these lesions in dogs ([Chapter 9](#)) and cats ([Chapter 20](#)). **Topical:** used in eye in conjunction with topical antiviral drugs in cats with chronic herpesvirus keratitis and conjunctivitis ([Ch 2](#), ref. 141). See [Chapter 93](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.86.7 APPROVED USES.

In people for various malignancies and viral diseases.

108.86.8 CONTRAINDICATIONS.

Limited efficacy of high-dose parenteral human interferon in cats because of neutralizing antibodies ([Ch 2](#), ref. 180). May become refractory 3-7 weeks after initiating treatment. PO, topical, or intralesional treatment does not induce this refractoriness.

108.86.9 ADVERSE REACTIONS.

Parenteral: in cats, allergic reactions, fever, lethargy, myalgia, myelotoxicity; in people, also neurotoxicity, hepatotoxicity. **Oral, intralesional, topical:** none.

108.86.10 INTERACTIONS.

Unknown.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Interferon- α_{2a} solution or powder for injection	3, 6, 36×10^6 U vials	<i>RoferonA</i> (Roche)
	Interferon- α_{2b} powder for injection	3, 5, 10, 18, 25, 50×10^6 U vials	<i>IntronA</i> (Schering-Plough Animal Health)
	Interferon- α_n solution for injection	5×10^6 U vials	<i>AlferonN</i> (Purdue Frederick)

108.86.11 HANDLING.

For 3-U/ml solution: make 1 : 100 dilution of commercial solution (3×10^6 U/ml) using sterile water giving 3×10^4 U/ml. Take 0.1 ml and add to 1 L of 0.9% NaCl containing 4 ml of 25% serum albumin (albumin is optional but adds stability at low concentrations). Package 3 U/ml solution in 15-ml aliquots in sterile injection vials and store frozen (-70°C desirable). Thaw vials as needed, then store refrigerated for administration. Discard unused portion 60 days after first using refrigerated solution. Discard unused 3×10^4 U/ml solution within 2-3 hr after making initial dilutions. **For 30-U/ml solution:** dilute entire contents of commercial solution (3×10^6 U/ml) into 1 L sterile IV fluid bag containing saline to give a solution of 3000 U/ml. This can be divided in 1- or 10-ml aliquots and frozen. The commercial solution or 3000-U/ml solution can be frozen for years without losing activity. The 3000-U/ml solution (1 ml or 10 ml, respectively) can be added to 100 ml sterile saline or to a 1 L IV fluid bag to produce either 100 or 1000 ml of 30-U/ml solution for administration ([Appendix 8](#), ref. 7). Some have advised aliquoting the diluted solution into 1 ml volumes for freezing up to 1 yr. Then the aliquots are defrosted as needed. Once they are defrosted, the drug can be kept refrigerated up to 1 week. Freezing the most dilute solutions is associated with loss in activity unless protein such as albumin is added during dilution. To get a concentration of 10^4 IU/ml, dilute a 1×10^6 IU vial of interferon into 99 ml sterile saline and divide into 1-ml doses and freeze. For 10^5 IU/ml, use 9 ml saline and proceed as above.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.86.12 ADMINISTRATION.

Oral: for 3 U/ml solution, remove 0.3 ml (1 U) using sterile needle and 1.0-ml syringe. For 30 U/ml, remove 1-ml solution. Remove needle from hub and squirt dose into the oral cavity once each day of treatment. If syringes are reused, a short reusable rubber or plastic catheter segment may aid in keeping syringe from contacting oral mucosae to help preserve sterility of 15- or 30-ml refrigerated aliquots. **Parenteral:** not recommended because it stimulates antibody formation. **Intralesional:** into papillomas, inject 1×10^6 μ /0.1 ml into up to five warts three times/week until regression occurs. **Topical ocular:** Same diluted preparation for oral use can be used by applying in drops to the eye 3-4 times daily.

1266

1267

Dosage					
INDICATIONS	DOSE	UNITS	ROUTE	INTERVAL (hr)	DURATION (days)
Cat					
FeLV and appetite stimulation	1 ^a	U/cat	PO	24	7 ^b
	30	U/cat	PO	24	7 ^c
Viral respiratory disease	10×10^6	U/kg	SC	21	≤ 21
FIP exudative (wet)	2×10^4	U/kg	IM	24	14-21
FIP nonexudative (dry)	30	U/cat	PO	24	7 ^c
Dog					
Immunosuppression	1	U/5kg	PO	24	7 [†]

a Although daily doses of 30U have been recommended ([Appendix 8](#), ref. 7), other studies with FeLV-infected cats have shown 1U to be superior to 5U ([Ch 2](#), ref. 25).

b Treat alternate weeks or continuously ([Ch 2](#), ref. 25).

c Treat alternate weeks ([Appendix 8](#), ref. 7).

108.86.13 ADDITIONAL DOSAGES.

FIP, [Table 11-4](#).

108.86.14 DISPENSING INFORMATION.

Keep medication refrigerated and discard unused portions after 60 days. Use a short catheter on the end of the syringe to keep it from becoming contaminated with oral bacteria. This treatment will not reverse the FeLV-positive status of the cat but may improve appetite, general attitude, health.

108.87 INTERFERON- β_{1B} , - β_{1A} (IFN- β , HUMAN RECOMBINANT)

108.87.1 CLASS.

Polypeptide cytokine from fibroblasts. Produced by recombinant DNA methods.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.87.2 ACTION.

Antiviral and immunoregulatory.

108.87.3 MORE INFORMATION.

Previously known as fibroblast interferon. See [Chapter 2](#), Antivirals and Immunotherapy. Reference: [Appendix 8](#), ref. 2.

108.87.4 PHARMACOKINETICS.

Not detectable in blood or tissues after SC administration. Bioavailability is 50% with SC use. After IV use, reaches low levels in blood with rapid clearance.

108.87.5 INDICATIONS.

In people for treatment of multiple sclerosis at time of first demyelinating event. Prevents or suppresses progression of disease. Used in immunosuppressed people with AIDS from HIV infection, myelogenous or metastatic neoplasia, some viral hepatitis. No immediate uses in dogs and cats but might be considered in similar disorders. For dogs, demyelinating canine distemper encephalomyelitis might be a potential use. For cats might consider it in retroviral infections.

108.87.6 CONTRAINDICATIONS.

Pregnancy, leukopenia, anemia.

108.87.7 ADVERSE REACTIONS.

In people similar to IFN- α : myelosuppression, fever, chills, myalgia, photosensitivity, systemic allergic reactions, abortion.

108.87.8 INTERACTIONS.

Decreased clearance of AZT given currently.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human- β_{1b}	Powder for injection	0.3 mg (9.6MIU) contains human albumin	<i>Betaseron</i> (Berlex)
Human- β_{1a}	Powder for injection	44 mg 6.6MIU	<i>Rebif</i> (Serono) <i>Avonex</i> (Bogen)

108.87.9 HANDLING.

Powder should be stored refrigerated. Inject sterile 0.9% NaCl into vial to dissolve drug. After reconstituting solution is 0.25 mg/ml. Only good for single use once reconstituted. Refrigerate, do not freeze if not used immediately.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.87.10 ADMINISTRATION.

Injected SC.

Dosage					
INDICATIONS	DOSE	UNITS	ROUTE	INTERVAL (hr)	DURATION (YEARS)
Antiviral, Immunoregulation					
Human ($-\beta_{1b}$)	0.25	mg (8MIU)	SC	48	≤ 2
Human ($-\beta_{1a}$)					
Multiple sclerosis	30	mg	IM	168	3

108.87.11 ADDITIONAL DOSAGES.

None.

1267

108.88 INTERFERON- γ_{1B} (IFN- γ , HUMAN RECOMBINANT)

1268

108.88.1 CLASS.

Polypeptide lymphokine with antiviral, immunomodulatory, and antiproliferative effects.

108.88.2 ACTION.

Biologic response modifier, potent phagocyte- activating effects potentiate killing of intracellular organisms such as virulent *Staphylococcus*, *Toxoplasma*, *Leishmania*, *Listeria*, *Mycobacterium avium-intracellulare* complex.

108.88.3 MORE INFORMATION.

Previously known as immune interferon. [Chapter 2](#); references: [Ch 2](#), ref. 38a.

108.88.4 PHARMACOKINETICS.

Absorbed slowly after IM or SC administration. Rapid clearance after IV use. Slower elimination and high bioavailability (89%) makes SC use desirable.

108.88.5 SPECTRUM.

Immunostimulating for defense against persistent intracellular organisms. Some dose relationship; higher dosages were associated with improved efficacy. Has been effective in experimental animal infections of toxoplasmosis, *Pneumocystis carinii* pneumonia, cryptosporidiosis ([Ch 71](#), ref. 76). Similar experiments were favorable for fungal infections such as histoplasmosis, coccidioidomycosis, candidiasis, aspergillosis, and cryptococcosis. Has been combined with Amphotericin B treatment to treat experimental CNS cryptococcosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.88.6 INDICATIONS.

Immunodeficiency caused by neutrophil phagocyte defects. Helps prevent infection.

108.88.7 CONTRAINDICATIONS.

Pregnancy, leukopenia, thrombocytopenia.

108.88.8 ADVERSE REACTIONS.

In people, CNS signs of mental depression and gait dysfunction, myelosuppression, abortion. Because these compounds are species specific, antibody might develop with chronic use in dogs and cats and limit effectiveness.

108.88.9 INTERACTIONS.

May be synergistic with concurrent antimicrobial chemotherapy such as roxithromycin, trimethoprim-sulfonamide, sodium stilboglucanate.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Solution for injection	100 mg (3×10^6 U)/0.5 ml	Actimmune (Genentech)

108.88.10 HANDLING.

No preservatives in vial; must be for single dose; keep refrigerated 2–8°C. Must be discarded if left unrefrigerated >12 hr.

108.88.11 ADMINISTRATION.

Drug is given SC. Liquid should be gently mixed but not shaken and should not be discolored or contain particulate matter.

Dosage				
INDICATIONS (Human)	DOSE	ROUTE	INTERVAL	DURATION (days)
Body surface >0.5 m ²	50 mg/m ²	SC	3 × weekly	prn
Body surface <0.5 m ²	1.5 mg/kg	SC	3 × weekly	prn

108.88.12 ADDITIONAL DOSAGES.

None.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.89.1 INTERFERON- ω (IFN- ω , IFN- ω , FELINE RECOMBINANT)

108.89.1 CLASS.

Cytokine produced by recombinant means to match the feline protein. It is produced in silkworms by a recombinant baculovirus expression system (Ch 2, ref. 159). Omega interferon is a type I interferon related to alpha interferon.

108.89.2 ACTION.

Does not act directly or specifically on the virus, but predominantly on virus-infected cells, by an inhibition of mRNA and translation proteins. May nonspecifically enhance immune defenses. Acts on the cell to inhibit the internal synthesis mechanism of terminal stages of virus production by preventing assembly and budding of mature virions.

108.89.3 MORE INFORMATION.

Chapters 2 and 8, References (Ch 8, ref. 15; 66; 44; 60; Ch 13, ref. 49a) www.virbagenomega.com.

108.89.4 PHARMACOKINETICS.

Parenteral: Similar to human interferons. After injection it is bound to specific receptors of a large variety of cells. The drug is distributed primarily to liver and kidneys. Filtered at renal glomerulus, catabolized by kidneys, and excreted in urine (Ch 2, ref. 158).

108.89.5 SPECTRUM.

Acts to suppress infection by many viruses. May be acting as an immunostimulant.

108.89.6 INDICATIONS.

Parenteral: may decrease viremia for limited periods. Use of this recombinant heterologous IFN parenterally in dogs may induce neutralizing antibody, which interferes with activity after several weeks.

108.89.7 APPROVED USES.

In dogs for the reduction of mortality and clinical signs from parvovirus infection. Animals should be older than 1 mo. In cats as adjunctive therapy for clinical illness associated with FeLV and or FIV infection. In addition to IFN, other forms of adjunctive therapy should be used for the disease being treated.

108.89.8 CONTRAINDICATIONS.

Prior or repeated use may theoretically interfere with activity due to the production of antibody to the heterologous protein. In long-term use, cats do not develop antibodies like dogs, which reduces activity with

Infectious Diseases of the Dog and Cat, 3rd Edition

time. Safety in pregnancy and lactation has not been determined. Animals should not be vaccinated during the course of interferon therapy.

1268

108.89.9 ADVERSE REACTIONS.

1269

No severe adverse signs have been reported in dogs or cats given this interferon. In dogs transient fever may be seen 3-6 hr after injection and WBC, erythrocyte, and platelet counts may be suppressed for 1 week. Overdose (10-fold) has caused mild lethargy, increased body temperature, increased respiratory rate, sinus tachycardia, which resolve within 7 days.

108.89.10 INTERACTIONS.

Never mix with any other IV preparation except supplied diluent.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Canine and feline	Interferon- ω lyophilized powder for injection with saline diluent	5 and 10 $\times 10^6$ U vials	<i>VirbagenOmega</i> (Virbac) ^a

a In the United States, it can be obtained for compassionate use through private vendors overseas (e.g., Abbeyvet.com), after obtaining FDA approval for importation.

108.89.11 HANDLING.

The product must be used immediately after reconstitution due to the lack of preservative. Store and transport at 4°C. Do not freeze. Stability is 2 yr. The freeze-dried fraction must be reconstituted with the specific solvent supplied.

108.89.12 ADMINISTRATION.

Parenteral: Reconstituted product is injected IV, once daily for 3-5 consecutive days. It should be given in conjunction with other supportive care for the infection being treated.

Dosage					
INDICATIONS	DOSE	UNITS	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs and Cats					
Parvoviral or acute viral infections	2.5	Million U/kg	IV, SC	24	3
Cats					
Feline leukemia or immunodeficiency virus infections, caliciviral gingivostomatitis or chronic viral infections	1	Million U/kg	SC	24	5 ^a

a For FeLV or FIV is given on day 0-4 and has been repeated on days 14-18 and 60-64 ([Ch 13](#), ref. 49a).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.89.13 ADDITIONAL DOSAGES.

See [Chapter 2](#) for those used in specific studies.

108.89.14 DISPENSING INFORMATION.

Product should be reconstituted and administered only with provided solvent. Vaccination of treated dogs is contraindicated until the animal recovers clinically.

108.90.1 IODIDE (POTASSIUM AND SODIUM)

108.90.1 CLASS.

Inorganic halogen.

108.90.2 ACTION.

Antifungal but exact mechanism uncertain. May facilitate phagocytic killing of fungal cells.

108.90.3 MORE INFORMATION.

[Chapter 57](#); [Chapter 63](#).

108.90.4 PHARMACOKINETICS.

Unknown.

108.90.5 SPECTRUM.

Sporothrix, *Basidiobolus*.

108.90.6 INDICATIONS.

Sporotrichosis, some treatment failures occur. Preferred for dogs owing to good clinical response and low toxicity. Has been effective in some cases of subcutaneous phycomycosis in people. Trials are being conducted on rhinosporidiosis.

108.90.7 APPROVED USES.

Antithyroidal agent, sporotrichosis, expectorant.

108.90.8 CONTRAINDICATIONS.

Hyperthyroidism, iodide hypersensitivity, renal failure, dehydration, pregnancy.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.90.9 ADVERSE REACTIONS.

Cats often develop toxic signs of iodism, including vomiting, anorexia, muscle twitching, cardiomyopathy, heart failure, death. Enteric-coated tablets have caused bowel ulceration in people. Prolonged use has caused hypothyroidism, goiter, thyroid adenomas, and dermatitis in people.

108.90.10 INTERACTIONS.

Concurrent use with other potassium-containing medications can cause hyperkalemia.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human KI	Oral solution	1gKI/ml (300/ml bottle)	SSKI (Upsher-Smith), generic (many)
	Oral syrup (black raspberry flavor)	325 mg/5 ml	Pima Syrup (Fleming)
Veterinary, NaI	Parenteral solution	200 mg/ml	Sodium Iodide (ProLabs, Vet Tek, Lextron, RXV)
KI, Potassium iodide; NaI, sodium iodide.			

1269

108.90.11 HANDLING.

Can produce saturated solution of KI in lieu of commercial preparations or 20% NaI solutions (200 mg/ml). Parenteral NaI solutions listed contain only water. If commercial KI or NaI solutions are used, they should not contain other ingredients intended as expectorants.

1270

108.90.12 ADMINISTRATION.

For accuracy, always aspirate dose in graduated 1-ml syringes. Always administer by placing drops directly on food to decrease GI irritation. Continue for at least 1 mo beyond clinical cure.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Sporotrichosis	40	PO	8	≥60
Cats				
Sporotrichosis	20	PO	12–24	≥60

108.90.13 ADDITIONAL DOSAGES.

Drug therapy for sporotrichosis, [Table 63-1](#).

108.90.14 DISPENSING INFORMATION.

Administer by placing liquid on animal's food or give orally immediately after feeding. Report any loss of appetite or other signs to veterinarian.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.91.1 IODOQUINOL

108.91.1 CLASS.

8-hydroxyquinoline; also called diiodohydroxyquin.

108.91.2 ACTION.

Antibacterial, antifungal, and antiprotozoal.

108.91.3 MORE INFORMATION.

See elsewhere, Clioquinol (Moebiquin, Vioform); [Chapter 71](#); [Table 71-1](#).

108.91.4 PHARMACOKINETICS.

Poorly absorbed (8%) from GI tract, high concentration in intestinal lumen. Will only treat luminal and not systemic spread.

108.91.5 SPECTRUM.

Entamoeba, *Balantidium*, yeasts. Acts strictly in the gut lumen.

108.91.6 INDICATIONS.

Intraluminal treatment of intestinal amebiasis and balantidiasis. Topical antifungal.

108.91.7 APPROVED USES.

Human amebiasis.

108.91.8 CONTRAINDICATIONS.

Not effective with extraintestinal (hepatic) amebiasis. Do not use in animals with neurologic, renal, or liver impairment or pre-existing thyroid dysfunction.

108.91.9 ADVERSE REACTIONS.

Dermatologic eruption, enlarged thyroids, vomiting, diarrhea; optic nerve or peripheral neuropathy after prolonged use at high dosages. Neurotoxicity found in dogs treated with 5 g of a 3% clioquinol topical preparation for 28 days. Causes discoloration of tongue, urine, feces. Oral use of this drug and Clioquinol is restricted because of neurotoxicity.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.91.10 INTERACTIONS.

Interferes with thyroid testing as a result of iodination.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	210 mg, 650 mg	<i>Yodoxin</i> (Glenwood)
	Oral powder	25g	<i>Yodoxin</i>

108.91.11 INTERNATIONAL PREPARATIONS.

Diodoquin, Direxiode, Floraquin, Sebaquin.

108.91.12 HANDLING.

Insoluble in water and minimally in alcohol. For smaller doses, tablets must be crushed or powder placed on moist food.

108.91.13 ADMINISTRATION.

Topical use of this drug as an antifungal has been toxic to dogs.

108.91.14 DOSAGE.

Not recommended for routine use in small animals. Amebiasis is uncommon in dogs and cats.

1270

108.92 IPRONIDAZOLE

1271

108.92.1 CLASS.

Nitroimidazole.

108.92.2 ACTION.

See METRONIDAZOLE.

108.92.3 MORE INFORMATION.

See METRONIDAZOLE, TINIDAZOLE.

108.92.4 SPECTRUM.

Giardia, Trichomonas.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.92.5 INDICATIONS.

Used in veterinary medicine to treat blackhead in turkeys. For giardiasis, when added to drinking water in kennel dogs.

108.92.6 CONTRAINDICATIONS.

Pregnancy.

108.92.7 ADVERSE REACTIONS.

Not noted, although mutagenesis is possible.

108.92.8 INTERACTIONS.

See METRONIDAZOLE.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Available as feed/water additive for turkeys ^a	Unknown	<i>Ipropran</i> (Roche)

a Not available in the USA.

108.92.9 ADMINISTRATION.

Mix desired amount in drinking water. Do not give other sources of water until dose is finished.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Dogs</i>	126–378 mg/L	In water	24	7–14

108.92.10 ADDITIONAL DOSAGES.

None.

108.93 ISONIAZID (INH)

108.93.1 CLASS.

Hydrazide: isonicotinic acid hydrazide.

108.93.2 ACTION.

Interferes with nucleic acid and lipid biosynthesis in bacteria.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.93.3 MORE INFORMATION.

[Chapter 34](#); [Chapter 50](#); [Table 50-4](#); reference: [Ch 34](#), ref. 395.

108.93.4 PHARMACOKINETICS.

Rapid and completely absorbed after PO administration. All formulations are well absorbed. Inactivated in liver and 85% of unchanged drug and metabolites are excreted in urine. Portion metabolized by acetylation and excreted in urine; 50%-70% excreted unchanged.

108.93.5 SPECTRUM.

Mycobacterium.

108.93.6 INDICATIONS.

M. tuberculosis or *M. bovis* infections.

108.93.7 APPROVED USES.

Human mycobacteriosis.

108.93.8 CONTRAINDICATIONS.

Reduce dose in hepatic dysfunction and in severe renal failure.

108.93.9 ADVERSE REACTIONS.

Vomiting; hepatotoxicity Elevated enzymes, bilirubin, hepatic necrosis; peripheral neuropathy in people. Vitamin B₆ (pyridoxine) deficiency, which in dogs causes recurrent tonic clonic seizures followed by salivation, diarrhea, vomiting, incoordination, cardiac arrhythmias ([Ch 34](#), ref. 395). To treat accidental overdosage, 50 mg/kg or more of pyridoxine hydrochloride at a gram-for-gram dose equal to the amount ingested as a 5%-10% total wt/vol IV infusion over 30-60 min. A bolus if in status epilepticus. Additional anticonvulsants diazepam and phenobarbital as needed.

108.93.10 INTERACTIONS.

Reduces levels of ketoconazole. Increases levels of benzodiazepines, diphenylhydantoin, hepatotoxicity enhanced with halothane, rifampin. Glucocorticoids decrease its effectiveness.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	50 mg, 100 mg, 300 mg	<i>Laniazid</i> (Ciba), generics (various)
	Parenteral injection	100 mg/ml	<i>Nydrazid</i> (Apothecon)

1271

Infectious Diseases of the Dog and Cat, 3rd Edition

1272

108.93.11 INTERNATIONAL PREPARATIONS.

Cemidon, Dipasic, Inapsade, Isotamine, Isozid, Laniazid, Nicazide, Nicotibine, Nydrasid, Pyreazid, Rimifon, Tibinide.

108.93.12 HANDLING.

Store in airtight and light-proof containers. Incompatible with sugars. Sterilize solution by autoclaving.

108.93.13 ADMINISTRATION.

A 10-mg/ml suspension can be prepared by using 12 100-mg tablets, distilled water to dissolve, and adding aqueous 50% sorbitol to bring the volume to 120 ml. This should be refrigerated and is stable for 3 weeks. Shake well before using. Always use in combination with other antimycobacterial drugs.

Aluminum-containing compounds interfere with absorption. Administer on empty stomach.

Dosage				
INDICATIONS (Dogs)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Tuberculosis	10 mg/kg	PO	24	prn

108.93.14 ADDITIONAL DOSAGES.

Mycobacterial Infections, [Table 50-4](#).

108.93.15 DISPENSING INFORMATION.

Give for 3-6 mo after cytologic or culture data suggest cure. Usual treatment is at least 6 mo.

108.94.1 TRACONAZOLE

108.94.1 CLASS.

Synthetic triazole antifungal.

108.94.2 ACTION.

Inhibits cytochrome P-450 14 α -demethylase preventing ergosterol synthesis in fungal cell membrane. It binds weakly to mammalian P-450. Greater potency and less toxicity than ketoconazole, presumably due to its triazole structure.

108.94.3 MORE INFORMATION.

See KETOCONAZOLE, FLUCONAZOLE, CLOTRIMAZOLE; [Chapter 57](#), Azoles; [Table 57-1](#); references: [Ch 57](#), ref. 9; 92; 44; 19; 33 [Ch 63](#), ref. 51.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.94.4 PHARMACOKINETICS.

Oral absorption of itraconazole (ITZ) is similar in dogs and people ([Ch 57](#), ref. 148a). **Capsules:** Variable GI absorption of capsules. PO bioavailability 40% with fasting but increases when given with food. Increased stomach acidity (low pH) increases absorption while alkalinity decreases absorption. Capsules can be opened, and a fraction of the dose can be mixed in the food. Variable in some cats requiring higher doses (10 mg/kg) for better efficacy. **Oral suspension** containing cyclodextrin is better (30% greater) absorbed with fasting and may exert some topical oral antifungal effects. Experimentally, oral dose of 5 mg/kg to cats is equivalent to 0.75-1 mg/kg IV or 1.25-1.5 mg/kg of oral solution because of the low bioavailability of oral capsules ([Ch 57](#), ref. 9). Compared to capsules oral solution may be more efficacious on a per milligram basis in cats. Unlike capsules, bioavailability of oral solution is higher under fasted conditions. Drug is highly lipophilic and keratinophilic. Once absorbed, highly (>99%) protein bound to albumin. Extensively distributed into lipophilic tissues: concentrations in liver, kidney, adrenals, lung, and fat at least twice (2-20 times) that in blood. In skin, concentrations may be 3-10 times plasma. Reaches stratum corneum by secretion in sebum. Most of the drug is bound to keratin and persists in skin up to 2-4 weeks after treatment is discontinued. Does not penetrate well into CSF, saliva, aqueous humor. However, it has been used to treat animals with fungal meningitis and ophthalmitis due to inflamed barriers. Fluconazole penetrates better in these areas. Therapeutic concentrations maintained longer in tissues than plasma. Oral formulations require 14-21 days to reach steady state in dogs and cats ([Ch 57](#), ref. 9). Drug concentrations increase after several weeks of therapy. They are three to five times higher compared with single dosing after 2 weeks of treatment of dogs and 21 days in cats. **IV formulation** achieves adequate blood levels consistently and more rapidly with a predicted bioavailability. This parenteral formulation achieves steady state within a short time period of 2-7 days in people ([Ch 57](#), ref. 14). Hepatotoxicity may be seen in 10% of dogs owing to inordinately high serum concentrations that develop. Primarily metabolized in liver with predominant biliary and lesser urinary excretion of inactive metabolites. Low activity in the urinary tract makes it unsuitable for treatment of urinary tract infections.

108.94.5 SPECTRUM.

Blastomyces, *Histoplasma*, *Cryptococcus*, *Coccidioides*, *Aspergillus*. **Variable activity:** *Trichophyton*, *Candida*, *Sporothrix*, *Acanthamoeba*, *Malassezia*, *Microsporum*, *Pythium*. Broader and more potent in vivo than ketoconazole. **Others:** *Acanthamoeba*, *Trypanosoma*.

108.94.6 INDICATIONS.

Fungal: blastomycosis, histoplasmosis, aspergillosis, coccidioidomycosis, candidiasis, cryptococcosis, sporotrichosis, fungal keratitis, zygomycosis, chromomycosis, onychomycosis. Also effective in some cases of dermatophytosis when griseofulvin was not effective or has caused toxicity. Cutaneous and systemic sporotrichosis least toxic and most effective, although expensive. Nasal, disseminated, and meningeal cryptococcosis. Poor to variable efficacy in nasal and disseminated aspergillosis and no additive effect to that produced by topical enilconazole alone. **Protozoal:** Acanthamebiasis not involving the CNS, cutaneous leishmaniasis. No need to adjust dose in renal insufficiency, unlike fluconazole ([Ch 57](#), ref. 57).

108.94.7 APPROVED USES.

Human systemic fungal infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.94.8 CONTRAINDICATIONS.

Hepatic disease or insufficiency. Must reduce if used with hepatic disease or dysfunction. Dosage does not need modification in renal failure. Teratogenic and embryotoxic effects have been seen at high dosages in lab animals, so should avoid in pregnancy and lactation.

108.94.9 ADVERSE REACTIONS.

Vomiting, diarrhea, abdominal pain, inappetence, increased serum liver enzymes and urea, peripheral edema, fever, hypertension, skin rash and ulcerations (Ch 57, ref. 38). Less hepatotoxic than ketoconazole and unlike ketoconazole, does not affect adrenal or reproductive steroid synthesis. Nausea, anorexia, vomiting, hepatic injury, increased serum ALT are more common in cats; anorexia is associated with increased ALT and serum alkaline phosphatase. ALT decreases after drug is stopped for 1-2 weeks or until appetite returns or serum hepatic enzymes return toward reference levels; then treatment can be restarted at 50% dose or alternate days. Monitor serum hepatic enzyme activity every 2 weeks thereafter. Serious hepatotoxicity leads to icterus and death (Ch 57, ref. 38; 92). Hepatotoxicity and death occurred in one cat given 27.8 mg/kg/day for several weeks. High doses can produce hypokalemia. Ulcerative dermatitis (cutaneous vasculitis) and hepatotoxicity occur more in dogs receiving higher (10 mg/kg) daily dosages. It subsides if dosage is stopped or reduced to 5 mg/kg once daily (see ITZ, Adverse Effects, Chapter 57). Generalized cutaneous drug eruption was observed in one dog (Ch 57, ref. 107)

1272

1273

108.94.10 INTERACTIONS.

Do not coadminister with ketoconazole, cisapride, terfenadine; fatal cardiac arrhythmias may occur. Absorption decreased with concurrent antacids (H₂ receptor antagonists, or proton pump blockers) or any disease raising gastric pH. Prolongs effects and increases toxicity of benzodiazepines (midazolam), cyclosporine, glucocorticoids, antihistamines, quinidine, digoxin, vincristine, warfarin, sulfonyleureas. H₂-receptor antagonists (cimetidine), diphenylhydantoin, itraconazole, rifampin, or terfenadine. Phenobarbital, which stimulates P-450 metabolism, decreases efficacy of itraconazole. May interfere with the efficacy of AMB when used in combination or succession (Ch 57, ref. 129). For blood levels, send to Fungus Testing Laboratory, University of Texas Health Science Center, 7703 Floyd Curl Dr, San Antonio, TX 78284; (210) 567-4131.

108.94.11 AVAILABILITY.

100-mg bead-containing capsules must be split or formulated for cats and small dogs before use. Expensive, which may limit use. PO suspension available, and injectable solution. Oral suspension has greater bioavailability than capsules.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules	100 mg	<i>Sporanox</i> (Janssen)
	Oral suspension (containing cyclodextrin)	10 mg/ml in 150 ml bottle	<i>Sporanox</i> (Janssen)
	IV solution in	10 mg/ml in 25 ml ampules;	<i>Sporanox</i> (Ortho Biotech)
	hydroxypropyl- β -cyclodextrin	50 ml bags	

Infectious Diseases of the Dog and Cat, 3rd Edition

108.94.12 INTERNATIONAL PREPARATIONS.

Beltop.

108.94.13 HANDLING.

Store capsules at room temperature and protected from light and moisture. Solution should be stored at room temperature and protected from freezing. The compounded preparations should be refrigerated and discarded after 35 days. Before availability of the commercially available solution, compounded liquid preparations were made, as follows, from capsules based on the manufacturer's recommendation. **Oral syrup:** a small amount of oral suspension can be made from capsules for cats and small dogs. Six 100-mg capsules are placed into glass mortar. Add 1.25 ml of 95% ethyl alcohol USP and let it stand 3 min to soften. Grind into a paste and let dry. Add 4 ml of corn syrup and transfer to 15-ml bottle. Continue to add up to 15-ml of syrup to wash the mortar and transfer it to the bottle. The final concentration is 40 mg/ml. It is stable refrigerated for 35 days. Should be shaken well before using and given with food. **Oral liquid:** each capsule can be dissolved in 2 ml of 0.2 N HCl. After 15 min, 20 ml of cranberry juice (pH < 2) is added. The final concentration (mg/ml) is total number of capsules × 100 divided by the total ml of juice used. Stable for 30 days when refrigerated. Shake well before use. **Oral suspension:** Commercially available in lieu of compounding of oral syrup or liquid forms.

108.94.14 ADMINISTRATION.

Minimum administration interval for any infection is 4-6 weeks. Minimum treatment interval of blastomycosis often ranges 2-6 months. Treatment of more resistant or "walled-off" systemic mycosis may require 10 mo or more. To achieve a higher steady state in rapidly advancing mycosis, consider initial higher loading dose followed by a lower maintenance level. For sporotrichosis in humans, treatment lasts 3-18 mo. Treatment for dermatophytosis is at least 1 week beyond clinical and mycologic cure ([Ch 57](#), ref. 95). Preadminister amphotericin B with rapidly progressive life-threatening infections. Increasing gastric acid secretion improves absorption. Administration of capsules with or immediately after a meal improves absorption. Note, however, the solution should be administered on an *empty* stomach. Monitor serum ALT monthly since it often increases in cats after 60 days of instituting therapy. Dogs seem less sensitive to the hepatotoxic effects than cats. Anorexia or increased ALT is managed by reducing or discontinuing the dosage. If toxicity develops at any dose, reinstitute dose at 50% after the adverse signs have abated. The capsules containing beads can be emptied and separated to smaller gelatin capsules or placed directly on food. For young kittens with dermatophytosis, can use 10 beads/day placed on food. Some concentration of itraconazole can be measured to ensure therapeutic level (≥ 2 µg/ml) is being achieved. Measured by Fungus Testing Laboratory, University of Texas, Health Science Center, 7703 Floyd Care Dr, San Antonio, TX 78284; (210) 567-4131.

108.94.15 PULSE DOSING.

Because ITZ accumulates in keratin, superficial infections (skin, nails or hair) may be treated with pulse therapy. Pulse doses in cats with dermatophytosis were 1-2 consecutive week treatment periods per month for a 3 month period ([Ch 57](#), ref. 88). Lower dosages than appear in the table below (1.5-3 mg/kg/day, for 15 days) were used in that study, where 50% of the cats improved; however, no control cats were compared to determine if spontaneous recovery was possible. Continuous pulse therapy has also been reported to be successful at doses listed in the table ([Ch 57](#), ref. 19). A dosage of 5 mg/kg/day for 1 week on an alternate

Infectious Diseases of the Dog and Cat, 3rd Edition

week basis during a 6-week period has also been effective for treatment of cutaneous mycoses, according to the manufacturer. In another study, administration of itraconazole for 2 consecutive days each week for 3 weeks was compared to 21-consecutive day administration in the treatment of *Malassezia* dermatitis and otitis in dogs (Ch 57, ref. 105). The pulse dosing was as effective as continuous therapy in reducing yeast numbers. This type of pulse dosing has been recommended for maintenance therapy for long-term treatment of other fungal infections.

1273

1274

Dosage ^a				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Systemic blastomycosis	5 mg/kg	PO	24 ^b	≥60 ^c
Ocular or CNS blastomycosis, cryptococcosis, histoplasmosis, nasal aspergillosis	5 mg/kg	PO	12	≥60 ^c
Sporotrichosis	7.3 mg/kg	PO	24	35 ^d
	10 mg/kg	PO	24	≥60 ^c
Sporotrichosis, <i>Malassezia</i> infections	5–10 mg/kg	PO	12–24	^e
Cats				
Dermatophytosis	10 mg/kg	PO	24	28–70 ^f
Histoplasmosis, Blastomycosis	5–10 mg/kg	PO	12	60–130 days ^g
Phaeohyphomycosis	20 mg/kg	PO	24	120 days ^h
Sporotrichosis	5 mg/kg	PO	12–24	^e
Cryptococcosis (<3.2kg weight)	50 mg/cat	PO	24	ⁱ
Cryptococcosis (≥3.2kg weight)	100 mg/cat	PO	24	ⁱ

a Dosages listed are for oral capsules. The bioavailability of the oral solution is better (approximately 2 mg solution equals 5 mg capsule) and the dosages may be reduced with the oral solution.

b Sometimes a loading dose of 5 mg/kg given every 12 hr, or 10 mg/kg given every 24 hr is used for the first 3–4 days of treatment to achieve a more rapid steady state of drug concentration in tissues.

c Continue therapy for at least 60 days after clinical recovery.

d Ch 63, ref. 51.

e Continue therapy for at least 30 days after clinical recovery.

f Some clear in 4–8 weeks; others take 6–10 weeks. One regimen involves this dose daily for 28 days (followed by 1-week on and 1-week off therapy) was reported to cure infected animals in 56–70 days (Ch 57, ref. 94a).

g If relapse, may need a second course. Time for treatment may vary; however the usual duration is listed here.

h Therapy was effective in treating a cat that did not respond to 10 mg/kg PO for 60 days (Ch 57, ref. 113a).

i For 8 weeks after clinical recovery.

108.94.16 ADDITIONAL DOSAGES.

Dermatophytosis, Table 58-5; blastomycosis, Table 59-1; histoplasmosis, Table 60-1; cryptococcosis, Table 61-5; coccidioidomycosis, Table 62-3; sporotrichosis, Table 63-1; nasal aspergillosis, Table 64-1;

Infectious Diseases of the Dog and Cat, 3rd Edition

disseminated aspergillosis, [Table 64-3](#); candidiasis, [Table 65-4](#); trichosporosis, [Table 66-1](#); protothecosis, [Table 69-1](#); fungal otitis, [Table 85-6](#).

108.94.17 DISPENSING INFORMATION.

Capsules should be given with food to improve absorption and reduce GI side effects. If achlorhydria is present, give drug with an acidic beverage such as carbonated cola. For cats, owners can mix small beads within 100-mg capsule with 1/2 to 1 teaspoon of soft food to a sausage shape on a plate, or aluminum foil, to be placed in freezer. This can be cut into appropriate amount for individual daily dosage. Most cats or dogs will readily eat this. **Oral solution** should be given *without* food, and dosage can be 25%-50% of that listed because of inherently better absorption. The drug should be given 2 hr before drugs are used that reduce gastric acidity. Recheck clinical signs and renal/hepatic tests at 2 weeks, monthly for 3 mo, and every 3 mo thereafter. **IV solution.** The drug is mixed in an IV bag after reconstitution. It should be stored away from light.

108.95.1 KANAMYCIN

108.95.1 CLASS.

Aminoglycoside.

108.95.2 ACTION.

Bactericidal; inhibits bacterial protein synthesis.

108.95.3 MORE INFORMATION.

See GENTAMICIN; [Chapter 34](#); [Table 34-5](#).

108.95.4 PHARMACOKINETICS.

See GENTAMICIN. For PO therapy, most of the dose is not absorbed and acts locally.

108.95.5 SPECTRUM.

Gram positive: Some *Staphylococcus*, *Listeria*. **Gram negative:** *Escherichia*, *Proteus*, *Salmonella*, *Citrobacter*. Similar to gentamicin except poor against *Pseudomonas*. **Anaerobes:** ineffective. **Ineffective:** *Pseudomonas*, inconsistent against *Staphylococcus*.

108.95.6 INDICATIONS.

Skin, soft tissue, and genitourinary infections caused by *Escherichia*, *Proteus*, *Enterobacter*, *Klebsiella*, *Serratia*, *Salmonella*, *Acinetobacter*, *Mycobacterium avium-intracellulare* complex infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.95.7 CONTRAINDICATIONS.

See GENTAMICIN; avoid or reduce dosage in renal failure.

108.95.8 ADVERSE REACTIONS.

Ototoxicity and nephrotoxicity. See GENTAMICIN. Pain and muscle injury after repeated IM injection.

108.95.9 INTERACTIONS.

See GENTAMICIN.

1274

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Solution for injection	250 mg/ml	<i>Kantrex</i> (Bristol-Myers Squibb), generic (various)
Veterinary	Solution for injection	50 mg/ml, 200 mg/ml	<i>Kantrim</i> (Fort Dodge)
		50 mg/ml	<i>Amiglyde-V</i> (Fort Dodge)
	Oral solution for enteric therapy (with bismuth and absorbent)	100 mg/5 ml	<i>Amforol</i> (Fort Dodge)
	Oral tablets for enteric therapy (with bismuth and absorbents)	100 mg	<i>Amforol</i>

1275

108.95.10 INTERNATIONAL PREPARATIONS.

Kamycine, Kanamytrex, Kanescin, Kannasyn, Kemicina.

108.95.11 HANDLING.

Can be diluted in 0.9% NaCl or 5% dextrose.

108.95.12 ADMINISTRATION.

For IV, do not mix with other antibacterials. Give as dilute solution over 1 hr. For IM, deep injection into large muscle. Can be given as aerosol by nebulization: add 250 mg to 3 ml 0.9% NaCl and put in nebulizer chamber. Repeat two to four times daily. Monitor for renal dysfunction and neurologic signs. Treat urinary infection until asymptomatic and culture results are negative. After 3 days of no response, re-evaluate treatment. Maximum treatment period is 10 days.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days) ^a
Dogs				
Skin, soft tissue infection	10–15	SC, IM	24	7
Genitourinary infection	10	SC, IM	24	7–10
Systemic infection	15	SC	24	7
Enteric only infection	5	PO	8	<5
Cats				
Soft tissue, systemic infection	5.5–8	IM, SC	24	<7

^a Must closely monitor renal function during treatment.

108.95.12 ADDITIONAL DOSAGES.

Plague, [Table 47-1](#); respiratory infections, [Table 88-8](#).

108.96 KETOCONAZOLE

108.96.1 CLASS.

Imidazole antifungal.

108.96.2 ACTION.

Antifungal; impairs ergosterol synthesis in fungal cell wall.

108.96.3 MORE INFORMATION.

See ITRACONAZOLE, FLUCONAZOLE, VORICONAZOLE; [Chapter 57](#); [Table 57-1](#).

108.96.4 PHARMACOKINETICS.

In fasted dogs ketoconazole (KTZ) tablets have highly variable (4%-89%) absorption from the GI tract. Acid environment, fats, and smaller amounts of food generally enhance absorption. Never give drug with co-administered antacids or H₂ blockers. Widely distributed in tissues with highest concentrations of drug reaching the liver, kidney, pituitary, adrenals. Highly protein bound (>84%) but reaches urine, saliva, milk, sweat, ceruminous secretions. CSF concentrations are minimal: dosages of 40 mg/kg/day are required for measurable amounts in CSF, although even then these levels are unpredictable. Higher dosages (>10 mg/kg/day) are similarly needed to reach tissue levels in the testes and intraocular tissues. Metabolized by liver to inactive metabolites, with majority excreted in bile and feces. Very low (3%-4%) amounts reach the urine unmetabolized. Reaches the stratum corneum by excretion in excretions of sebum. May require 10-14 days of treatment to reach steady state and effective therapeutic tissue concentrations.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.96.5 SPECTRUM.

Fungi: *Blastomyces*, *Candida*, *Histoplasma*, *Paracoccidioides*, *Coccidioides*, *Trichophyton*, *Microsporium*, *Malassezia*, *Phialophora*. **Others:** *Leishmania*.

108.96.6 INDICATIONS.

Antifungal: Localized or disseminated candidiasis, systemic mycoses: blastomycosis, histoplasmosis, coccidioidomycosis, cryptococcosis. Less effective against aspergillus or sporotrichosis. In rapidly progressing systemic mycoses, treat with amphotericin B first or 1 week of high-dose itraconazole. High (often toxic) doses of KTZ required for CNS mycoses. For dermatophytes resistant to topical therapy; but griseofulvin or itraconazole are preferred for feline dermatophytosis. Not a first choice if CNS or ocular involvement. In more resistant canine nasal aspergillosis, may use KTZ combined with topical enilconazole or clotrimazole, but itraconazole or fluconazole preferred (Ch 57, ref. 118). Although KTZ is less expensive, toxicity and treatment failure rates are higher (Ch 57, ref. 117). For sporotrichosis, but more side effects and less effective than itraconazole. Has been used in treatment of leishmaniasis (see Chapter 73). **Other:** High dosages have been used to suppress steroidogenesis in canine hyperadrenocorticism. It has also been used concurrent with cyclosporine to reduce its clearance and required dosage as a cost-saving measure in treatment of perianal fistulas in dogs (Ch 57, ref. 102).

1275

1276

108.96.7 APPROVED USES.

Antifungal for human use. Licensed for dogs in France.

108.96.8 CONTRAINDICATIONS.

Pregnancy or lactation since it is embryotoxic and teratogenic; itraconazole or fluconazole a better choice for CNS, intraocular, or testicular infections. Avoid use in lactating animals. The slow response to therapy has made itraconazole preferred for animals with severe or rapidly progressing mycoses. Avoid in patients with hepatic dysfunction since extensively metabolized by that organ. Avoid in patients with thrombocytopenia or previously recognized hypersensitivity to this drug.

108.96.9 ADVERSE REACTIONS.

Anorexia may be observed within the first 30 days of therapy in some animals. Fever, depression, vomiting, diarrhea, abdominal pain, weight loss, hepatocellular necrosis, thrombocytopenia, occasional nonregenerative anemia, teratogenic in pregnant and mutagenic in nursing animals. Fetal death causing abortion of mummified fetuses and stillbirths has been found in treated bitches. Hepatotoxicity is associated with increased hepatic enzymes, anorexia, vomiting, and/or icterus. Frequently, adverse effects of GI effects and hepatotoxicity necessitate dosage reduction. Signs may be alleviated by reducing the dose 50%, dividing the dose twice daily or alternate days, or administering each dose with food. At clinical dosages (10-30 mg/kg/day), cats are more sensitive to the hepatotoxic effects than are dogs, although the tolerance is individualistic. Reduced production of cortisol and testosterone in dogs at greater than 10-30 mg/kg/day. Only a transient reduction in testosterone in male cats. In people (and potentially in animals) decreased libido, gynecomastia, azoospermia, impotence in males, and suppressed reproductive cycling in females. Pruritus and alopecia when used at high dosages for extended periods in dogs and cats. Lightening of the haircoat owing to loss of guard hairs and more visible

Infectious Diseases of the Dog and Cat, 3rd Edition

undercoat occurs after 3-4 mo of treatment. It resolves when the drug is discontinued or the dosage is reduced. Months of therapy in dogs induces cataract development. Cats most consistently develop dry haircoats and weight loss from reduced appetite.

108.96.10 INTERACTIONS.

Avoid use with mitotane, rifampin, or theophylline owing to KTZ decreasing their activity. Effects of glucocorticoids enhanced due to increased absorption and reduced clearance by enzymatic degradation. Diphenylhydantoin, rifampin, barbiturates, and cyclosporine may increase the metabolism of KTZ. Gastric alkalinizing agents (antacids, H₂ blockers, proton pump inhibitors) and achlorhydria decrease oral absorption. Increases activities of midazolam and diphenylhydantoin and activity and toxicity of cyclosporine. In the case of cyclosporine, KTZ increases the bioavailability and decreases systemic degradation of cyclosporine by decreasing the effective degradative microsomal enzymes in the intestinal cells and liver respectively. Co-administration of KTZ and cyclosporine has been used to lower the dose needed of the latter drug in an attempt to reduce cost of therapy. Midazolam levels were increased in dogs where KTZ was given in combination (Ch 57, ref. 76).

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral tablets, scored	200 mg	<i>Nizoral</i> (Janssen)
	Topical ointment, shampoo, or cream	many	<i>Ketofungal</i> (Janssen)

108.96.11 INTERNATIONAL PREPARATIONS.

Panfungal.

108.96.12 HANDLING.

To make suspension: dissolve or crush 200-mg tablet +0.8 ml 1 N HCl + 3.1 ml water; gives 50 mg/ml concentration. Add this solution to syrup and 13 mg/ml methylcellulose or 2 g/100 ml DMSO (increases odor and dermal penetration) for topical applications. Stable for 6 mo if refrigerated. Shake well before using. Can be formulated for smaller dosage sizes by compounding pharmacies.

108.96.13 ADMINISTRATION.

Monitor serum hepatic enzyme (ALT and ALP) activities, bilirubin, bile acids before and during treatment (at least monthly). Transient subclinical elevations in liver enzymes are tolerated and expected. With significant hepatotoxicity, temporarily discontinue or decrease dosage, go to alternate-day therapy or switch to alternative drugs. Do not give simultaneously with H₂ blockers, anticholinergics, antacids. Space 2 hr between. Treat dermatophyte infections at least 1 mo. Dividing daily dose and giving with small amounts of food help produce an acidic gastric environment favorable to absorption. Higher doses may be used during initial treatment. Once daily therapy may be used because of half life. Once the disease is under control, the dosage can be reduced and therapy continued for months or years if relapse is anticipated.

1276

Infectious Diseases of the Dog and Cat, 3rd Edition

1277

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION
Dogs				
Nasal aspergillosis, candidiasis or dermatomycosis	10 mg/kg	PO	24	6 weeks ^{a,b}
	5 mg/kg	PO	12	2–18 weeks ^{a,b}
Systemic mycosis	10–20 mg/kg	PO	12	2–9 mo ^a
	15–30 mg/kg	PO	24	2–9 mo ^a
Sporotrichosis	15 mg/kg	PO	12	2–4 mo ^a
Malassezia	5–10 mg/kg	PO	24	3 weeks ^c
Cats				
Dermatomycosis	5–10 mg/kg	PO	24	1–9 mo ^{a,d}
Coccidioidomycosis	50 mg/cat	PO	24	9–12 mo ^a
	25–75 mg/cat	PO	12–48	9–12 mo ^a
Sporotrichosis	5–10 mg/kg	PO	12–24	2–4 mo ^a

a This is an expected range of time. Therapy should continue for at least 1 mo beyond last detection of infection.

b Drug is somewhat less effective than itraconazole in treatment of aspergillosis or sporotrichosis.

c Ch 57, ref. 6.

d Cats almost always require systemic treatment for this infection, while topical therapy is often adequate for localized lesions in dogs.

108.96.14 ADDITIONAL DOSAGES.

Dermatophytosis, Table 58-5; histoplasmosis, Table 60-1; cryptococcosis, Table 61-5; coccidioidomycosis, Table 62-3; sporotrichosis, Table 63-1; candidiasis, Table 65-4; trichosporosis, Table 66-1; protozoal infections, Table 71-1; oral infections, Table 89-4.

108.96.15 DISPENSING INFORMATION.

Medication should be given with a meal to facilitate absorption. If vomiting occurs give with a small amount of food. Treating every other day may reduce side effects of nausea if they develop.

108.97 LACTOFERRIN

108.97.1 CLASS.

Protein of bovine origin.

108.97.2 ACTION.

Binds iron, reducing its availability for bacteria.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.97.3 MORE INFORMATION.

See Stomatitis, [Chapter 89](#); reference: [Ch 14](#), ref. 552. See [Chapter 2](#). References [Ch 2](#), ref. 2; 131.

108.97.4 PHARMACOKINETICS.

Used for its local effects in the oral cavity. Applied in oral cavity.

108.97.5 INDICATIONS.

Stomatitis resulting from chronic calicivirus infections, dental disease, secondary to concurrent FeLV and FIV infections.

108.97.6 CONTRAINDICATIONS.

None.

108.97.7 ADVERSE REACTIONS.

None.

108.97.8 INTERACTIONS.

None.

108.97.9 AVAILABILITY.

Must be purchased from chemical suppliers.

108.97.10 HANDLING.

Powder is mixed in solution. Has also been applied dry by brushing directly to lesions ([Ch 2](#), ref. 2).

108.97.11 ADMINISTRATION.

Drug is given by syringe into oral cavity to contact local mucosal surfaces. Soft toothbrush may also be dipped in powder and applied directly to affected areas.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Stomatitis	40 mg/kg solution	PO topically	24	14
	200 mg powder	PO topically	24	14

Infectious Diseases of the Dog and Cat, 3rd Edition

108.97.12 ADDITIONAL DOSAGES.

FIV Infection, [Table 14-6](#).

108.97.13 DISPENSING INFORMATION.

Take specified amount of liquid in syringe and squirt into cat's mouth. Do not mix with food. If applied dry, dip a soft toothbrush in powder and lightly brush on affected areas in the mouth.

1277

108.98 LAMIVUDINE (SEE ANTIVIRAL THERAPY, [CHAPTER 2](#))

1278

108.99 LEVAMISOLE (SEE IMMUNOMODULATORS, [CHAPTER 2](#))

108.100 LINCOMYCIN

108.100.1 CLASS.

Lincosamide.

108.100.2 ACTION.

Bacteriostatic, binds to 50s bacterial ribosomal subunit inhibiting protein synthesis.

108.100.3 MORE INFORMATION.

See CLINDAMYCIN and LINCOMYCIN; [Chapter 34](#).

108.100.4 PHARMACOKINETICS.

Absorption from GI tract is incomplete and further impaired by food. IM or IV administration yields higher blood concentrations. Good tissue penetration except for meninges, where concentrations reach 40% of those in blood, even with meningitis. Concentrates in areas of low pH (e.g., abscesses). Metabolized in liver, unchanged drug and metabolites excreted in milk, bile, feces, urine. Most (77%) of PO dose given to a fasting animal is excreted in the bile, only 14% in urine. When given IM, 38% and 49% are excreted in bile and urine, respectively.

108.100.5 SPECTRUM.

Gram positive: *Staphylococcus*, *Streptococcus*, *Nocardia*, *Corynebacterium*, *Erysipelothrix*. **Gram negative:** poor activity. **Anaerobes:** *Bacteroides*, *Propionibacterium*, *Fusobacterium*, *Peptostreptococcus*, *Peptococcus*, *Clostridium*, *Actinomyces*. **Others:** *Mycoplasma*, *Leptospira*. **More effective:** gram-positive aerobes, obligate anaerobes. **Ineffective:** most gram-negative aerobes, *Enterococcus*, *Mycobacterium*. Bacterial resistance may develop during treatment and usually also involves clindamycin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.100.6 INDICATIONS.

Staphylococcal pyoderma in dogs. Infections caused by gram-positive bacteria involving upper respiratory tract, skin, wound infections, septicemia, abscesses in dogs and cats. Clindamycin is less toxic and better absorbed and may be preferred but is more costly.

108.100.7 APPROVED USES.

Oral preparations for dogs and cats. Parenteral solution for dogs and swine.

108.100.8 CONTRAINDICATIONS.

Malassezia or *Candida* infection or previous hypersensitivity to a lincosamide. Avoid or reduce dose with renal or hepatic dysfunction. In dogs, no problems with breeding performance, during gestation, or with neonates. May cause diarrhea in nursing puppies if dam is being medicated.

108.100.9 ADVERSE REACTIONS.

Diarrhea, occasional vomiting (especially cats), anorexia, polydipsia, polyuria. Slight increases in blood hepatic enzyme activities may occur. IM injections cause local pain, and too-rapid IV infusion may cause hypotension and cardiopulmonary arrest.

108.100.10 INTERACTIONS.

Reduces activity of coadministered erythromycin, enhanced activity of neuromuscular blockers.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Oral tablets	100 mg, 200 mg, 500 mg	<i>Lincocin</i> (Pharmacia & Upjohn)
	Oral liquid (hydrochloride)	50 mg/ml	<i>Lincocin</i> Aquadrops
	Parenteral solution (licensed for swine)	100 mg/ml	<i>Lincocin</i> Sterile Solution

108.100.11 INTERNATIONAL PREPARATIONS.

Albionic, Lincocine, Cillimicina, Cillimycin.

108.100.12 HANDLING.

Store at controlled room temperature (15–30°C). IV solution stable for at least 24 hr when mixed with IV fluids.

108.100.13 ADMINISTRATION.

Ingesta and kaolin-pectin preparations reduce PO absorption. Can be given IM with slight pain or discomfort. For IV, dilute with 5% dextrose or 0.9% saline and give as slow (drip) infusion.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Skin, soft tissue infection	15.4	PO	8	21–42, ^a or 56 ^b

1278

108.100.14 ADDITIONAL DOSAGES.

1279

Rhodococcus equi infection, [Table 35-7](#); canine pyoderma, [Table 85-3](#).

108.100.15 DISPENSING INFORMATION.

Give on empty stomach.

108.101 LINEZOLID

108.101.1 CLASS.

Synthetic antibiotic of the oxazolidinones.

108.101.2 ACTION.

Antibacterial, inhibits initiation process of protein synthesis. Binds to the 23s ribosomal RNA of the 50s subunit, thereby preventing the formation of a functional 70S initiation complex. Works at an earlier and different mechanism from other drugs so that cross-resistance is not a problem. Reversible nonselective inhibition of monamine oxidase.

108.101.3 MORE INFORMATION.

LINEZOLID; [Chapter 34](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.101⁴ PHARMACOKINETICS.

Well absorbed from GI tract (~100%). In people, most of the drug is metabolized by the liver with renal (30%) and fecal (5%) excretion. Can switch from IV to oral therapy with little therapeutic adjustment. In dogs, rapidly absorbed after oral dosing with 95% bioavailability (Ch 34, ref. 346a). Limited protein binding (<35%) and well distributed to most extravascular sites. Circulating and excreted largely unchanged. Renal excretion of parent drug and metabolites is complete by 24-48 hr after a single dose.

108.101⁵ SPECTRUM.

Gram positive: Including certain drug-resistant enterococci (vancomycin-resistant) and staphylococci (methicillin-resistant). Bacteriostatic for enterococci and staphylococci and bactericidal for most streptococci.

108.101⁶ INDICATIONS.

Bacterial infections in people with multidrug resistant gram-positive organisms that are resistant to vancomycin. Since this drug is reserved for restricted treatment in people with highly resistant gram-positive bacterial infections its use in dogs or cats is discouraged.

108.101⁷ APPROVED USES.

Humans: for multidrug resistant infections with gram-positive bacteria. Use should be limited or avoided in animals to help prevent emerging bacterial resistance.

108.101⁸ CONTRAINDICATIONS.

High blood pressure.

108.101⁹ ADVERSE REACTIONS.

Diarrhea, nausea, myelosuppression (leukopenia and thrombocytopenia), neuropathy (Ch 34, ref. 217a). Secondary oral or vaginal candidiasis.

108.101¹⁰ INTERACTIONS.

Related to the MAO inhibitors. Avoid use with adrenergic or serotonergic agents such as dopamine, pseudoephedrine, and serotonin reuptake inhibitors. Avoid foods high in tyramine. When used with these drugs dramatic and potentially dangerous increases in blood pressure can occur.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral suspension, Tablets, Injection	Suspension: 100 mg/5 ml Tablets: 400 mg, 600 mg Injection: 2 mg/ml	Zyvox (Pharmacia & Upjohn)

Infectious Diseases of the Dog and Cat, 3rd Edition

108.101¹¹ HANDLING.

Store in airtight, light-proof containers at controlled room temperature (25°C). Keep away from moisture.

108.101¹² ADMINISTRATION.

Oral suspension makes medication of small animals more convenient.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION(days)
Human				
Resistant bacterial infections	400–600 mg/person ^a	PO	12	14
^a Beagle dogs were given 25 mg/kg, IV or PO, had an elimination half-life of 3.9 or 3.6 hr, respectively. ^{346a}				

108.101¹³ ADDITIONAL DOSAGES.

None.

108.101¹⁴ DISPENSING INFORMATION.

The oral liquid should be gently mixed without shaking before each use.

108.102¹ LYSINE

108.102¹ CLASS.

L-form of an essential amino acid.

108.102² ACTION.

Interferes with arginine use by FHV-1 through either by substitution, competition, or inducing arginase activity.

108.102³ MORE INFORMATION.

Antivirals, [Chapter 2](#); Feline Respiratory Disease, [Chapter 16](#). References [Ch 16](#), ref. 11; 93; 53.

108.102⁴ PHARMACOKINETICS.

Serum levels of L-lysine are increased after oral administration; however those of arginine are minimally affected.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.102.5 SPECTRUM.

Viruses: FHV-1.

108.102.6 INDICATIONS.

For ocular FHV-1 keratitis and conjunctivitis. Reduces the severity of clinical signs of infection.

108.102.7 APPROVED USES.

Available for human use over the counter in drugstores.

108.102.8 CONTRAINDICATIONS.

Hepatic insufficiency. Kittens or pups <6 mo old.

108.102.9 ADVERSE REACTIONS.

Occasional vomiting, diarrhea or inappetence which is controlled by reducing the dose or discontinuing therapy. Dietary restriction of arginine is recommended for people receiving oral lysine; however this is not advised in cats. Cats fed a diet deficient in arginine develop hyperammonemia, vomiting, neurologic signs and potential fatal complications. Pups <6 mo develop toxicities. Heinz body anemia in cats if propylene glycol containing tablets are used.

1279

1280

108.102.10 INTERACTIONS.

Appears safe in addition to regular diet and other medications.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human (Over the counter)	Oral tablets	250, 500 mg tablets	Many
FHV-1, Feline herpesvirus, type 1.			

108.102.11 HANDLING.

Store tablets away from moisture at room temperature (15–30°C). No special precautions for human contact.

108.102.12 ADMINISTRATION.

Tablets are large and must be crushed in moist food or broken into small pieces that can be given directly. Arginine should not be restricted from the diet.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
FHV-1 Ocular Disease	250–500 mg total	PO	12	prn

Infectious Diseases of the Dog and Cat, 3rd Edition

108.102.13 ADDITIONAL DOSAGES.

Feline respiratory disease, [Table 16-2](#).

108.102.14 DISPENSING INFORMATION.

Crush tablets and mix into moist food twice daily. If vomiting, anorexia or diarrhea develop discontinue medication and contact your veterinarian.

108.103.1 FUFENURON

108.103.1 CLASS.

Benzoylphenyl urea, insect growth regulator, acts by inhibiting chitin synthesis.

108.103.2 ACTION.

Interferes with formation of fungal cell wall and insect exoskeleton.

108.103.3 MORE INFORMATION.

Coccidioidomycosis, [Chapter 62](#); Dermatophytosis, Chapter Antifungal chemotherapy; Reference ([Ch 57](#), ref. 7).

108.103.4 PHARMACOKINETICS.

Rapid and complete absorption from the GI tract after PO administration. Highly lipophilic, it enters the adipose, then redistributes back into the blood for approximately 30 days. Concentrates in the milk of lactating dams.

108.103.5 SPECTRUM.

Fungi: *Coccidioides*, *Candida*, Dermatophytes, perhaps other systemic fungi, fleas.

108.103.6 INDICATIONS.

Resistant systemic mycotic infections, alone or in combination with a polyene or azole antifungal drug. Efficacy in treating fungal infections is controversial and has not been shown to be effective in controlled studies. See information under dosage regimens below.

108.103.7 APPROVED USES.

Flea control for dogs and cats, when given on a once monthly basis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.103.8 CONTRAINDICATIONS.

None; appears safe in breeding animals (Ch 57, ref. 125).

108.103.9 ADVERSE REACTIONS.

None at recommended concentrations for fungal infections, which are much higher than flea dosages. Mild anorexia, and occasional increase in hepatic transaminases at supratherapeutic doses (Ch 57, ref. 125).

108.103.10 INTERACTIONS.

Appears safe in combination with other insecticides and does not alter cholinesterase activity.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Oral tablets	Dogs: 45 mg, 90 mg, 204.9 mg, 409.8 mg Cats: 90 mg, 204.9 mg	Program (Novartis)
	Tubes	Cats: Tube containing liquid 133 mg	Program

108.103.11 HANDLING.

Stored at room temperature (15–30°C). No special precautions for human contact.

108.103.12 ADMINISTRATION.

Feeding enhances absorption. Suspension for cats is mixed in a palatable diet.

1280

1281

Dosage (see note on questionable efficacy below) ^a				
INDICATIONS	MINIMUM DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dermatophytosis and other mycoses				
Dogs	80	PO	24	1
Cats —household	50–80	PO	24	1
Cats —cattery	100	PO	24	1
A recommended maintenance dose for flea control was suggested for several months.				
NOTE: Other investigators have not found this treatment to be effective. In these other controlled studies, a dose as high as 133 mg/kg was unable to prevent dermatophytosis in uninfected cats exposed to experimentally infected cats (Ch 57, ref. 23). As with one treatment group in another study, lufenuron given at doses of 60 mg/kg PO given twice at a 1-mo interval in conjunction with topical enilconazole rinses once weekly was not able to control dermatophytosis in a cattery (Ch 57, ref. 47). Fungal cultures became negative in some cats after several weeks and relapses were observed. In another study, cats pretreated with lufenuron at 30–133 mg/kg were no more resistant to challenge with <i>Microsporum canis</i> spores than cats given placebo (Ch 57, ref. 95a). This drug is not recommended for treatment of fungal infections as efficacy in controlled studies is lacking.				

a Efficacy of lufenuron for treatment of fungal infections has not been documented consistently. In uncontrolled studies by one group of investigators (Ch 57, ref. 7; 8), treatment effectiveness was reported; however, the dosage level was found to critical for a favorable response. For dogs, the

Infectious Diseases of the Dog and Cat, 3rd Edition

recommendation was to avoid dividing tablets and to avoid rounding-off to higher dosage. For grouped cats, the entire population was treated at one time and rounding-off to higher dosage was also done by giving entire tube. For treated dogs with dermatophytosis, hair regrowth began 10–11 days after treatment with lesion recovery by 16–25 days. Mycologic recovery preceded this by 6 days. In cats, hair growth occurred after 5–6 days with lesion recovery by 10–15 days. Retreatment was needed after 2 weeks in some cases to prevent reinfection.

108.103¹³ ADDITIONAL DOSAGES.

Coccidioidomycosis, [Table 62-3](#); candidiasis, Table 64-4.

108.103¹⁴ DISPENSING INFORMATION.

Administer in conjunction with a full meal. Tablets or liquid can be placed in small amount of food to ensure it is eaten. For free-fed cats, food must be temporarily withheld to facilitate eating of an entire meal with medication.

108.104¹ MARBOFLOXACIN

108.104¹ CLASS.

Fluoroquinolone.

108.104² ACTION.

Bactericidal; inhibits bacterial DNA gyrase.

108.104³ MORE INFORMATION.

See ENROFLOXACIN; [Chapter 34](#); [Table 34-11](#).

108.104⁴ PHARMACOKINETICS.

Well absorbed from GI tract. Widely distributed in tissues. Concentrations in muscle, liver, kidney, lung, skin are \geq those in blood. Low protein binding occurs. Minimal metabolism (<5% of dose). Renal excretion of 2/3 of dose with therapeutic levels in urine 2-5 days after 4-mg/kg dose. In urine 40% drug excreted unchanged. Liver metabolizes 10%-15% of the drug. Approximately 33% of the dose appears in feces.

Infectious Diseases of the Dog and Cat, 3rd Edition

TISSUE DISTRIBUTION OF MARBOFLOXACIN IN DOGS (Single Oral Dose)^a

Time After Dosing (hr)	2		18		24	
Dosage (mg/kg)	2.5	5.0	2.5	5.0	2.5	5.0
Tissue Concentration (µg/ml)						
Urinary Bladder	4.8	12	2.6	6.0	1.11	1.8

Kidney	7.1	12.7	1.4	2.7	0.9	1.6
Lung	3.0	5.48	0.8	1.45	0.57	1.0
Lymph Node	5.5	8.3	1.3	2.3	1.0	2.03
Muscle	4.1	7.5	1.0	1.8	0.7	1.20
Prostate	5.6	11	1.8	2.7	1.1	2.0
Skin	1.9	3.2	0.41	0.71	0.32	0.46

a Data provided by product insert for marbofloxacin.

108.104.5 SPECTRUM.

Gram positive: *Staphylococcus*, some *Streptococcus*. **Gram negative:** *Escherichia*, *Klebsiella*, *Pseudomonas*, *Proteus*, *Salmonella*, *Serratia*, *Shigella*, *Citrobacter*, *Enterobacter*, *Brucella*, *Pasteurella*. Anaerobes: poor. Others: see ENROFLOXACIN. **More effective:** gram-negative aerobes and facultative anaerobes. **Ineffective:** obligate anaerobes. See ENROFLOXACIN.

108.104.6 INDICATIONS.

See ENROFLOXACIN.

108.104.7 APPROVED USES.

Dog and cat, skin and urinary infections.

1281

108.104.8 CONTRAINDICATIONS.

1282

Has been given at 6 mg/kg for 3 mo to growing dogs. Do not use in growing dogs (<18 mo for large breeds) or growing cats (<16 weeks). Do not need to adjust dosages in renal failure in dogs as pharmacokinetics are not altered (Ch 34, ref. 218).

108.104.9 ADVERSE REACTIONS.

As with other quinolones, See ENROFLOXACIN. Anorexia and vomiting most common; rare reports of polydipsia, diarrhea, tremors, ataxia or seizures in field studies.

108.104.10 INTERACTIONS.

See ENROFLOXACIN.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Oral tablets	80 mg, 20 mg, 5 mg	<i>Marbocyl</i> (Vetoquinol, Lure Cedex, France)
		25 mg, 50 mg, 100 mg, 200 mg tablets	<i>Zeniquin</i> (Pfizer Animal Health, Exton PA)

108.104.11 HANDLING.

Store tablets in airtight, moisture-proof containers at room temperature.

108.104.12 ADMINISTRATION.

See ENROFLOXACIN.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Urinary infections	2	PO	24	10–28
Skin, pyoderma	2–2.5	PO	24	49–213 ^a
Systemic infection	2–4	PO	12	<10
Cats				
Urinary, skin infection	2	PO	24	10–28
<i>Mycoplasma haemofelis</i> infection	2	PO	24	43 ^b
a Ch 85, ref. 22; 115; Ch 34, ref. 172a.				
b Appendix 8, ref. 5 and 6.				

108.104.13 ADDITIONAL DOSAGES.

Enteric bacterial infections, [Table 39-1](#); canine pyoderma, [Table 85-3](#).

108.104.14 DISPENSING INFORMATION.

Can give medicine with food, especially if vomiting is noted.

108.105 MEGLUMINE ANTIMONIATE

108.105.1 CLASS.

Pentavalent antimonial, antiprotozoal.

108.105.2 ACTION.

Antiprotozoal; interferes with glycolysis of *Leishmania*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.105.3 MORE INFORMATION.

See STIBOGLUCONATE; [Chapter 71](#); [Table 71-1](#); references: [Ch 71](#), ref. 27; 92; 94; 5; [Ch 73](#), ref. 84; 205.

108.105.4 PHARMACOKINETICS.

Bioavailability in dogs is 92% after IM and SC injection because polar molecule has limited tissue distribution ([Ch 71](#), ref. 92). High concentrations are reached in skin, spleen, liver in decreasing order. Rapidly eliminated by renal excretion with 80% of dose excreted within 9 hours. Liposomal-encapsulated formulations are being evaluated to reduce side effects ([Ch 71](#), ref. 93). Even with these preparations, repeated dosing may be needed to achieve effective levels in bone marrow ([Ch 71](#), ref. 81). These formulations have delayed uptake following SC compared with IM. Repetitive dosing at 75 mg/kg every 12 hr produced steady-state peak plasma concentrations after 6 days that exceeded a single 100 mg/kg dose ([Ch 71](#), ref. 94).

108.105.5 SPECTRUM.

Leishmania. Resistance to drug may develop during treatment of infected dogs ([Ch 71](#), ref. 27). Parasite strains have been developing resistance and dosage regimens have had to be increased in some regions to effectively treat the clinical signs. Twice daily dosing is often indicated to achieve these aims.

108.105.6 INDICATIONS.

Leishmaniasis.

108.105.7 APPROVED USES.

Humans and dogs for leishmaniasis; not available in U.S.

108.105.8 CONTRAINDICATIONS.

Previous hypersensitivity, hepatic or renal insufficiency, cardiac arrhythmias, leukopenia.

108.105.9 ADVERSE REACTIONS.

Pain, swelling, lameness with IM injection, SC preferred. Thrombophlebitis with IV use. See also STIBOGLUCONATE.

108.105.10 INTERACTIONS.

May combine with allopurinol for increased efficacy.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	N-methylglucamine antimoniate	300 mg/ml as antimony in 5 ml ampules	<i>Glucantime</i> (Merial) ^a

^a Human preparation is available from Rhone Poulenc, Paris, France.

1282

Infectious Diseases of the Dog and Cat, 3rd Edition

1283

108.105.11 HANDLING.

Store solution in sterile container at room temperature.

108.105.12 ADMINISTRATION.

Continue medication until clinical signs or skin lesions have resolved which usually occurs within 1-3 mo. Give by slow IV, deep IM, or by SC or IP. For resistant cases, can give alternate dosing with Pentamidine (*Lomidine*). Treatment involves 10-12 injections in succession if initiated early and 18-20 injections if chronic manifestations (dermatitis) are present. Injections are given 2-3 days apart.

Dosage				
INDICATIONS (Dogs)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Leishmaniasis	100 mg/kg ^a	SC	24	21-30 ^b
	75-100 mg/kg ^a	SC	12	10
Treatments with meglumine alone on a 10-day cycle have lasted for 1-8 mo. Steady state is reached after 6 days reaching therapeutic levels (Ch 71, ref. 94).				

- a Dose has been modified from that on label based on newer clinical information and evidence of drug resistance. Treatment is more effective if meglumine at the above dosages is combined with allopurinol at 15-30 mg/kg every 12 hr. Allopurinol treatment is continued up to 8 mo or longer (Ch 71, ref. 17), see also ALOPURINOL. Meglumine has also been combined with paromomycin where a pharmacokinetic modification of the antimonials delays their excretion allowing for higher blood levels.
- b Prior regimens have been for 10 days on and off; however, treatment is more effective if meglumine is given for at least 30 days.

108.105.13 ADDITIONAL DOSAGES.

Leishmaniasis, Table 73-4.

108.106 MELARSOPROL

108.106.1 CLASS.

Arsenical. It is a melaminophenyl-based organic arsenical initially formed from Melarsen oxide, the trivalent equivalent of Melarsen after incorporation of dimercapol (BAL) and contains 18.8% arsenic. Other names include Mel B, Arsobal, 2-[p-(4,6-diamino-1,3,5-triazin-2ylamino phenyl)-4-hydroxymethyl-1,3,2-dithiarsolan).

108.106.2 ACTION.

Antiprotozoal. Initially used as an anti-trypanosomiasis reagent from 1949 (Ch 72, ref. 21a). Melarsoprol is amphipathic and will diffuse across cellular membranes. The drug is, however, rapidly converted to the highly hydrophilic melarsen oxide in plasma (96% clearance within 1 hr) (Ch 72, ref. 33). Melarsen oxide levels peak

Infectious Diseases of the Dog and Cat, 3rd Edition

within 15 min and has a half-life of 3.9 hr. Only limited quantities of the drug up to 1%-2% of maximum plasma levels cross the blood-brain barrier. This information was used in the experimental treatment of dogs at 2.2 mg/kg/of body weight. Affects *Trypanosoma brucei* parasites after uptake through the P2 transporter (Ch 72, ref. 34). Trypanosomes exposed to arsenicals lyse very rapidly due to a possible loss of ATP due to inhibition of glycolysis caused by the drug in bloodstream forms.

108.106.3 MORE INFORMATION.

See Chapter 72; Table 72-1. References: Ch 71, ref. 10d; 21a; 10c.

108.106.4 SPECTRUM.

African trypanosomes. Drug is reserved for trypanosomiasis control programs.

108.106.5 INDICATIONS.

The response to treatment in trypanosomiasis is usually rapid with mental dullness subsiding within days of the initial treatment.

108.106.6 CONTRAINDICATIONS.

Cross resistance may result due to similar mode of action at the P2 transporter level.

108.106.7 ADVERSE REACTIONS.

The solution is intensely irritating and care should be taken to see that the injections are given strictly IV. Antihistamine (oxomemazine) should be included to counter allergic reactions and irritation at the injection site. A Jarisch-Herxheimer reaction results due to the rapid killing of the parasite. Additional adverse effects relate to the drugs arsenic content. A severe febrile reaction may occur after the first injection in heavily parasitized hosts. The greatest risk is from a reactive encephalopathy and is usually seen between the end of the day 3 or 4 of treatment. Treatment of this encephalopathy involves use of corticosteroids, hypertonic solutions to combat cerebral edema, and anticonvulsants. Other adverse reactions include myelosuppression, hypotension, diarrhea, myocardial damage and hepatic inflammation.

108.106.8 INTERACTIONS.

Should not be used in otherwise ill animals. Severe hemolytic reactions have occurred in human patients with G6PD deficiency. Patients should be hospitalized during treatment.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Solution for injection in propylene glycol	3.6%, 5 ml vial	Mel B, Melarsen, Arsobal (Rhône-Poulenc-Rorer S. Africa) (Specia, France) ^a

^a The drug is no longer marketed actively by the manufacturer.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.106.9 HANDLING.

The drug is presented in ampules as 3.6% solution in propylene glycol. It should be given in a completely dry unused syringe. Glass syringes should be used as the propylene glycol is destructive to plastic. The dry syringe is needed because the solution precipitates in water. When disposable syringes are used the solution should not be prepared in advance.

1283

108.106.10 ADMINISTRATION.

1284

Drug can be given at 2.2 mg/kg. body weight using a dry syringe and needle. The dose can be given in one dose or divided in two doses given at a 24-hr interval. There is a low safety margin as a dosage of 3.6 mg/kg. body weight is lethal.

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
African trypanosomiasis	2.2	IV	24	10

108.106.11 ADDITIONAL DOSAGES.

None.

108.107 MEROPENEM

108.107.1 CLASS.

Meropenem is a β -lactam of the carbapenem group. As with biapenem and ertapenem, other newer carbapenems of this group, it does not require cilastatin coadministration.

108.107.2 ACTION.

Bactericidal; ertapenem inhibits synthesis of bacterial cell wall peptidoglycan. As other carbapenems, this drug is relatively resistant to hydrolysis by β -lactamases.

108.107.3 MORE INFORMATION.

See penicillins, [Chapter 34](#).

108.107.4 PHARMACOKINETICS.

Available for humans. Poorly absorbed from GI tract, but good systemic availability if given parenterally. It is poorly protein bound and, as a result, has a short elimination half-life of approximately 1 hr in people. The drug is generally eliminated from the body by 6 hr after administration. Approximately 60%-80% is excreted in the urine unchanged, the rest as inactive metabolites. Plasma clearance correlates with creatinine clearance.

Infectious Diseases of the Dog and Cat, 3rd Edition

In dogs, plasma elimination half-life was 45 min with >90% being excreted in the urine within 24 hr (Ch 34, ref. 152b).

108.107⁵ SPECTRUM.

Broad-spectrum carbapenem antibacterial drug. It is bactericidal by interfering with cell-wall synthesis. Readily penetrates the cell wall of most gram-positive and gram-negative bacteria to reach penicillin-binding protein receptors. **Gram positive:** streptococci susceptible to penicillin. **Gram negative:** *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*. **Anaerobes:** *Bacteroides fragilis*, *Peptostreptococcus* spp. See imipenem-cilastatin for further bacterial susceptibility data for this class of drugs.

108.107⁶ INDICATIONS.

For treatment of organisms resistant to other antibiotics and for mixed infections that require a broad spectrum including anaerobes. For treatment of intraabdominal or meningeal infections. Restricted use in animals is recommended to avoid bacterial resistance.

108.107⁷ APPROVED USES.

Serious and multiple drug-resistant bacterial intraabdominal infections and bacterial meningitis.

108.107⁸ CONTRAINDICATIONS.

The dosage should be reduced in renal failure. Dosage adjustments are not likely with hepatic impairment. Cross-hypersensitivity to other β -lactams. No complications have been observed in human or animal pregnancy; however, only clear indications should permit its use during this period.

108.107⁹ ADVERSE REACTIONS.

Diarrhea, vomiting, increased hepatic aminotransferase activities, and thrombophlebitis. Allergic reactions to vehicle, treat as anaphylaxis. All β -lactams can cause seizures if underlying brain disease or if overdosed related to body size and renal function. As with other β -lactams, monitor renal, hepatic, and hematopoietic systems during treatment.

108.107¹⁰ INTERACTIONS.

Antagonistic interaction may reduce effectiveness of this drug coadministered with other β -lactam drugs. Co-administration of drugs such as probenecid, which competes for active renal excretion, will increase the drug concentrations posing potential toxicity. Dose must be reduced in renal failure.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for IV injection	500 mg and 1gm vials	Merrem IV (Zeneca)

108.107¹¹ INTERNATIONAL PREPARATIONS.

Same.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.107.12 HANDLING.

Supplied as a powder, soluble in water and 0.9% NaCl. Stable in this solution for up to 4 hr at 15–25°C. Reduce dosage in renal failure. Give over at least 15-30 min as an infusion. Do not mix with solutions containing any other drugs.

108.107.13 ADMINISTRATION.

Administer over 15-30 min ideally or for smaller doses as a bolus injection over 3-5 min.

Dosage				
INDICATIONS (Dogs and Cats) ^a	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Bacteremia/sepsis	24 mg/kg	IV	24	prn
	12 mg/kg	SC	8	prn
Urinary infections	12 mg/kg	SC	12	prn
CNS infections ^a	40 mg/kg	IV or SC	8	prn

a This is an extrapolated dose for children, and maximum dose per administration is 2gm. To help prevent development of resistant strains that might infect humans, use should be limited or avoided unless ultimately necessary.

1284

108.107.14 ADDITIONAL DOSAGES.

1285

None.

108.108 METHENAMINE MANDELATE (OR HIPPPURATE)

108.108.1 CLASS.

Urinary antiseptic.

108.108.2 ACTION.

Produces acid urine, which is bacteriostatic.

108.108.3 MORE INFORMATION.

[Chapter 34.](#)

108.108.4 PHARMACOKINETICS.

Readily absorbed from GI tract but 10%-30% destroyed by gastric acid unless enteric-coated tablets are used. Minimal blood or tissue levels but enters placenta and milk. Excreted (>90%) in urine within 24 hr. In acid

Infectious Diseases of the Dog and Cat, 3rd Edition

urine, methenamine is hydrolyzed to ammonia and formaldehyde. The acid salts (mandelate and hippurate) help lower urine pH. Co-administration of acids (e.g., ascorbate) may help maintain low urine pH.

108.108.5 SPECTRUM.

Gram positive: *Staphylococcus*, *Enterococcus*. **Gram negative:** *Escherichia*. **Ineffective:** in alkaline urine or against *Enterobacter* and other urea-splitting organisms (*Proteus*, *Pseudomonas*), which raise urine pH.

108.108.6 INDICATIONS.

Chronic or recurrent urinary tract infections for long-term suppression/elimination of infection. Do not use in place of appropriate antimicrobial therapy to eliminate infection. Must eliminate infection by urea-splitting bacteria to allow methenamine to be effective. Only choice in predisposed animals in which anatomic causes cannot be eliminated.

108.108.7 APPROVED USES.

Human: urinary infections.

108.108.8 CONTRAINDICATIONS.

Pregnancy, lactation, renal or hepatic insufficiency (because of ammonia loading). Use of sulfonamides. Drug itself is not toxic in renal failure; organic acids it produces may be detrimental with mandelate; crystals may form in renal failure.

108.108.9 ADVERSE REACTIONS.

Dysuria, bladder irritation, increased serum hepatic transaminases, vomiting, oral irritation.

108.108.10 INTERACTIONS.

Urinary alkalinizing agents reduce effectiveness. Co-administration with sulfonamides may induce crystalluria and renal tubular damage in some species, but, because of unique sulfonamide metabolism, dogs are usually not affected. Drug combines with sulfonamides in urine, which results in mutual ineffectiveness of the drugs.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	1g (as hippurate)	<i>Hiprex</i> (Marion Merrell Dow), <i>Urex</i> (3M Pharmaceuticals)
	Oral tablets	500 mg (as mandelate)	<i>Mandelamine</i> (Parke-Davis), Generic (various)
	Oral suspension	500 mg/5 ml (as mandelate)	Generic (various)

108.108.11 HANDLING.

Store at room temperature and avoid contact with acids or metallic salts.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.108.13 ADMINISTRATION.

Offer animal free choice water. Give with meals to reduce GI irritation. Also available in combinations with other antimicrobials, pH reducers, urinary analgesics. Feeding diets that decrease urine pH are additive.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs	16.5 mg/kg	PO	24	prn ^a
a Therapy can be extended for months to suppress bacterial growth.				

108.108.13 ADDITIONAL DOSAGES.

None.

108.108.14 DISPENSING INFORMATION.

Report any GI signs to your veterinarian.

108.109 METRONIDAZOLE

108.109.1 CLASS.

Nitroimidazole.

108.109.2 ACTION.

Bactericidal, also antiprotozoal; penetrates cells by diffusion, metabolized in anaerobic organisms to intermediates that prevent DNA synthesis. Has anti-inflammatory activity reducing neutrophil and lymphocyte functions.

108.109.3 MORE INFORMATION.

See TINIDAZOLE; [Chapters 34](#) and [71](#); references: [Ch 34](#), ref. 268; 275; [Ch 71](#), ref. 18; 60; 20; 83.

108.109.4 PHARMACOKINETICS.

Virtually 100% GI absorption. Food delays systemic availability in people but not in dogs; also absorbed rectally. Good tissue penetration to all sites, including hard-to-reach areas such as brain, bone, placenta, fetal tissues, fluids (CSF, milk, saliva). Higher concentration in prostate than plasma of dog ([Ch 34](#), ref. 275). Penetrates abscesses and pyothorax well. Metabolized in liver with predominantly active metabolites (60%-80%). Excreted mainly in urine and 10%-15% in feces. PO and IV routes give similar blood drug concentrations, but parenteral route is more expensive.

1285

Infectious Diseases of the Dog and Cat, 3rd Edition

1286

108.109⁵ SPECTRUM.

Anaerobic protozoa: *Trichomonas*, *Giardia*, *Entamoeba* (trophozoites), *Balantidium*. **Anaerobic bacteria:** *Bacteroides*, *Veillonella*, *Fusobacterium*, *Peptococcus*, most *Clostridium*, *Eubacterium*, few *Peptostreptococcus*. Alternative choices for anaerobic bacteria are chloramphenicol, clindamycin, cefoxitin. **Others:** *Helicobacter*, oral spirochetes, variable for *Campylobacter*. **More effective:** consistently good against *Bacteroides*. **Ineffective:** *Actinomyces*, yeasts, aerobic bacteria, and aerobic protozoa. Resistance among gram-negative anaerobic bacteria to metronidazole is rare (Ch 41, ref. 26a). Metronidazole resistance is more common among gram-positive anaerobic bacteria, including most *Propionibacterium acnes* and *Actinomyces*, as well as some strains of lactobacilli and anaerobic streptococci.

108.109⁶ INDICATIONS.

Recurrent or persistent anaerobic infections that fail to respond to penicillins, clindamycin, chloramphenicol. Anaerobic infections: intraabdominal, anaerobic meningitis, intracranial abscesses, bacteremia, osteomyelitis, dermatitis, synovitis, soft tissue infections, chronic colitis, intestinal bacterial overgrowth (Ch 34, ref. 268), stomatitis, oral ulceration, tetanus, *Helicobacter*-associated gastritis, bacterial vaginitis, and prophylaxis (with aminoglycosides) for colorectal surgery. Diagnosis of canine “antibiotic responsive enteropathy” and feline inflammatory bowel disease may be considered by a response to therapy. As antiprotozoal, indicated for trichomoniasis, giardiasis, amebiasis, and balantidiasis.

108.109⁷ APPROVED USES.

Human: anaerobic infections and abscesses, gastric helicobacteriosis.

108.109⁸ CONTRAINDICATIONS.

Dose reduction (50%) with liver failure and some reduction with severe renal failure. Reduced dosage for neonates. Avoid in pregnancy because carcinogenic and mutagenic when laboratory rodents given chronic high doses. Benzoate salt must be conjugated in the liver unlike the hydrochloride form; therefore, it should be used with caution in cats, when this pathway is deficient.

108.109⁹ ADVERSE REACTIONS.

Profuse salivation, anorexia, weight loss with PO administration to cats. The benzoate formulation is less likely to cause this problem. Can discolor urine reddish-brown. Vomiting, diarrhea, glossitis, stomatitis. Peripheral neuropathy with long-term use in people. Rarely pancreatitis, reversible mild leukopenia, thrombocytopenia. Long-term use may cause *Candida* overgrowth in GI tract. Treatment for 1 mo decreased aerobic and anaerobic bacterial counts and increased the quantity of *Streptococcus* spp and *Corynebacterium* spp in the duodenum of healthy cats (Ch 71, ref. 39). High dosages IV to cats can cause pancreatitis. Neurologic complications are seizures, encephalopathy, cerebellar dysfunction. Generalized ataxia and vertical positional nystagmus. *Never* exceed 30 mg/kg/day for dogs and cats. CNS toxicity in dogs has resulted with high (≥ 60 mg/kg/day) dosages, often after 7-40 days treatment (Ch 71, ref. 12; 60; 20). Cerebellar and vestibular nuclear injury (Ch 71, ref. 18). Degenerative changes in Purkinje's cells and associated cerebellar and vestibular axons. CNS signs may progress rapidly and develop after acute or chronic overdosage. Signs may take several days to months to resolve, but some dogs develop uncontrollable seizures, fatal

Infectious Diseases of the Dog and Cat, 3rd Edition

encephalopathy, coma. CSF analysis may show increased protein concentration. Treatment of neurotoxicity involves discontinuing the drug and instituting supportive care. Dogs with the toxicosis have recovered quicker when they are treated with diazepam (Ch 71, ref. 20). The range for IV dosing with diazepam is 0.2-0.625 mg/kg, and for oral dosing thereafter is 0.31- 0.69 mg/kg. Dogs treated with diazepam respond in an average of 13 hr and recover in an average time of 38.7 hr, compared to 4.25 days response time and 11.6 days recovery time in untreated dogs. Diazepam may competitively reverse the binding of metronidazole to the benzodiazepine site on GABA receptors in the CNS.

108.109.10 INTERACTIONS.

Barbiturates may alter metabolism, reducing metronidazole's therapeutic efficacy. Potentiates vitamin K antagonist rodenticides. Cimetidine may increase its concentration and enhance toxicity, whereas phenobarbital and diphenylhydantoin may decrease it. May interfere with measurement of serum triglycerides or some hepatic enzymes. In people, has been given in combination with tetracycline or amoxicillin and bismuth subsalicylate tablets to treat *Helicobacter*-associated gastritis and ulcers (see Chapter 39). Clarithromycin has been substituted for metronidazole when resistance is suspected. In some countries, metronidazole is available combined with spiramycin for treatment of mixed aerobic and anaerobic infections such as stomatitis, abscesses, genital and cutaneous infections. See SPIRAMYCIN.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	250 mg, 500 mg	<i>Flagyl</i> 500 mg (Searle), generic (various)
	Oral solution as benzoate	25 mg/ml of base	PCCA, Houston TX
	Powder for injection	500 mg (as HCl)	<i>Flagyl</i> IV (SCS Pharmaceuticals)
	Solution for injection	500 mg	<i>Flagyl</i> IV, <i>Metronidazole Redi-Infusion</i> (Elkins-Sinn)
Veterinary	Solution for injection	5 mg/ml	<i>Torgyl</i> (Merial)

In U.S., only HCl salt is approved. It is unpalatable. Benzoate salt, available in Europe and Mexico, is more palatable to animals. Dose of HCl must be multiplied by 1.6 to convert to the benzoate because of the larger molecular weight of the benzoate.

108.109.11 INTERNATIONAL PREPARATIONS.

Abbonidazole, Acuzole, Anabact, Anaerobex, Anaeromet, Arilin, Ascacea, Bemetrazole, Clinazole, Elyzol, Metrazole, Metrogyl, Metrolyl, Metronide, Metrostat, Metrozol, Metryl, Narobic, Nidazol, Oecozol, Pharmaflex, Protostat, Rathimed, Rozex, Trichozole, Triacide, Zagyl, Stomorgyl (combined with *Spiramycin*).

108.109.12 HANDLING.

Store tablets and powders in airtight, light-resistant containers. IV solution can be diluted with 0.9% NaCl or bacteriostatic water for injection, and further diluted in lactated Ringer's, 0.9% NaCl, or 5% dextrose. The pH is low (0.5-2), so before infusion add 5 mmol sodium bicarbonate for each 500 mg used to raise pH to 6-7. CO₂ bubbles may form during this, and the pressure needs an outlet. The neutralized solution should not be refrigerated, or precipitates may form. It must be used in 24 hr. If not neutralized, it is stable for 96 hr at room temperature. Should not contact aluminum (including needles), or solution may discolor to reddish-brown. Can be mixed in solutions with most aminoglycosides, cephalosporins, and penicillins. Protect from exposure to light. Refrigerated or concentrated (>8 mg/ml) solutions will precipitate.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.109.13 ADMINISTRATION.

1286

When possible, preferably give whole coated tablets to cats to reduce oral contact with bitter drug. Has a metallic taste that is distasteful to cats. Generic tablets can be crushed and powder placed in syrup gum, tragacanth, or melted butter to improve palatability. See administration of ITRACONAZOLE for details on mixing with butter. Can be formulated for smaller doses by compounding pharmacies. This drug is less palatable to cats than furazolidone for giardiasis, and there is risk of neurotoxicity at higher dosages (Ch 71, ref. 18). Can be given with food, and in dogs, absorption is enhanced. When using the drug IV, the lower end of the dosage range should be used and the drug should be infused over 30 min.

1287

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Giardiasis, trichomoniasis	30–50 mg/kg	PO	24	5–7
Stomatitis, colitis, helicobacteriosis	10–15 mg/kg	PO	12	10
	20 mg/kg	PO	24	10
Stomatitis, soft tissue infection	7.5 mg/kg	PO	8	10
Systemic bacteremia, meningitis	10 mg/kg	PO, IV	8	14
Cats				
Giardiasis, trichomoniasis	10–30 mg/kg	PO	24	5
	8–10 mg/kg	PO	12	10
	250 mg/cat	PO	24	5–7
	25 mg/kg ^a	PO	12	7
Helicobacteriosis, bacterial overgrowth	15–20 mg/kg	PO	12	prn
Anaerobic bacteremia meningitis	10 mg/kg	PO, IV	8	prn
Soft tissue infection	7.5 mg/kg	PO	8–12	prn

^a Base formulation equivalent to 40 mg benzoate. At this dose, treatment was effective in cats that failed to respond to 50 mg/kg daily PO fenbendazole for 5 days (Ch 71, ref. 83).

108.109.14 ADDITIONAL DOSAGES.

FIV infection, Table 14-5; enteric bacterial infections, Table 39-2; gastric helicobacteriosis, Table 39-6; *Clostridium perfringens* diarrhea, Table 39-10; anaerobic infections, Table 41-12; tetanus, Table 43-2; feline abscesses, Table 52-3; enteric protozoal infections, Table 78-3; bacteremia and endocarditis, Table 87-6; oral infections, Table 89-4; gastrointestinal infections, Table 89-16; colitis, Table 89-19; intraabdominal infections, Table 89-21; hepatobiliary infections, Table 90-5; CNS infections, Table 92-5.

108.109.15 DISPENSING INFORMATION.

Has an unpleasant metallic taste. May cause excessive salivation if tablets are bitten; do not crush or break. May darken urine color. May cause GI upset; take with food.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.110.1 MILTEFOSINE (PHOSPHOCHOLINE, OLEYL-PC, HEXADECYLPHOSPHOCHOLINE)

108.110.1 CLASS.

Alkyl phosphocholine (ether-lipid) analogue.

108.110.2 ACTION.

Antiprotozoal against *Leishmania* and *Trypanosoma*. Closely related miltefosine was developed as an antitumor agent; however, it was ineffective for that purpose. These hemoflagellates have similar lipids on their surfaces and this drug interferes with synthesis of these lipids.

108.110.3 MORE INFORMATION.

See [Chapter 71](#), [Table 71-1](#); References [Ch 71](#), ref. 90; 5; 87; 75.

108.110.4 SPECTRUM.

Leishmania, *Trypanosoma*.

108.110.5 INDICATIONS.

The first oral treatment for leishmaniasis. Possible choice for resistant leishmaniasis, alternative for trypanosomiasis. Should avoid miltefosine and use phosphocholine when it becomes available.

108.110.6 CONTRAINDICATIONS.

Pre-existing hepatic or renal failure. For *Leishmania* strains, activity varies depending on strain of the organism.

108.110.7 ADVERSE REACTIONS.

Vomiting, diarrhea, increased serum transaminases, increased urea and creatinine, myelosuppression. Miltefosine causes these side effects in people; however, more severe reactions have been observed in dogs; therefore it is not recommended for dogs. Dogs tolerate phosphocholine with less side effects ([Ch 71](#), ref. 5).

108.110.8 INTERACTIONS.

Elevates hepatic transaminases so may be interactions with drugs involving hepatic excretion or metabolism.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human Miltefosine ^a	Oral capsules	50 mg	<i>Impavido</i> (Zentaris)

a Only miltefosine is available at this time for clinical use.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.110.9 HANDLING.

Store in a dry temperature controlled environment of 22°C.

108.110.10 ADMINISTRATION.

Give orally after a meal to increase absorption.

1287

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Leishmaniasis ^a	2.5	PO	12	30
a This dose is for miltefosine as used in people.				

1288

108.110.11 ADDITIONAL DOSAGES.

None.

108.111 MINOCYCLINE

108.111.1 CLASS.

Tetracycline.

108.111.2 ACTION.

Bacteriostatic; inhibits protein synthesis by binding to 30s ribosomal unit.

108.111.3 MORE INFORMATION.

DOXYCYCLINE, TETRACYCLINES; [Chapter 34](#); [Table 34-7](#).

108.111.4 PHARMACOKINETICS.

More lipid soluble (10×) than tetracycline; 100% absorbed from GI tract. Penetrates well into most tissues, body fluids, difficult areas such as prostate, female reproductive tract, lung, bronchial secretions, saliva, bile, CSF, CNS. The only tetracycline that penetrates CNS with noninflamed meninges. Crosses the placenta to accumulate in fetal bones and teeth. Clears primarily by extensive hepatic metabolism and biliary elimination. Only small amount excreted in feces in unchanged form; active drug does not accumulate in liver failure. Minimal (4%-9%) urinary excretion; dose reduction not needed for renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.111 **5** SPECTRUM.

See DOXYCYCLINE. **More effective:** than tetracycline against *Staphylococcus* and *Nocardia*. **Ineffective:** see DOXYCYCLINE.

108.111 **6** INDICATIONS.

Brucellosis (combined with other drugs), borreliosis, nosocomial infections against bacteria resistant to other drugs. Has been unsuccessful as an antipruritic drug for atopic dermatitis (Ch 34, ref. 23).

108.111 **7** APPROVED USES.

Human: bacterial infections of skin and respiratory and urinary tracts. Has been marketed as a locally-administered (subgingival) paste to treat periodontal disease (Ch 34, ref. 164; 158).

108.111 **8** CONTRAINDICATIONS.

Pregnancy, lactation, and young (<6 mo). Dosage does not need reducing in renal failure because drug is excreted by biliary tract. However, drug does not accumulate in liver disease.

108.111 **9** ADVERSE REACTIONS.

Nausea, vomiting, potential yellow dental staining in young animals, increased hepatic enzyme activity, rare ototoxicity. Hypotension, shivering, dyspnea, cardiac arrhythmias, shock, and urticaria have developed in dogs given rapid IV doses that may have been caused by the drug vehicle. Certain vehicles such as propylene glycol in other IV tetracycline preparations may be responsible for acute systemic allergic reactions. In comparison, rapid IV infusions of doxycycline (5 mg/kg) has not produced systemic reactions. Vestibular side effects seen in people are related to a peculiar biotransformation of minocycline that does not occur in dogs and cats. Minocycline, at 10-20 mg/kg daily for 1 mo, decreased erythrocyte mass and increased blood alanine transaminase activity. Daily IV doses of 40 mg/kg produced increased urine calcium and Bromsulphalein retention, decreased food consumption, and weight loss. None of the effects were seen with similar PO dosages. A rare systemic granulomatous reaction has been observed in people.

108.111 **10** INTERACTIONS.

GI absorption reduced by iron preparations, aluminum hydroxide gels, sodium bicarbonate, calcium, and magnesium salts.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules	50 mg, 100 mg	Minocin (Lederle)
	Oral tablets	50 mg, 100 mg	Minocin
	Oral suspension	50 mg/5 ml	Minocin
	Powder for injection (IV)	100-mg vial	Minocin
	Dental ointment ^a	2%	PerioCare (Pulpdent); Arestin (OraPharma)

^a See Doxycycline, Topical Administration, for veterinary use.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.111 **11** INTERNATIONAL PREPARATIONS.

Aknosan, Aknoral, Dynacin, Klinotab, Mestacine, Minoclin, Minogal, Minomycin, Mynocine, Oracyclin.

108.111 **12** HANDLING.

Reconstituted IV solution is stable at room temperature for 24 hr; activity declines to 92% after 1 week storage at room temperature and to 98% if refrigerated. Oral capsules should be stored at room temperature away from light. Oral suspension should be stored at room temperature but not frozen.

108.111 **13** ADMINISTRATION.

For IV, given diluted in 5% dextrose or 0.9% NaCl. Feeding does not affect absorption of oral preparations. Do not administer rapidly IV.

1288

1289

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Soft tissue, urinary infections	5–12	PO, IV	12	7–14
Brucellosis (in combination)	12.5	PO	12	14–21
Cats				
Hemotropic mycoplasmosis	6–11	PO	12	21

108.111 **14** ADDITIONAL DOSAGES.

Ehrlichiosis, [Table 28-4](#); canine brucellosis, [Table 40-2](#); actinomycosis, [Table 49-2](#); nocardiosis, [Table 49-3](#); musculoskeletal infections, [Table 86-4](#).

108.111 **15** DISPENSING INFORMATION.

Can be given with food.

108.112 **1** MUPIROCIN

108.112 **1** CLASS.

Natural product, produced by *Pseudomonas fluorescens*.

108.112 **2** ACTION.

Bactericidal when used topically; inhibits bacterial protein synthesis. No cross resistance with other antimicrobial agents.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.112.3 PHARMACOKINETICS.

Topical ointment is rapidly inactivated after absorption; systemic levels are undetectable. The drug penetrates and persists in the stratum corneum for up to 72 hr after application. Has been given IV or PO in some countries. Drug is rapidly metabolized into monic acid which is rapidly renally excreted.

108.112.4 SPECTRUM.

Most strains of staphylococci and streptococci, including methicillin-resistant and multiple-drug resistant organisms. Active against *Listeria monocytogenes* and some gram-negative bacteria.

108.112.5 INDICATIONS.

Feline acne, alternative therapies are topical and systemic retinoids, fatty acid supplements, and metronidazole. Has some activity against *Malassezia*.

108.112.6 CONTRAINDICATIONS.

Topical application over large infected areas leads to resistant strains. Not for ophthalmic use. Not for use on mucosal surfaces where causes stinging and drying. A paraffin-based formulation ointment is available for intranasal use.

108.112.7 ADVERSE REACTIONS.

Irritation, pruritis, urticaria. Hypersensitivity to mupirocin or polyethylene glycol (PEG)-containing ointment.

108.112.8 INTERACTIONS.

PEG can be absorbed from open wounds and damaged skin and is excreted by kidneys. Excessive use should be avoided with renal impairment.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Topical ointment, 2% ^a	50 mg, 100 mg, 200 mg	<i>Bactoderm</i> (Pfizer)

^a In bland water miscible ointment base of PEG.

108.112.9 INTERNATIONAL PREPARATIONS.

Bactroban, Mupirax, Supirocin, T-bact.

108.112.10 HANDLING AND ADMINISTRATION.

Apply cream three times daily for 1-2 weeks. May be covered with a dressing. Store at room temperature (<25°C), out of the reach of children.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Dogs and cats</i>				
Burns or open wounds	Small amount	Topical	8–12	<10

108.112.11 ADDITIONAL DOSAGES.

None.

108.112.12 DISPENSING INFORMATION.

Apply topical to lesions, twice daily, for 3 weeks.

1289

108.113 MYCOBACTERIAL CELL WALL EXTRACT

1290

108.113.1 CLASS.

Bacterial component.

108.113.2 ACTION.

Immunostimulatory. Production of tumor necrosis factor and other cytokines.

108.113.3 MORE INFORMATION.

[Chapter 2.](#)

108.113.4 PHARMACOKINETICS.

From nonpathogenic species and strain of mycobacteria, contains purified mycobacterial cell wall fractions with known immunostimulatory properties. Contains low-level analgesic and a green tracking solution to facilitate location of intra-tumor administration.

108.113.5 SPECTRUM.

Stimulates activation of macrophages and thymic lymphocytes in tissue and blood cells. Increases interleukin-1 production.

108.113.6 INDICATIONS.

Parenteral nonspecific immunostimulant, vaccine adjuvant, intralesional for antitumor therapy. Canine mammary tumors.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.113.7 APPROVED USES.

Adenocarcinomas in dog and sarcoids in horses.

108.113.8 CONTRAINDICATIONS.

Previous allergic reactions to the drug. Pre-existing mycobacterial disease. Concurrent immunosuppression or glucocorticoid therapy.

108.113.9 ADVERSE REACTIONS.

Fever, anorexia, systemic inflammatory reaction. Pain at the time of injection.

108.113.10 INTERACTIONS.

Increased response of horses to herpesvirus vaccination when given IM, at the same time, but different site.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Intratumoral (canine and equine)	10-ml vials	<i>Regressin-V</i> (Vetrepharm)
	IV (equine)	1.5-ml syringes	<i>Equimmune I.V.</i> (Vetrepharm)

108.113.11 HANDLING.

Store in a refrigerator (36–45°F [2–7°C]) but do not freeze. Mix the emulsion thoroughly until milky white in color immediately before use. May heat to 65°C to facilitate mixing.

108.113.12 ADMINISTRATION.

Using a 20-gauge needle or smaller, mammary tumors are injected intralesionally and perilesionally under sedation or anesthesia once 2-4 weeks before surgery. Without surgery, repeat injections every 1-3 weeks for up to 4 treatments. Tumors that fail to respond after 4 treatments are considered refractory.

Dosage				
INDICATIONS	DOSE (ml)	ROUTE	INTERVAL (hr)	DURATION (days)
Equine vaccine adjuvant	1.5	IM (deep)	24	1
Equine respiratory disease	1.5	IV	24	1
Dosages for immunostimulation of dogs and cats would have to be extrapolated.				

108.113.13 ADDITIONAL DOSAGES.

None.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.114.1 NEOMYCIN

108.114.1 CLASS.

Aminoglycoside.

108.114.2 ACTION.

Bactericidal, inhibits protein synthesis.

108.114.3 MORE INFORMATION.

See GENTAMICIN; Aminoglycosides, [Chapter 34](#); [Tables 34-5](#), [34-6](#).

108.114.4 PHARMACOKINETICS.

Poorly absorbed (<5%) from intact GI tract. Topical use for ulcerative lesions may allow increased uptake and potential toxicity. Majority of oral dose is excreted unchanged in feces. Any absorbed drug is excreted unchanged in urine. Effects are on intestinal microflora.

108.114.5 SPECTRUM.

See GENTAMICIN, less effective than gentamicin against many *Pseudomonas*, *Klebsiella*, *Escherichia*.

108.114.6 INDICATIONS.

Not used parenterally because more toxic and less effective than other aminoglycosides. Commonly used orally for reduction of enteric flora or pathogens. Effect lasts for 48-72 hr after single dosing. Used orally for prophylaxis before intestinal or colonic surgery and to reduce bacterial ammonia production in hepatic insufficiency or coma.

108.114.7 APPROVED USES.

Veterinary, farm animals.

108.114.8 CONTRAINDICATIONS.

Pregnancy, because small absorbed amounts are fetotoxic; GI obstruction or ulcerative disease of GI tract suggested by hemoptysis, melena, or hematochezia.

108.114.9 ADVERSE REACTIONS.

Diarrhea owing to microflora alterations, nephrotoxicity, ototoxicity, interference with intestinal bacterial vitamin K synthesis and fat malabsorption.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.114.10 INTERACTIONS.

Potentiates vitamin K deficiency and associated coagulopathy. Decreases absorption of digoxin, methotrexate, penicillin V, vitamin K.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets (as sulfate)	500 mg	Generic (Biocraft)
	Oral solution (as sulfate)	125 mg/5 ml	<i>Mycifradin</i> (Pharmacia & Upjohn), generic (various)
Veterinary	Oral liquid (as sulfate)	140 mg/ml	<i>Biosol</i> (Pharmacia & Upjohn)
	Oral solution (as sulfate)	50 mg/ml	<i>Biosol</i>
	Oral tablets (as sulfate)	100 mg	<i>Biosol</i> tablets

1290

108.114.11 INTERNATIONAL PREPARATIONS.

Bykomycin, Francetin, Myciguent, Nebacetin, Neo-fradin, Neointestin.

1291

108.114.12 HANDLING.

Store at room temperature in airtight and light-proof container.

108.114.13 ADMINISTRATION.

PO: can give undiluted or diluted with water. Can be added to the sole source of drinking water to be consumed in 24 hr but must be made as fresh solution each day. Can also give by syringe or gavage. Not recommended for parenteral use.

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Bacterial enteritis, reducing GI flora, hepatic encephalopathy	10–15 mg/kg	PO	6–24	≤14

108.114.14 ADDITIONAL DOSAGES.

Endotoxemia, [Table 38-6](#); otitis externa (topical), [Tables 85-6](#) and [85-8](#).

108.114.15 DISPENSING INFORMATION.

If animal shows persistent vomiting or bloody diarrhea, discontinue medication and notify veterinarian immediately.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.115.1 **NIFURTIMOX**

108.115.1 **CLASS.**

Nitrofuran derivative.

108.115.2 **ACTION.**

Antiprotozoal; oxidative effects on trypanosomal enzymes, especially involving nucleic acid biosynthesis.

108.115.3 **MORE INFORMATION.**

See [Chapters 71, 72](#); [Table 71-1](#).

108.115.4 **PHARMACOKINETICS.**

Well absorbed from GI tract after PO administration, low plasma concentrations. Undergoes rapid biotransformation in liver to metabolites; little ($\leq 0.5\%$) of active drug is excreted in urine.

108.115.5 **SPECTRUM.**

Trypanosoma cruzi. African trypanosomiasis at higher dosages (second choice).

108.115.6 **INDICATIONS.**

American trypanosomiasis. Some effect on African trypanosomiasis. Reduces severity of acute disease but ineffective in chronic phases; suppresses infection rather than cures. Preexisting seizures or renal or hepatic disease. Alternative drug is benznidazole. Use of allopurinol as adjunctive therapy has not been well studied in this disease.

108.115.7 **CONTRAINDICATIONS.**

Despite toxicity, may be one of few effective drugs for this disease. Preexisting seizures or renal or hepatic disease. Alternative drug is benznidazole.

108.115.8 **ADVERSE REACTIONS.**

Frequent toxicity, including anorexia, vomiting, weight loss, CNS signs, polyneuritis, pulmonary infiltrates, skin eruptions, mitogenic (chromosomal aberrations). Hemolysis with glucose-6 phosphate dehydrogenase deficiency. In people, children tolerate the drug better than adults.

108.115.9 **INTERACTIONS.**

Alcohol ingestion in people enhances adverse reactions.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Investigation drug for human use only in U.S. from CDC, (404) 639-3670; available in other countries.	Oral tablets 120 mg	<i>Lampit</i> (Bayer)

108.115.10 HANDLING.

Store at room temperature in airtight container.

108.115.11 ADMINISTRATION.

Reduce dosage if GI disturbances occur.

Dosage				
INDICATIONS (Human)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Trypanosomiasis (<i>T. cruzi</i>)				
Adults	2-2.5	PO	6	90
Children	3-3.5	PO	6	90

108.115.12 ADDITIONAL DOSAGES.

Trypanosomiasis, [Table 72-1](#).

108.115.13 DISPENSING INFORMATION.

Can be given with food but may cause GI upsets. Food tends to reduce the GI irritation.

1291

108.116.16 NITAZOXANIDE

1292

108.116.1 CLASS.

Thiazolide: A nitrothiazolyl-salicylamide derivative.

108.116.2 ACTION.

Antiprotozoal. Anaerobic antibacterial, anthelmintic.

108.116.3 MORE INFORMATION.

See [Chapter 71](#) and Reference [Ch 71](#), ref. 1; 4.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.116.4 PHARMACOKINETICS.

In humans is absorbed rapidly with peak levels of its metabolite, tizoxanide, are attained between 2-3 hr after a dosing and are no longer detectable by 24 hr. High degree of protein binding. Excreted as metabolites in the urine, bile, and feces.

108.116.5 SPECTRUM.

Active against *Giardia*, *Cryptosporidium*, *Sarcocystis neurona*.

108.116.6 INDICATIONS.

For the treatment of drug-resistant *Giardia* and *Cryptosporidium* infections in people. Response is lower in immunocompromised individuals.

108.116.7 APPROVED USES.

For use in people with drug-resistant *Giardia* and *Cryptosporidium* infections. Has been used to treat horses with *Sarcocystis neurona* infection. Could be considered for treatment of dogs or cats with these infections; however, data is lacking on effectiveness.

108.116.8 CONTRAINDICATIONS.

Generally has a wide margin of safety; however, should be used with caution in animals that are ill or debilitated.

108.116.9 ADVERSE REACTIONS.

GI signs such as diarrhea and anorexia caused by effects on the GI microflora.

108.116.10 INTERACTIONS.

Since highly protein bound, this drug may displace those bound drugs and increase their activity and potential toxicity.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	20 mg/ml oral suspension	60 ml bottles	<i>Alinia</i> (Romark Laboratories, Tampa FL)
	Oral tablets	500 mg	<i>Alinia</i> (Romark Laboratories, Tampa FL)
Equine	Oral paste 32%	85g syringes	<i>Navigator</i> (IDEXX)

108.116.11 INTERNATIONAL PREPARATIONS.

Heliton, Daxon, PH-5776.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.116.12 HANDLING.

Powder for oral suspension for people is stable at 25°C (77°F), with a range of 15–30°C. When mixed the suspension is stable at room temperature for 7 days. The paste for horses should be stored below 30°C and can be refrigerated but not frozen.

108.116.13 ADMINISTRATION.

Horse product is dispensed from a prefilled dose syringe with stops to ensure accurate dosage.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Cryptosporidium</i> (human)	100 mg/kg ^a	PO	12	5 ^b
	200 mg/kg ^a	PO	12	5–7 days ^c
Horses	25 mg/kg day 1–5	PO	24	28
	50 mg/kg/day day 6–28			

a Human dose that is effective for children, higher dose range is needed in immunodeficient people. Dose range has not been established for dogs or cats but a similar regimen could be considered. Doses of 250–500 mg/kg were required to successfully treat *C. parvum* infection in pigs (Ch 71, ref. 91a).

b For children 24–47 mo old.

c For children 4–11yr old.

108.116.14 ADDITIONAL DOSAGES.

Dosages for dogs and cats would have to be extrapolated.

108.116.15 DISPENSING INFORMATION.

Paste or suspension should be given as directed; however, animal should be monitored at least once daily for fever, anorexia, lethargy, depression.

108.117 NITROFURANTOIN

108.117.1 CLASS.

Nitrofurant.

108.117.2 ACTION.

Bactericidal or bacteriostatic; inhibits bacterial carbohydrate metabolism and cell wall formation.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.117³ MORE INFORMATION.

See Nitrofurans, [Chapter 34](#); [Table 34-9](#).

108.117⁴ PHARMACOKINETICS.

Well absorbed (85%-95%) from GI tract after PO administration. Bioavailability enhanced and irritation reduced by giving with food. The macrocrystalline formulation is less irritating to GI tract but more slowly absorbed. The microcrystals are absorbed faster, reaching higher and more rapid peak urinary bladder levels. Most of the drug is metabolized with 30%-50% excreted unchanged in urine. Concentrations in blood or tissues are too low to be effective but are sufficient to treat urinary tract infections.

1292

108.117⁵ SPECTRUM.

Gram positive: *Staphylococcus*, *Streptococcus*, *Enterococcus*. **Gram negative:** *Escherichia*, some *Klebsiella*, some *Enterobacter*, *Salmonella*. **Ineffective:** *Proteus*, *Serratia*, *Pseudomonas*, *Acinetobacter*.

1293

108.117⁶ INDICATIONS.

Urinary tract infections caused by susceptible organisms.

108.117⁷ APPROVED USES.

Human urinary tract infections.

108.117⁸ CONTRAINDICATIONS.

Reduce dosage in renal failure, oliguria, pregnancy, breeding males or females.

108.117⁹ ADVERSE REACTIONS.

Interstitial pneumonitis, hemolysis with glucose-6-phosphate dehydrogenase deficiency, cholestatic hepatitis, LMN paralysis. The latter, (myasthenic-like syndrome) has been noted in a dog by the author (CEG), and by others in personal communications. The weakness resolves after withdrawing the drug. Vomiting is most common side effect in dogs and cats. May discolor urine to dark brown.

108.117¹⁰ INTERACTIONS.

Co-administered anticholinergics increase bioavailability while magnesium salts reduce absorption. May interfere with efficacy of fluoroquinolones.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral suspension	25 mg/ml	<i>Furadantin</i> (Proctor & Gamble)
	Oral capsules (microcrystalline)	25 mg, 50 mg, 100 mg	<i>Macrodantin</i> (Proctor & Gamble), generics (various) Nitrofurantoin generic (various)
	Oral capsules (regular)	50 mg, 100 mg	<i>Furadantin</i>

108.11711 INTERNATIONAL PREPARATIONS.

Chemiofuran, Cistofuran, Cystit, Furabid, Furedan, Macrobid, Microdoïne, Nephronex, Novofuran, Phenurin, Urantoin, Urodid, Urolong.

108.11712 HANDLING.

Store in airtight, light-proof containers at room temperature. May darken with light exposure. Avoid contact with most metals.

108.11713 ADMINISTRATION.

Bioavailability and GI tolerance is enhanced by giving with food. For long-term prophylaxis, give in evening to maintain nighttime levels in urine. Suspension can be mixed with milk to facilitate administration to animals.

Dosage					
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)	
Urinary Infections					
Severe or difficult	4	PO	6	14–28	
Routine	2.2–4.4	PO	8	7–14	
Long-term, prophylaxis, or giardiasis	3–4	PO	24	≥90	

108.11714 ADDITIONAL DOSAGES.

Urinary infections, [Table 91-10](#).

108.11715 DISPENSING INFORMATION.

Give with food.

108.118 NORFLOXACIN

108.1181 CLASS.

Fluoroquinolone.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.118.2 ACTION.

Inhibits bacterial DNA gyrase.

108.118.3 MORE INFORMATION.

See ENROFLOXACIN, MARBOFLOXACIN; Fluoroquinolones, [Chapter 34](#); [Table 34-11](#).

108.118.4 PHARMACOKINETICS.

Lower bioavailability (30%-40%) than other quinolones after PO administration. Food reduces absorption. Hepatic metabolism to less active metabolites with biliary and urinary excretion. Penetrates well into genitourinary tract and its secretions.

108.118.5 SPECTRUM.

Gram positive: *Staphylococcus*. **Gram negative:** *Escherichia*, *Proteus*, *Pseudomonas*, *Enterobacter*. Activity is lower than with ciprofloxacin and enrofloxacin. **Anerobes:** Minimal activity against obligate anaerobes. Resistance may develop when treating infections caused by *Klebsiella*, *Pseudomonas*, *Enterococcus*. **Others:** See ENROFLOXACIN. **More Effective:** aerobic or facultative anaerobic gram-negative bacteria. **Ineffective:** obligate anaerobes.

108.118.6 INDICATIONS.

See ENROFLOXACIN.

108.118.7 CONTRAINDICATIONS.

See ENROFLOXACIN.

108.118.8 ADVERSE REACTIONS.

See ENROFLOXACIN. Interactions: See ENROFLOXACIN.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral tablets	400 mg	Noroxin (Merck)

1293

108.118.9 HANDLING.

Store in airtight, light-proof containers at room temperature.

1294

108.118.10 ADMINISTRATION.

Food can delay absorption but not considered to be critical.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Skin, urinary infections ^a	5–11	PO	12	14–21
Soft tissues, systemic infections ^b	11–22	PO	12	14–21
Bacteremia	22	PO, IM	12	prn
a <i>Staphylococcus</i> , <i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Serratia</i>				
b <i>Pseudomonas</i> , <i>Enterobacter</i> .				

108.118.11 ADDITIONAL DOSAGES.

None.

108.118.12 DISPENSING INFORMATION.

Give medication on empty stomach. Do not give with dairy products or other antacids.

108.119.1 NOVOBIOCIN

108.119.1 CLASS.

Coumarin antibiotic.

108.119.2 ACTION.

Usually bacteriostatic; interferes with bacterial cell wall synthesis and nucleic acid synthesis.

108.119.3 MORE INFORMATION.

See Novobiocin, [Chapter 34](#).

108.119.4 PHARMACOKINETICS.

Well absorbed from the GI tract, but food may reduce. High degree of serum protein binding so tissue and body fluid concentrations are low. Little penetration of CSF, even in meningitis. Predominantly excreted in bile and feces with little appearing in urine.

108.119.5 SPECTRUM.

Gram positive: some *Streptococcus*, *Staphylococcus*, few *Enterococcus*. **Gram negative:** most resistant except *Proteus*, *Pasteurella*, and some *Pseudomonas*. **Anaerobes:** most resistant. **Ineffective:** most *Enterococcus*, and gram negatives.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.119.6 INDICATIONS.

Staphylococcal infections, upper respiratory tract infections in dogs, in combination with tetracycline with or without prednisolone.

108.119.7 CONTRAINDICATIONS.

Hepatic insufficiency, biliary obstruction, myelosuppressive diseases.

108.119.8 ADVERSE REACTIONS.

Allergic hypersensitivity, dermal eruptions, hepatic dysfunction, vomiting, diarrhea, bone marrow dyscrasia.

108.119.9 INTERACTIONS.

May prolong excretion and increase blood concentrations of β -lactam and cephalosporin drugs. May inhibit excretion of bilirubin and bromsulphalein. Often administered in combination with tetracycline or rifampin to prevent resistance.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules	250 mg	<i>Albamycin</i> (Pharmacia & Upjohn)
	Oral syrup	125 mg/5 ml	<i>Albamycin</i>
Veterinary	Novobiocin (as sodium) and tetracycline (as HCl)	60 mg each or 180 mg each also with prednisolone (1.5 or 4.5 mg)	<i>Albaplex</i> and <i>Albaplex-3X</i> (Pharmacia & Upjohn) <i>Delta Albaplex</i> and <i>Delta Albaplex-3X</i>

108.119.10 HANDLING.

Store in airtight containers at room temperature.

108.119.11 ADMINISTRATION.

Preferably give on empty stomach. If vomiting occurs, give with small amount of food. Available in combination with tetracycline, with or without prednisolone, for use in dogs. Tetracycline absorption in the combined preparations is more affected by ingesta than is novobiocin.

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Respiratory infections	10	PO	8	5–7
	22 ^a	PO	12	5–7

^a Combined with tetracycline.

1294

Infectious Diseases of the Dog and Cat, 3rd Edition

1295

108.119.13 ADDITIONAL DOSAGES.

None.

108.119.13 DISPENSING INFORMATION.

Give at least 1 hr before or 2 hr after feeding. If vomiting occurs, consult veterinarian.

108.120.1 OFLOXACIN

108.120.1 CLASS.

Fluoroquinolone.

108.120.2 ACTION.

Bactericidal; inhibits bacterial enzyme DNA gyrase.

108.120.3 MORE INFORMATION.

See ENROFLOXACIN; [Chapter 34](#), [Tables 34-11](#) and [34-12](#).

108.120.4 PHARMACOKINETICS.

Systemic availability after PO administration, bioavailability is 98% (the highest of the class). Maximum blood concentrations in 1-2 hr. Wide distribution in body tissues and fluids. Detected in blister fluid, genital tissues, lung. CSF concentrations are 40%-90% serum, if inflamed. Human aqueous humor concentration is 44%-88% serum. Minimal metabolism, primarily renally excreted.

108.120.5 SPECTRUM.

Gram positive: *Staphylococcus*, some *Streptococcus*, poor activity against *Enterococcus*. **Gram negative:** *Enterobacter*, *Klebsiella*, *Pseudomonas*, *Proteus*, *Salmonella*, *Serratia*, *Yersinia*, *Campylobacter*. **Anaerobes:** poor activity. *Bacteroides* and *Clostridium* are inhibited in vitro.

108.120.6 INDICATIONS.

Complicated urinary tract infections; also lower respiratory tract, skin, and soft tissue infections caused by susceptible gram-negative bacteria.

108.120.7 CONTRAINDICATIONS.

Drug clearance reduced with renal failure so must use lower dosages. Avoid in pregnancy or lactation.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.120.8 ADVERSE REACTIONS.

Arthropathies in immature animals. High overdosages have not produced lenticular opacities or crystalluria, although these can occur with other drugs of this class. Nausea, vomiting, diarrhea may occur. All quinolones have potential to cause CNS hyperexcitability and seizures. Phototoxicity has been seen with use of some compounds in this class.

108.120.9 INTERACTIONS.

Theophylline concentrations will increase when given concurrently. Should not give orally within 2-4 hr of receiving sucralfate or preparations containing polyvalent cations (Al, Ca, Mg, Fe, Zn). Should not give orally within 2-4 hr of receiving sucralfate or preparations containing polyvalent cations (Al, Ca, Mg, Fe, Zn).

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Tablets	200 mg, 300 mg, 400 mg	400 mg <i>Floxin</i> (Ortho)
	IV solution	200 mg, 400 mg	<i>Floxin</i>

108.120.10 INTERNATIONAL PREPARATIONS.

Floxal, Surnox, Tarivid, Trafloxal.

108.120.11 HANDLING.

Store tablets in tightly closed containers below 30°C. Solution can be added to 0.9% NaCl, 5% dextrose, or solutions containing KCl.

108.120.12 ADMINISTRATION.

Effect of food on absorption has not been well studied, but it may be better to avoid dosing with food.

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Uncomplicated urinary infections	2.5	PO	12	7
Complicated urinary, genital infections	5–7.5	PO	12	10
Lower respiratory infections	7.5–10	PO	12	14

108.120.13 ADDITIONAL DOSAGES.

None.

108.120.14 DISPENSING INFORMATION.

Monitor animal for adequate water intake; avoid sucralfate and vitamin with iron and mineral supplements and antacids within 4 hr of administration.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.121 **1** ORBIFLOXACIN

108.121 **1** CLASS.

Fluoroquinolone.

108.121 **2** ACTION.

Bactericidal; inhibits bacterial DNA gyrase.

108.121 **3** MORE INFORMATION.

See ENROFLOXACIN, MARBOFLOXACIN, DIFLOXACIN; [Chapter 34](#); [Tables 34-11](#) and [34-12](#).

108.121 **4** PHARMACOKINETICS.

Well absorbed orally (97% bioavailable) with peak plasma concentrations within 1 hr of administration. Plasma protein binding low (7%-14%). In dogs, after 3 hours of giving 5 mg/kg dose, tissue concentrations are 6.0 µg/ml in prostate and 4.1 µg/ml in lung. It is predominantly (50%) excreted unchanged in urine with concentrations of 100 µg/ml, between 0 and 6 hours after administration of 2.5 mg/kg. After SC injection of 5 mg/kg to cats and dogs, urine recoveries were 28% and 45% and fecal recoveries were 15% and 18% respectively ([Ch 34](#), ref. 241). In the urine, nonmetabolized parent drug comprised 96% and 87% of the amounts recovered, respectively. Following a 7.5 mg/kg daily dose for 4-6 days, mean concentrations in skin of dogs with pyoderma were higher (9.47 ± 6.23 µg/g) than in clinically healthy dogs (5.43 ± 1.02 µg/g) ([Ch 34](#), ref. 191). Skin concentrations were approximately equal to those in plasma for the clinically healthy dogs and 1.4 times those in plasma for the dogs with pyoderma. At this dose, the mean concentration of orbifloxacin in skin of dogs with pyoderma was approximately 24 times the MIC₉₀ for *Staphylococcus intermedius*. Extrapolated mean concentration in the skin of dogs with pyoderma following the 2.5 mg/kg dose was estimated at 8 times this MIC₉₀ ([Ch 34](#), ref. 191).

1295

1296

108.121 **5** SPECTRUM.

Gram-negative and some gram-positive bacteria. Not effective against anaerobes. See ENROFLOXACIN.

108.121 **6** INDICATIONS.

Skin and soft tissue infections (wounds, abscesses, pyoderma) and urinary tract infections.

108.121 **7** CONTRAINDICATIONS.

Young growing animals, seizure-prone animals. Safety in pregnancy and breeding dogs has not been established.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.121 **8** ADVERSE REACTIONS.

Can cause CNS stimulation and seizures in predisposed animals. Immature animals may develop arthropathy when treated. Avoid in rapid growth phase of 2-8 mo in small and medium breeds and up to 18 mo in giant breeds. Cats receiving higher than recommended dosages (45 or 75 mg/kg PO every 24 hr) developed focal, well-delineated tapetal hyperreflectivity ([Ch 34](#), ref. 420). See also ENROFLOXACIN.

108.121 **9** INTERACTIONS.

See also ENROFLOXACIN. Compounds such as sucralfate, antacids, and multivitamin that contain divalent and trivalent cations (iron, aluminum, calcium, magnesium or zinc) may interfere with absorption.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary (dogs and cats)	Oral tablets (scored)	5.7 mg (yellow), 22.7 mg (green), 68 mg (blue)	<i>Orbax</i> (Schering-Plough Animal Health)
Veterinary (dogs and cats)	Solution	5% concentration	<i>Victas Injection</i> (Dainippon Pharm, Osaka Japan)

108.121 **10** HANDLING.

Store tablets at controlled temperature between 2–30°C.

108.121 **11** ADMINISTRATION.

For skin and soft tissue infections, give for 2-3 days beyond cessation of signs for a maximum of 30 days. Effect of feeding on dose has not been determined. Although not clinically available in all countries, the SC route was shown to give similar pharmacokinetic data as compared to oral administration in dogs and cats ([Ch 34](#), ref. 242).

Dosage				
INDICATIONS	DOSE ^a (mg/kg)	ROUTE	INTERVAL	DURATION
			(hr)	(days)
Urinary infections	2.5–5.0	PO	24	10 ^b
Soft tissue infections	5.0–7.5	PO	24	10 ^b
Skin infection with resistant pathogens (dogs)	7.5	PO	24	10 ^b
Systemic infection, bacteremia	5.0	PO	12	prn
a Flexible dosage labeling.				
b A maximum of 30 days has been evaluated in safety trials.				

108.121 **12** ADDITIONAL DOSAGES.

None.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.12213 DISPENSING INFORMATION.

Give medication without feeding, unless vomiting occurs. Never give antacids or GI protectants within 2 hr of medication.

108.12223 ORMETROPRIM-SULFONAMIDE

108.12224 CLASS.

Diaminopyrimidine and sulfonamide.

108.12225 ACTION.

Combination is bactericidal, causes synergistic two-step inhibition of microbial folic acid synthesis. Antibacterial, antiprotozoal.

108.12226 MORE INFORMATION.

Similar to baquiloprim- sulfadimethoxine licensed in Europe. See TRIMETHOPRIM- SULFONAMIDE, BAQUILOPRIM-SULFONAMIDE; [Chapter 34](#); [Table 34-10](#); references: [Ch 34](#), ref. 256; [Ch 34](#), ref. 339.

108.12227 PHARMACOKINETICS.

Sulfadimethoxine and ormetoprim in a 5 : 1 ratio. Both have an extended blood half-life permitting once-a-day dosing. The sulfadimethoxine is highly protein bound, maintaining high and long-duration blood levels, is slowly excreted by dogs largely unchanged in the urine. Sulfadimethoxine has high solubility in the urine and kidney of dogs precluding precipitation and crystalluria. See also TRIMETHOPRIM-SULFONAMIDE.

108.12228 SPECTRUM.

Gram positive: *Staphylococcus*, *Nocardia*. **Gram negative:** *Proteus*, *Escherichia*, *Salmonella*, *Klebsiella*, *Brucella*, *Bordetella*, coccidiosis. **Anaerobes:** *Clostridium*. **Others:** *Coccidia*, *Pneumocystis*, *Neospora*. **Ineffective:** *Pseudomonas*. The combined drugs potentiate activity of each other.

108.12229 INDICATIONS.

Treatment of pyoderma, wounds, abscesses in dogs caused by susceptible strains of *Staphylococcus* and gram-negative organisms like *Escherichia*.

108.12230 APPROVED USES.

Skin and soft tissue infections caused by susceptible organisms in dogs.

1296

Infectious Diseases of the Dog and Cat, 3rd Edition

1297

108.122.8 CONTRAINDICATIONS.

Preexisting hepatic disease, blood dyscrasias, or known previous reaction to sulfonamide. Safety in breeding and pregnant animals is not established; should avoid.

108.122.9 ADVERSE REACTIONS.

See also TRIMETHOPRIM- SULFONAMIDE. Keratoconjunctivitis, immune complex– mediated reaction (polyarthrititis, urticaria, facial swelling, fever, hemolytic anemia, thrombocytopenia, leukopenia), hepatotoxicity, vomiting, anorexia, diarrhea, polydipsia, polyuria. Rare: generalized anaphylaxis. PO administration of this drug to dogs for 8 weeks at 27.5 mg/kg/day resulted in hypothyroidism (thyroid enlargement, follicular hyperplasia, reduced serum thyroid hormone), reflecting interference with thyroidal hormone synthesis (Ch 34, ref. 146). Very high doses in dogs cause CNS signs, depression, and seizures.

108.122.10 INTERACTIONS.

Prolonged use can cause hypothyroidism.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Oral tablet (sulfadimethoxime-orometoprim in 5:1 ratio)	120 mg, 250 mg, 600 mg, 1200 mg	Primor (Pfizer Animal Health)

108.122.11 HANDLING.

Keep tablets stored in airtight containers at room temperature.

108.122.12 ADMINISTRATION.

Not recommended by manufacturer for treatment longer than 21 days; longer periods require careful monitoring. Treatment for infections such as pyoderma requires 3-9 weeks. Continue therapy for at least 2 days after remission of signs. Can be dosed once daily, even in bacterial skin disease (Ch 34, ref. 176). Although soluble in urine, adequate water should be provided at all times. Dehydration and acid urine favor crystal formation.

Dosage				
INDICATIONS	DOSE ^a (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Soft tissue, infection	27.5	PO	24	21
Chronic pyoderma	27.5 ^b	PO	24	21–63 ^c
Coccidiosis	66 ^b	PO	24	23
Cats				
Coccidiosis	66	PO	24	≤23

^a Dose includes combined sulfadimethoxime-orometoprim in 5:1 ratio.

Infectious Diseases of the Dog and Cat, 3rd Edition

b Use twice this dose on the first day.

c Not approved for longer than 21 days, but chronic skin disease often warrants longer treatment.

108.122.13 ADDITIONAL DOSAGES.

Coccidiosis, [Table 81-2](#); Canine pyoderma, [Table 85-3](#); otitis externa, [Table 85-6](#).

108.122.14 DISPENSING INFORMATION.

Supply animal with unlimited water to drink; notify clinician of any signs of dry eyes, fever, GI upsets, skin eruptions, swelling, lameness, or worsening of clinical condition.

108.123 OSELTAMIVIR PHOSPHATE

108.123.1 CLASS.

Antiviral.

108.123.2 ACTION.

Inhibition of influenza virus neuraminidase. This may alter virus particle aggregation and release from the cell.

108.123.3 MORE INFORMATION.

U.S. Food and Drug Administration at <http://www.fda.gov/cder/drug/infopage/tamiflu/default.htm>, last accessed 04/05/05.

108.123.4 PHARMACOKINETICS.

The drug is a pro-drug requiring conversion for its activity. Readily absorbed from the GI tract after oral administration. Extensively converted predominantly by hepatic esterases to oseltamivir carboxylate. Co-administration with food has no significant effect on the peak plasma concentration and the area under the plasma concentration curve. Excreted in the kidney by glomerular filtration and tubular secretion. Less than 20% of an oral radiolabeled dose is eliminated in feces.

108.123.5 SPECTRUM.

Parainfluenza virus neuraminidase. There is no evidence for efficacy on any viruses other than influenza A and B.

108.123.6 INDICATIONS.

The drug must be given within the first 2 days of onset of clinical illness. Has only been shown to be effective against neuraminidase on the surface of parainfluenza viruses. Although this drug has been suggested for use to treat dogs and cats infected by parvoviruses, there is no valid or logical reason that this should be effective.

Infectious Diseases of the Dog and Cat, 3rd Edition

The parvoviruses are nonenveloped and there is *no* evidence or experimental basis that these viruses would be susceptible. The closest viral infections of dogs and cats would be infection with one of the strains of influenza virus or perhaps canine parainfluenza virus. Use of this drug may help reduce the prevalence of canine infectious tracheobronchitis in a kennel.

108.123.7 APPROVED USES.

Humans with influenza beginning the first 2 days after the onset of infection.

108.123.8 CONTRAINDICATIONS.

Use during pregnancy or neonates is not recommended.

108.123.9 ADVERSE REACTIONS.

Generally well-tolerated. Nausea, vomiting, and diarrhea are most prevalent among the reactions. Taking with food can reverse the potential of side effects. Not recommended for use during pregnancy or nursing.

108.123.10 INTERACTIONS.

Clinically significant drug interactions are unlikely.

1297

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral capsules	75 mg	<i>Tamiflu</i> (Roche)
Human	Pediatric suspension	12 mg/ml	<i>Tamiflu</i> (Roche)

1298

108.123.11 HANDLING.

Store at 25°C (77°F), with limits of 15–30°C (59–86°F). Store constituted suspension under refrigeration at 2° C to 8°C (36–46°F).

108.123.12 ADMINISTRATION.

Must be given orally within the first 2 days of infection and never used for longer than 5 days.

Dosage				
INDICATIONS	DOSE ^a	ROUTE	INTERVAL (hr)	DURATION (days)
Humans				
Influenza (>40kg)	75 mg total	PO	12	5
23–40kg	60 mg total	PO	12	5
15–23kg	45 mg total	PO	12	5
≤15kg	30 mg total	PO	12	5

^a Treatment should begin within 2 days of onset of signs of influenza.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.123.13 ADDITIONAL DOSAGES.

None.

108.123.14 DISPENSING INFORMATION.

Administer fasting; however if vomiting or nausea occur then give with food.

108.124.1 OXACILLIN

108.124.1 CLASS.

Isoxazolyl penicillin.

108.124.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.124.3 MORE INFORMATION.

[Chapter 34; Table 34-1.](#)

108.124.4 PHARMACOKINETICS.

Bioavailability after PO administration is 60%-70%. One of few penicillins that has predominant hepatic inactivation and biliary excretion. Urinary excretion of unchanged drug is 30%-70% of that absorbed.

108.124.5 SPECTRUM.

Gram positive: *Staphylococcus* (including β -lactamase producers), other gram-positive aerobic cocci, some gram-positive anaerobes.

108.124.6 INDICATIONS.

Staphylococcal pyoderma, staphylococcal infections of the respiratory tract or soft tissues.

108.124.7 CONTRAINDICATIONS.

Penicillin hypersensitivity.

108.124.8 ADVERSE REACTIONS.

See PENICILLIN. Thrombophlebitis when given IV. Neutropenia in people when given IV for several weeks. Vomiting and diarrhea with oral formulations.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.124.9 INTERACTIONS.

Inactivates aminoglycosides when given in the same parenteral solution. Amikacin is most stable aminoglycoside in the presence of penicillins. Antagonism in activity with tetracyclines or chloramphenicol. Sulfonamides inhibit GI absorption of oxacillin.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Capsules	250 mg, 500 mg	<i>Bactocill</i> (SmithKline Beecham), <i>Prostaphlin</i> (Apothecon)
	Powder for oral solution	250 mg/5 ml	<i>Bactocill</i>
	Powder for injection	250 mg, 500 mg, 1g, 2g, 4g, 10g	<i>Bactocill</i>

108.124.10 INTERNATIONAL PREPARATIONS.

Bristopen, Penstapho, Stapenor.

108.124.11 HANDLING.

Reconstitute powder for injection with sterile NaCl or water. For IV, solution stable for 6 hr at room temperature at concentrations of 0.5-40 mg/ml. Compatible with 5% dextrose, Ringer's solution, and 0.9% NaCl. For IM, solution of 250 mg/1.5 ml stable for 3 days at room temperature, 7 days if refrigerated.

108.124.12 ADMINISTRATION.

Infuse IV over at least 10 min. Food interferes with PO absorption.

Dosage				
INDICATIONS (Dogs)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Bacterial pyoderma	22	PO	8	14-21
Bacterial pyoderma	15-25	PO	12	14-21
Orthopedic infection	22	IV, IM, SC, PO	6-8	21-42

1298

108.124.13 ADDITIONAL DOSAGES.

1299

Canine pyoderma, [Table 85-3](#); musculoskeletal infections, [Table 86-4](#); CNS infections, [Table 92-5](#).

108.124.14 DISPENSING INFORMATION.

Administer at least 1 hr before feeding or 2 hr after a meal.

108.125 OXYTETRACYCLINE

108.125.1 CLASS.

Tetracycline.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.125.2 ACTION.

Bacteriostatic; interferes with bacterial protein synthesis. See TETRACYCLINE.

108.125.3 MORE INFORMATION.

TETRACYCLINE; Tetracyclines, [Chapter 34](#); [Table 34-7](#).

108.125.4 PHARMACOKINETICS.

See TETRACYCLINE. For long-acting preparation, the elimination half-life and volume of distribution are increased in *Ehrlichia canis*—infected dogs as compared to uninfected dogs ([Ch 34](#), ref. 198).

108.125.5 SPECTRUM.

See TETRACYCLINE.

108.125.6 INDICATIONS.

See TETRACYCLINE.

108.125.7 APPROVED USES.

Equine and food animal.

108.125.8 CONTRAINDICATIONS.

See TETRACYCLINE.

108.125.9 ADVERSE REACTIONS.

See TETRACYCLINE. Localized pain and allergic or anaphylactic reactions have occurred in dogs after parenteral use. This has been a particular problem with repeated doses of long-acting IM formulations.

108.125.10 INTERACTIONS.

See TETRACYCLINE.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Capsules	250 mg (as HCl)	<i>Terramycin</i> (Pfizer)
	Solution for injection (IV)	500-mg vials	<i>Terramycin</i> IV
	Solution for injection (IM) with lidocaine	500 mg/ml, 125 mg/ml	<i>Terramycin</i> IM
Veterinary	Solution for injection	50 mg/ml, 100 mg/ml	<i>Oxytet</i> (Vedco), <i>Oxybiotic</i> 100 (Butler), <i>Intacycline</i> (Intervet), <i>Terramycin</i> (Pfizer), generic (various)
	Repositol solution for injection (licensed for cattle and pigs in U.S., dogs and cats in U.K.)	200 mg/ml	<i>Liquamycin</i> LA—200 (Pfizer), <i>Terramycin</i> LA (Pfizer)
		50 mg/ml, 100 mg/ml	<i>Engemycin</i> (Mycofarm)

108.125.12 INTERNATIONAL PREPARATIONS.

Aknin, Imperacin, Innolyre, Oxymycin, Terramycine.

108.125.13 HANDLING.

Store in airtight containers protected from light. Solutions are acidic and incompatible with alkaline solutions and many parenteral antimicrobials and other drugs.

108.125.14 ADMINISTRATION.

No more than 1-2 ml should be injected at any one site when using IM route. IM route is painful and produces lower blood concentrations than by oral or IV route. Nonsteroidal analgesics have been given 15 min prior to IM injections to reduce discomfort. Not recommended to use LA—200 by IV route. It is a long acting, less painful formulation developed for use in food-producing animals consisting of a vehicle containing a solvent, 2-pyrrolidone, with a povidone base. Administer PO to fasting animal. Do not give oral formulations with dairy products or substances containing multivalent cations (Fe, Al, Mg, Ca, Bi).

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL	DURATION (days)
Dogs				
Systemic infections	22	PO	8 hr	7–14
	20	IM (repositol)	7 days	7 ^a
Cats				
Hemotropic mycoplasmosis	10–25	PO, IV	8 hr	5–7

^a May be repeated every 7 days. For pharmacokinetics, see reference [Ch 28](#), ref. 198.

108.125.15 ADDITIONAL DOSAGES.

Salmon poisoning disease, [Table 27-2](#); ehrlichiosis, [Table 28-4](#); hemotropic mycoplasmosis, [Table 31-1](#); bacterial overgrowth, [Table 89-16](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.125¹⁵ DISPENSING INFORMATION.

Give PO on an empty stomach.

1299

108.126¹⁶ PARAPOXVIRUS OVIS AND PARAPOXVIRUS OVIS (PIND-AVI/PIND-ORF, BAYPAMUN®): PARAIMMUNITY INDUCER. SEE [CHAPTER 2](#).

1300

108.127¹⁷ PAROMOMYCIN (ANIMOSIDINE)

108.127¹ CLASS.

Aminoglycoside.

108.127² ACTION.

Antiprotozoal, antibacterial, anthelmintic. Inhibits protein synthesis by interfering with the 50S and 30S ribosomal subunits causing misreading of mRNA codons.

108.127³ MORE INFORMATION.

See [Chapter 34](#); Trichomoniasis, [Chapter 78](#); Cryptosporidiosis, [Chapter 82](#); Leishmaniasis, [Chapter 73](#); [Table 34-5](#); [Table 71-1](#); reference: [Ch 71](#), ref. 9.

108.127⁴ PHARMACOKINETICS.

Minimal absorption from GI tract after PO administration. Most (~100%) excreted unchanged in the feces. Approximately 1%-3% of a dose appears in urine; however this may be higher with disrupted gastrointestinal mucosal barrier.

108.127⁵ SPECTRUM.

Gram positive: poor. **Gram negative:** *Salmonella*, *Shigella*. **Protozoa:** *Cryptosporidium*, *Pentatrichomonas*. Other: some tapeworms. **Less effective:** *Giardia*, *Leishmania*, *Entamoeba*.

108.127⁶ INDICATIONS.

Cryptosporidiosis, amebiasis, hepatic insufficiency, to reduce enteric microflora production of NH₃. Second choice for *Entamoeba* and *Leishmania* ([Ch 71](#), ref. 74).

108.127⁷ CONTRAINDICATIONS.

Intestinal stasis or obstruction, GI ulceration. Not effective in extraintestinal infections (not absorbed when given PO).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.127⁸ ADVERSE REACTIONS.

Nephrotoxicity or ototoxicity if absorbed from ulcerative bowel lesions or if given parenterally. Has caused renal failure in cats with infectious enteritis (Ch 34, ref. 133). Overgrowth of resistant bacterial or fungal enteric microflora. Oral use: self-limiting diarrhea, malabsorption at high doses. If given parenterally: ototoxicity, nephrotoxic, pancreatitis. Renal failure may be reversible if it is detected early and the animal is given parenteral fluid diuresis. Drug has been associated with inducing bilateral hypermature cataracts with lens resorption and uveitis during treatment and recovery from drug induced renal failure (Ch 34, ref. 133).

108.127⁹ INTERACTIONS.

See as for NEOMYCIN (oral).

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral capsules	250 mg (as sulfate)	Humatin (Parke-Davis)

108.127¹⁰ INTERNATIONAL PREPARATIONS.

Gabbroral, Humagel, Sinosid.

108.127¹¹ HANDLING.

Store in airtight containers.

108.127¹³ ADMINISTRATION.

Given orally without concern for fasting. Dosage must be reduced or avoided if there is evidence of gastrointestinal hemorrhage. For parenteral use, must be certain animal is not dehydrated and diuresis with fluids may be helpful in averting toxicity. Monitoring of renal function is indicated with any treatment with this drug.

Dosage				
INDICATIONS (Dogs and Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Cryptosporidiosis	125–165 ^a	PO	12	5
Leishmaniasis (dog)	10–20 ^b	IM, SC	24	28
Leishmaniasis (dog)	5.25	SC	12	21
Trichomoniasis (cat)	70	PO	12	5
Amebiasis ^c	70	PO	12	7

a Higher oral dosages of the drug have been tolerated in cats treated with cryptosporidiosis, while the same dosages have been nephrotoxic to cats with trichomoniasis. Presumably the damaged integrity of the intestine from trichomoniasis results in increased systemic absorption. Therefore the maximum dose of 125 mg/kg should not be exceeded in these animals or any showing gross evidence of intestinal hemorrhage in their feces. Dosage levels appear to be important in therapeutic studies in experimental animals. For example, 100 mg/kg/day in dairy calves and

Infectious Diseases of the Dog and Cat, 3rd Edition

immunosuppressed mice is effective, whereas 25 mg/kg/day and 50 mg/kg/day is not. In piglets, 500 mg/kg/day is effective, whereas doses of 250 mg/kg/day and 125 mg/kg/day are less or not effective.

- b Must be given parenterally for *Leishmania* infections and, therefore, has greater risk of toxicity. Doses of 20 mg/kg/day parenterally for leishmaniasis were not as effective as 40 mg/kg/day; however, the higher dosage was associated with greater prevalence of nephrotoxicity (Ch 71, ref. 5). Nephrotoxicity may also be greater if it is co-administered with antimonials. Clinical improvement may occur during treatment period, but relapse may occur 50–100 days after it is discontinued.
- c For luminal infection only, if disseminated, must also use metronidazole.

108.127.13 ADDITIONAL DOSAGES.

Cryptosporidiosis, [Table 82-1](#); *Pentatrichomonas*, [Table 78-3](#).

108.127.14 DISPENSING INFORMATION.

Give with meals. Observe pet for vomiting or diarrhea, dizziness, hearing loss.

1300

108.128.1 PENICILLIN G

1301

108.128.1 CLASS.

Benzylpenicillin.

108.128.2 ACTION.

Bactericidal, inhibits bacterial cell wall synthesis.

108.128.3 MORE INFORMATION.

Penicillins, [Chapter 34](#); [Table 34-1](#).

108.128.4 PHARMACOKINETICS.

PO: Unpredictable inactivation by gastric acid when given PO. **IV:** rapid high but transient blood levels. **IM:** procaine salt lasts 12-15 hr; benzathine lasts up to 4 weeks but produces very low concentrations. Diffuses readily into liver, lung, heart, skin, kidneys, bone, prostate, spleen, intestines, serosal fluids (synovial, peritoneal, ascitic), bile, urine, wound secretions. Penetration into CSF, brain, or ocular tissues poor unless inflammation present. Crosses placenta but does not enter milk. Excretion occurs unchanged in the urine.

108.128.5 SPECTRUM.

Gram positive: *Staphylococcus*, *Streptococcus*, *Corynebacterium*, *Erysipelothrix*, *Bacillus*, *Listeria*. **Gram negative:** *Proteus*, *Salmonella*, *Enterobacter*, *Escherichia*, *Streptobacillus moniliformis*, *Pasteurella*.

Infectious Diseases of the Dog and Cat, 3rd Edition

Anaerobes: *Clostridium*, *Peptococcus* sp, *Peptostreptococcus*, *Fusobacterium*, *Eubacterium*, *Actinomyces*.
Other: *Borrelia*, *Leptospira*. **Ineffective:** *Enterococcus* (*Streptococcus faecalis*), β -lactamase-producing *Staphylococcus*.

108.128.6 INDICATIONS.

PO administration requires higher doses because of gastric acid activation. Generally used parenterally. Penicillin V is an alternative for oral use. Use IV soluble form in presence of severe systemic infections or bacteremia. Recommended for actinomycosis, tetanus, rat bite fever, listeriosis, pasteurellosis, erysipelas, anthrax, streptococcosis, fusospirochetosis of oropharynx, some gram-negative bacteremias, leptospirosis (bacteremic phase), borreliosis.

108.128.7 CONTRAINDICATIONS.

Use lower dosages in renal failure.

108.128.8 ADVERSE REACTIONS.

IV: thrombophlebitis, convulsions, hyperkalemia with potassium salt. **IM:** peripheral nerve damage.

108.128.9 INTERACTIONS.

Penicillins may inactivate aminoglycosides if mixed before administration.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Aqueous solutions (potassium or sodium)	2,000,000–20,000,000/U in powder for reconstitution.	Generic (various)
	Oral tablets (as potassium)	200,000–800,000/U	Generic (various)
Veterinary	Procaine suspension for IM injection	300,000–500,000U/ml	<i>Crystacillin</i> (Solvay), <i>Microcillin</i> (Anthony)
	Benzathine parenteral	300,000U/ml	<i>Crystiben</i> (Solvay), <i>Flo-Cillin</i> (Fort Dodge)
	Procaine and benzathine combined equally	300,000–600,000 units/ml total	<i>Ambi-Pen</i> (Butler), <i>Crystiben</i> (Solvay), <i>Duo-Pen</i> (AgriPharm, RXV, Vet Tek), <i>DuraPen</i> (Vedco)

108.128.10 HANDLING.

Dry aqueous powder for injection stable in refrigerator. Dissolve in sterile water, 0.9% sodium chloride, or dextrose. Avoid alkaline dextrose solutions. After reconstitution, keep refrigerated, good for 1 week. Store procaine and benzathine preparations in refrigerator (not frozen). Before use, warm to room temperature and shake well.

108.128.11 ADMINISTRATION.

Aqueous sodium or potassium solutions: given IM or by continuous IV infusion; give highest dose IV. For IM, use 100,000 U/ml concentration. For IV, determine daily fluid needs; add required aqueous penicillin and infuse over 24 hr. Local infusion (pleural, peritoneal) prepare as for IM, dilute in 1/4 to 1/2 volume compared

Infectious Diseases of the Dog and Cat, 3rd Edition

with that of fluid aspirated from cavity. **Oral tablets:** administer 1 hr or more before feeding or at least 2 hr or more afterward. Dose for oral use is higher because of gastric acid degradation. **Procaine or benzathine:** administer by deep IM injection. Maximum volume at one site 10 ml.

Dosage				
INDICATIONS	DOSE (U/kg) ^a	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
<i>Potassium</i>

a Na penicillin G for injection = 1600U/mg; procaine penicillin G = 1000U/mg; benzathine penicillin G = 1200U/mg.

b Given 1 hr prior to surgery, and if surgery lasts greater than 90 min, a second dose is given (Ch 86, ref. 131).

c *Actinomyces*.

1301

108.128.13 ADDITIONAL DOSAGES.

1302

Streptococcal infections, Table 35-2; anaerobic infections, Table 41-10; tetanus, Table 43-2; leptospirosis, Table 44-4; Lyme borreliosis, Table 45-3; actinomycosis, Table 49-2; feline abscesses, Table 52-3; musculoskeletal infections, Table 86-3; bacteremia and endocarditis, Table 87-6; hepatobiliary infections, Table 90-5; CNS infections, Table 92-5; local ocular infections, Table 93-5.

108.128.13 DISPENSING INFORMATION.

Give all PO tablets at least 1 hr before, or 2 hr after feeding.

108.129.1 PENICILLIN V POTASSIUM (PHENOXYMETHYLPENICILLIN)

108.129.1 CLASS.

Penicillin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.129.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.129.3 MORE INFORMATION.

PENICILLIN G.

108.129.4 PHARMACOKINETICS.

Acid stable with absorption two to five times greater than penicillin G from GI tract after oral administration. For distribution in tissues and body fluids, see PENICILLIN G.

108.129.5 SPECTRUM.

See PENICILLIN G. Same as for penicillin G except less active against *Salmonella*, *Escherichia*, *Proteus*, *Fusobacterium*, *Eubacterium*.

108.129.6 INDICATIONS.

Preferred oral therapy when narrow- spectrum penicillin is indicated; borreliosis, streptococcal infections, staphylococcal infections.

108.129.7 CONTRAINDICATIONS.

See PENICILLIN G.

108.129.8 ADVERSE REACTIONS.

See PENICILLIN G.

108.129.9 INTERACTIONS.

See PENICILLIN G.

108.129.14 DISPENSING INFORMATION.

Give at least 1 hr before or 2 hr after feeding pet.

108.130 PENTAMIDINE ISETHIONATE

108.130.1 CLASS.

Aromatic diamidine.

108.130.2 ACTION.

Interferes with nuclear metabolism and inhibits the synthesis of DNA, RNA, proteins and phospholipids.

108.130.3 MORE INFORMATION.

[Chapter 71](#); [Table 71-1](#); for inhalation therapy, reference: [Ch 71](#), ref. 36; 85

108.130.4 PHARMACOKINETICS.

Not absorbed from GI tract after PO administration. Must be given IV, topical (by inhalation), or IM (well absorbed). Lung tissue levels are lower after parenteral injection than by nebulization. One third excreted unchanged in urine within a few hours, but urinary excretion continues for weeks.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.130.5 SPECTRUM.

Acanthamoeba, *Pneumocystis*, *Leishmania*, *Babesia*. Less effective: for treatment of babesiosis, diminazene, imidocarb, or amicarbalide are preferred if available.

108.130.6 INDICATIONS.

Invasive acanthamebiasis not involving the CNS. *Pneumocystis carinii* pneumonia by inhalation (nebulization). May add trimethoprim-sulfonamide plus pentamidine for some *Babesia* infections.

108.130.7 APPROVED USES.

Humans: aerosolized drug for prophylaxis of *Pneumocystis* pneumonia.

108.130.8 CONTRAINDICATIONS.

Renal failure: elimination is impaired but renal elimination is a minor factor in dogs.

1302

108.130.9 ADVERSE REACTIONS.

1303

Systemic therapy (IV or IM): hypotension (vasodilation and reduced blood pressure); systemic anaphylaxis, nausea, salivation, vomiting, diarrhea; hypoglycemia (islet cell necrosis and hyperinsulinemia), then diabetes mellitus; myelosuppression; renal failure. Hypocalcemia and hypokalemia are frequent. To avoid allergic reactions, pretreatment with antihistamines just before administration is recommended. IM use causes pain or necrosis at the site of injection. **Inhalation therapy** is associated with lower toxicity. In dogs results in cilia loss, epithelial atrophy, submucosal hemorrhage in the nasal passages.

108.130.10 INTERACTIONS.

Concomitant use of potentially nephrotoxic drugs should be avoided.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection	300 mg/vial	<i>Pentam</i> (Lyphomed)
	Powder for aerosolization	300 mg/vial	<i>NebuPent</i> (Lyphomed)
Veterinary	Solution for injection	40 mg/ml in 20-ml vial	<i>Lomidine</i> (Merial)

108.130.11 INTERNATIONAL PREPARATIONS.

Pentacarinat; *Pneumopent*.

108.130.12 HANDLING.

Store powders away from light at controlled room temperature. For aerosolization reconstitute with sterile water (6 ml) to 50 mg/ml. For IM dissolve in 3 ml sterile water. For IV dissolve in 3-5 ml sterile water or 5% dextrose; can be further diluted into 50-250 ml of 5% dextrose. Do not dilute with any other solution or precipitate will form. Solution stable for 48 hr at room temperature.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.130.13 **ADMINISTRATION.**

Aerosol: fit mask over the dog's muzzle. **IV:** give over 60 min to reduce risk of hypotension. Should monitor for azotemia once or twice weekly. Do not give IV or SC. People administering drug in this manner should wear face masks and protective eyewear to prevent exposure to nebulized drug. **IM:** give deep injection in a large muscle or split dose at several sites. Use aseptic technique with a new needle at each site. In dogs, the IP route can be used by diluting product with 10 volumes physiologic saline and using long needles.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Human				
Acanthamebiasis	4.0	IV or IM	24	28
<i>Pneumocystis</i> prophylaxis	1.3	Aerosolized	24	7 days every 4th week
Leishmaniasis ^a	4.0	IM, IP	48	30 to 40
Leishmaniasis	4.0	IM	72	24 ^b
Babesiosis	4.0	IM	24	1
a Alternate with meglumine (<i>Glucantime</i>) if resistant to treatment.				
b This cycle of 8 injections is repeated after a 3-week interval (Ch 71, ref. 77).				

108.130.14 **ADDITIONAL DOSAGES.**

Pneumocystosis, [Table 68-2](#); babesiosis, [Table 77-3](#).

108.131 **PENAMIDINE ISETHIONATE**

108.131.1 **CLASS.**

Aromatic diamidine.

108.131.2 **ACTION.**

Antiprotozoal.

108.131.3 **MORE INFORMATION.**

See PENTAMIDINE as an alternative and closely related drug; [Chapter 71](#); [Table 71-1](#).

108.131.4 **SPECTRUM.**

Babesia.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.131 **5** INDICATIONS.

Second choice for babesiosis, other aromatic diamidines (e.g., imidocarb) are preferred for dogs and cats.

108.131 **6** CONTRAINDICATIONS.

See PENTAMIDINE.

108.131 **7** ADVERSE REACTIONS.

Vomiting, diarrhea, nervous signs, anaphylaxis, urticaria. See PENTAMIDINE, antihistamine (oxememazine) included to counter allergic reactions and irritation at the injection site.

108.131 **8** INTERACTIONS.

See PENTAMIDINE.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Solution for injection	15 mg/ml in 10-ml ampules with 1 mg/ml oxememazine	<i>Oxopirvedine</i> (Merial)

1303

108.131 **9** HANDLING.

May be diluted in sterile 5% dextrose solution immediately before injection.

108.131 **10** ADMINISTRATION.

One 10-ml ampule can be given (SC preferred) for each 8.5 to 12.5 kg body weight. The dose can be given in one dose or divided in two doses given at a 24-hr interval.

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Babesiosis (<i>B. gibsoni</i>)	7.5	IM, SC	24	2
	15–20	IM, SC	24	1

1304

108.131 **11** ADDITIONAL DOSAGES.

Babesiosis, [Table 77-3](#).

108.132 **1** PIPERACILLIN SODIUM

108.132 **1** CLASS.

Semisynthetic penicillin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.132.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis.

108.132.3 MORE INFORMATION.

[Chapter 34](#), Penicillins; [Table 34-1](#).

108.132.4 PHARMACOKINETICS.

Not absorbed from the GI tract so administered parenterally. Penetrates blood-brain barrier. CSF-serum concentration ratio is 0.06 in noninflamed states and 0.3 in inflammation. Larger volume of distribution and more rapid clearance in pregnancy. Undergoes both biliary and renal excretion; can be used with renal compromise or biliary or hepatic dysfunction and to treat hepatobiliary infections. Majority (60%-80%) of dose is renally excreted.

108.132.5 SPECTRUM.

Gram positive: *Enterococcus*, *Streptococcus*, non β -lactamase-producing *Staphylococcus*. **Gram negative:** *Escherichia*, *Proteus*, *Serratia*, *Klebsiella*, *Enterobacter*, *Citrobacter*, *Salmonella*, *Shigella*, *Pseudomonas* (synergistic with aminoglycosides), *Yersinia*. **Anaerobes:** *Actinomyces*, *Bacteroides*, *Clostridium*, *Eubacterium*, *Fusobacterium*, *Peptococcus*, *Peptostreptococcus*. **Others:** against *Pseudomonas*, use in combination with an aminoglycoside. Combine for treatment of bacteremia, endocarditis, osteomyelitis, pneumonia; use alone in treating of meningitis, urinary infection, invasive otitis. Combination with β -lactamase inhibitor, tazobactam, which increases spectrum to include resistant *Escherichia*, *Enterobacter*, *Pseudomonas*, *Enterococcus*. Useful combination to treat skin, soft tissue, respiratory, intraabdominal, gynecologic infections.

108.132.6 INDICATIONS.

Serious infections of abdomen, urinary, genital, lower respiratory tracts, skin, soft tissue, bone, joints, septicemia. Prophylaxis for intraabdominal surgery. To treat suspected polymicrobial infections, singly, before isolation of causative organisms.

108.132.7 CONTRAINDICATIONS.

Reduce dose in severe renal or hepatic failure.

108.132.8 ADVERSE REACTIONS.

Local or systemic allergic reactions such as thrombophlebitis or anaphylaxis. Sudden endotoxin release when treating sepsis. Low toxicity characteristic of the penicillin group. Occasional diarrhea, azotemia, reversible neutropenia, thrombocytopenia, hemorrhagic manifestations.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.132.9 INTERACTIONS.

Prolongs action of some muscle relaxants.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	2g, 3g, 4g, 40g	Pipracil (Lederle)

108.132.10 INTERNATIONAL PREPARATIONS.

Avocin, Ivacin, Picillin, Pipcil, Piperacine, Pipérilline, Piperzam, Pipril.

108.132.11 HANDLING.

Stable in sterile water, 0.9% NaCl, 5% dextrose. Should not be refrigerated or frozen, stable for 24 hr at room temperature. **IV:** can also use Ringer's or lactated Ringer's or additives such as 40 mmol/L KCl; dissolve powder in at least 5 ml diluent, then add to desired infusion. **IM:** dilute to 2 g/5 ml, can use 0.5%-1.0% lidocaine without epinephrine. Do not mix with aminoglycosides or will cause inactivation.

108.132.12 ADMINISTRATION.

IV for serious infections: given as a 20- to 30-min infusion every 4-6 hr. IV bolus over 3-5 min is shortest possible duration but risks phlebitis. For surgical prophylaxis, begin IV infusion 30 min before incision and continue no longer than 24 hr afterward. **IM:** limit to 2 g (5 ml) per site, use large muscle, avoid peripheral nerves.

Dosage				
INDICATIONS (Dogs)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Skin infection, bacteremia	25-50 mg/kg	IV, IM	8-12	prn

108.132.13 ADDITIONAL DOSAGES.

Bacteremia and endocarditis, [Table 87-6](#); respiratory infection, [Table 88-8](#).

1304

108.133 PIPERACILLIN-TAZOBACTAM

1305

108.133.1 CLASS.

Semisynthetic penicillin + β -lactamase inhibitor in 8 : 1 ratio.

108.133.2 ACTION.

Bactericidal; inhibits bacterial cell wall synthesis and β -lactamase activity.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.133.3 MORE INFORMATION.

See other β -lactam- β -lactamase inhibitor combinations such as AMPICILLIN-SULBACTAM, TICARCILLIN-CLAVULANATE, AMOXICILLIN-CLAVULANATE; [Chapter 34](#); [Tables 34-1](#) and [34-2](#).

108.133.4 PHARMACOKINETICS.

Tazobactam does not affect pharmacokinetics of piperacillin. High, rapid onset of plasma concentration after IV infusion. Piperacillin is partially metabolized to an active metabolite, whereas tazobactam is metabolized to an inactive form. About 70% of piperacillin and 80% of tazobactam are excreted unchanged in urine, and there is some biliary excretion.

108.133.5 SPECTRUM.

Gram positive: see PIPERACILLIN. **Gram negative:** See PIPERACILLIN. *Acinetobacter*, *Klebsiella*. **Anaerobes:** see PIPERACILLIN. **More effective:** piperacillin alone is active against most *Streptococcus*, some *Pseudomonas*, many Enterobacteriaceae. Adding tazobactam extends the spectrum to include *Staphylococcus*, more anaerobes, and additional gram-negative bacteria, including *Acinetobacter* and *Klebsiella*.

108.133.6 INDICATIONS.

Lower respiratory tract, skin, soft tissue, intraabdominal, gynecologic infections. Treatment of bacteremia or life-threatening infections in neutropenic or immunocompromised hosts. For piperacillin-resistant bacteria.

108.133.7 APPROVED USES.

For humans with resistant intraabdominal, cutaneous, and lower respiratory tract infections.

108.133.8 CONTRAINDICATIONS.

Lower dosage advisable in renal impairment. Previous allergic reaction to penicillins, cephalosporins, or β -lactamase inhibitors.

108.133.9 ADVERSE REACTIONS.

Vomiting, diarrhea, systemic allergies, leukopenia, elevated liver enzymes, hyperbilirubinemia.

108.133.10 INTERACTIONS.

Not compatible in solution with lactated Ringer's, Ringer's, aminoglycosides but can infuse separately. False-positive urine glucose with copper reduction methods.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	2g, 3g, 4g piperacillin with 0.25g, 0.375g, 0.5g tazobactam, respectively	Zosyn (Lederle)

Infectious Diseases of the Dog and Cat, 3rd Edition

108.133.11 INTERNATIONAL PREPARATIONS.

Fluxapril, Tazobac, Tazobac, Tazocilline, Tazocin.

108.133.12 HANDLING.

Reconstitute powder in at least 5 ml, then place into IV fluid (0.9% NaCl, 5% dextrose). Compatible with 40 milliequivalents of KCl added. Stability of stock solutions is 24 hr at room temperature or 48 hr if refrigerated.

108.133.13 ADMINISTRATION.

IV: 30-min infusions every 6 hr, usually treat for 1 week in hospitalized animals.

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE (g/dog)	ROUTE	INTERVAL (hr)	DURATION (days)
Bacterial sepsis	3.4	IV	6	7
	4.5	IV	8	7

108.133.14 ADDITIONAL DOSAGES.

Intraabdominal infections, [Table 89-21](#).

108.134.1 PONAURIL

108.134.1 CLASS.

Triazinon; toltrazuril-sulfone.

108.134.2 ACTION.

Anticoccidial developed for the treatment of equine protozoal myeloencephalitis caused by *Sarcocystis neurona*.

108.134.3 MORE INFORMATION.

See TOLTRAZURIL, below and Neosporosis, [Chapter 80](#).

108.134.4 PHARMACOKINETICS.

Studies in other animals such as the horse and mouse show good absorption from GI tract following oral administration. Widely distributed in tissues and body fluids including the CSF. Repeated administration at the pharmacologic dose does not lead to drug accumulation in serum or CSF. Serum concentrations are approximately 30 times those in CSF. The drug is a weak acid with high lipid solubility and, as a result,

Infectious Diseases of the Dog and Cat, 3rd Edition

should penetrate many tissues and cross the blood-brain barrier. Inflammation in the CNS associated with treated infections should aid in penetration.

108.134.5 SPECTRUM.

Coccidia and members of the Apicomplexa. Concentration to kill *Sarcocystis neurona* in vitro is 0.1 to 1.0 µg/ml.

108.134.6 INDICATIONS.

Neosporosis or toxoplasmosis unresponsive to clindamycin or folate synthesis inhibitors such as trimethoprim or pyrimethamine combined with sulfonamides. Has been effective in treatment of experimental *Neospora caninum* infections in calves and mice and *Sarcocystis neurona* infections in horses. Effectiveness in clearing encysted organisms is uncertain.

108.134.7 CONTRAINDICATIONS.

Should avoid in pregnant animals.

108.134.8 ADVERSE REACTIONS.

In horses, oral blisters, loose stools, and skin rashes were noted. At higher dosages inappetence and weight loss were noted as was endometrial edema.

108.134.9 INTERACTIONS.

See TOLTRAZURIL.

1305

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Equine	Oral paste, 15% w/w	127 gram syringes	Marquis (Bayer, USA)

1306

108.134.10 INTERNATIONAL PREPARATIONS.

Same.

108.134.11 HANDLING.

Store at controlled room temperature 15–30°C.

108.134.12 ADMINISTRATION.

Assemble syringe barrel and plunger which is a multidose tool. Rotate dosage ring to proper amount and insert tip of syringe into animal's mouth while depressing the plunger. Lift head to aid in swallowing the paste.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Dogs and Cats</i> Neosporosis or toxoplasmosis	7.5–15	PO	24	28

108.134.13 ADDITIONAL DOSAGES.

Dosage above is extrapolated between that for horses and mice.

108.134.14 DISPENSING INFORMATION.

Drug can be given with or without food.

108.135.1 PRIMAQUINE PHOSPHATE

108.135.1 CLASS.

8-aminoquinolone.

108.135.2 ACTION.

Antiprotozoal; binds to protozoal DNA and alters mitochondria.

108.135.3 PHARMACOKINETICS.

Rapid absorption after PO administration; highest concentrations in liver, brain, lungs, cardiac and skeletal muscle. Metabolizes to compounds with variable activity with small amount (<1%) excreted unchanged in urine.

108.135.4 SPECTRUM.

Hepatozoon, Babesia, Pneumocystis.

108.135.5 INDICATIONS.

Hepatozoonosis.

108.135.6 APPROVED USES.

Human malaria. Being evaluated in combination with clindamycin for pneumocystosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.135⁷ CONTRAINDICATIONS.

Concurrent hemolysis or bone marrow suppression. Concurrent quinacrine or other myelosuppressive drugs, leukopenia, other hemolytic drugs.

108.135⁸ ADVERSE REACTIONS.

Methemoglobinemia, hemolysis (with glucose-6-phosphate dehydrogenase), myelosuppression.

108.135⁹ INTERACTIONS.

Quinacrine increases toxicity.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral tablets	26.3 mg (15 mg active base)	Primaquine phosphate base (Sanofi-Winthrop)

108.135¹⁰ HANDLING.

Store tablets in airtight container away from heat, light, and moisture.

108.135¹¹ ADMINISTRATION.

Check CBC at least once weekly while being treated. May be given with food to avoid GI side effects.

Dosage				
INDICATIONS	DOSE ^a	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs	0.3 (active base) mg/kg	PO	24	14
Cats (<i>Babesia</i>)	0.5 (active base) mg/kg	PO	24	1–3
^a Human dose, extrapolated.				

108.135¹² ADDITIONAL DOSAGES.

Babesiosis, [Table 77-3](#).

108.135¹³ DISPENSING INFORMATION.

Give drug with a small amount of food to reduce vomiting if it occurs.

1306

108.136¹ PROPIONIBACTERIUM ACNES (CORYNEBACTERIUM PARVUM)

1307

108.136¹ CLASS.

Bacterial product, killed bacterial cells.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.136.2 ACTION.

Stimulates macrophage activation resulting in the release of various cytokines. Immunostimulant.

108.136.3 MORE INFORMATION.

[Chapter 2](#); references [Ch 2](#), ref. 80; 10.

108.136.4 SPECTRUM.

Antiviral and immunostimulatory. Stimulates mononuclear phagocytes and interleukin (IL-1, IL-6, tumor necrosis factor).

108.136.5 INDICATIONS.

Canine staphylococcal pyoderma, FeLV infection, feline herpesvirus infection. Aids in achieving clinical remission or improvement in pyoderma of dogs. May increase hematopoiesis in FeLV-positive cats but does not alter viremic status.

108.136.6 CONTRAINDICATIONS.

Canine lymphoma or leukemia with CNS involvement or in animals receiving concurrent glucocorticoids.

108.136.7 ADVERSE REACTIONS.

Fever, chills, lethargy involvement within 24 hr after administration. Localized pain and swelling if IV extravasation occurs. Proliferative glomerulonephritis and chronic active hepatitis with cirrhosis was reported in a dog ([Ch 2](#), ref. 79).

108.136.8 INTERACTIONS.

Not recommended for animals concurrently receiving glucocorticoids. Concurrent antibacterial therapy recommended.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary ^a	Solution for injection	5-ml vials	<i>ImmunoRegulin</i> (Immunovet, Vetoquinol)
	0.4 mg/ml (in ethanol)		
	0.4 mg/ml (in ethanol)	5-ml and 50-ml vials	<i>Equine product EqStim</i> (Immunovet)

^a Human products *Arthrokehlán "A"*, *Coparvax* (Immunovet).

108.136.9 HANDLING.

Unopened vials are stored at room temperature. Keep refrigerated once opened.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.136.16 ADMINISTRATION.

IV or IP. Direct intralesional injection in tumors has also been done. No improvement after 12 weeks indicates that treatment is ineffective and should be discontinued. Some give one injection per month to maintain remission of pyoderma.

Dosage				
INDICATIONS/BODY WEIGHT	DOSE (ml)	ROUTE	INTERVAL	DURATION (weeks)
Dogs				
Pyoderma^a				
7kg	0.250	IV, IP	Twice weekly	2 ^b
7–20kg	0.50	IV, IP	Twice weekly	2 ^b
20–34kg	1.00	IV, IP	Twice weekly	2 ^b
>34kg	2.00	IV, IP	Twice weekly	2 ^b
Cats				
Antiviral				
5lb	0.25	IV, IP	Twice weekly	2 ^b
10lb	0.50	IV, IP	Twice weekly	2 ^c

- a Maximum dose in any dog is 2.0 ml. Some protocols suggest a dosage range of 0.1 to 0.8 ml/dog based on weight.
- b Once weekly thereafter until remission and once monthly after that to maintain clinical improvement.
- c Once weekly thereafter for 3 weeks and once monthly for 2 mo for a total of nine injections. Some protocols for FeLV suggest follow-up with injections once weekly for 20 weeks or longer as needed. Other protocols suggest follow-up with once weekly until clinical remission, and then once per mo.

108.136.17 ADDITIONAL DOSAGES.

None.

108.137 PYRIMETHAMINE (and SULFONAMIDE)

108.137.1 CLASS.

Folic acid inhibitor.

108.137.2 ACTION.

Inhibits dihydrofolate reductase.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.137³ MORE INFORMATION.

Toxoplasmosis and neosporosis, [Chapter 71](#); [Table 71-1](#).

108.137⁴ PHARMACOKINETICS.

After PO administration, well absorbed. Enters many tissues including CNS and CSF. Highly protein bound and suppressive effects of the drug may remain in the plasma for 1-2 weeks. Metabolized by the liver, and metabolites are excreted in urine.

1307

108.137⁵ SPECTRUM.

1308

Protozoa: *Toxoplasma gondii*, *Neospora caninum*, *Pneumocystis carinii*. **Ineffective:** bacteria (pyrimethamine).

108.137⁶ INDICATIONS.

Used for treatment of toxoplasmosis, neosporosis, pneumocystosis in combination with sulfonamides.

108.137⁷ CONTRAINDICATIONS.

Pregnancy because teratogenic. Folate deficiency or previous hypersensitivity. Reduced dose needed with hepatic but not with renal impairment.

108.137⁸ ADVERSE REACTIONS.

Vomiting, leukopenia, myelosuppression, fetal teratogenesis, myelodysplasia. Folate deficiency can be treated with folinic acid at 5-15 mg/day PO or parenterally.

108.137⁹ INTERACTIONS.

Use care in dosing with other folate inhibitors (trimethoprim or methotrexate) or other myelosuppressive drugs.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	25 mg	<i>Daraprim</i> (Burroughs Wellcome)
	Combined product	25 mg pyrimethamine; 500 mg sulfadoxine	<i>Fansidar</i> (Roche)

108.137¹⁰ HANDLING.

Tablets should be stored in airtight containers away from heat, direct light, and moisture. Formulation of smaller dosage sizes can be done by compounding pharmacies.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.137.11 ADMINISTRATION.

If vomiting occurs, give with meals. Periodically check hemogram.

Dosage					
INDICATIONS	DRUG COMBINATION	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs					
Neosporosis	Pyrimethamine plus	1	PO	24	14
	Sulfonamide	60	PO	24	13
	Pyrimethamine plus	1	PO	24	28
	Trimethoprim-sulfonamide	15	PO	12	28
Cat					
Toxoplasmosis	Pyrimethamine plus	0.25–1	PO	24	14–28
	Trimethoprim-sulfonamide	15	PO	12	14–28

108.137.12 ADDITIONAL DOSAGES.

Hepatozoonosis, [Table 74-2](#); toxoplasmosis, [Table 80-3](#); neosporosis, [Table 80-7](#).

108.137.13 DISPENSING INFORMATION.

If GI signs develop, they can be minimized by giving this drug with food.

108.138 QUINACRINE (MEPACRINE) HYDROCHLORIDE

108.138.1 CLASS.

9-aminocridine dye.

108.138.2 ACTION.

Antiprotozoal.

108.138.3 MORE INFORMATION.

Antiprotozoal Chemotherapy, [Chapter 71](#); [Table 71-1](#); Giardiasis, [Chapter 78](#).

108.138.4 PHARMACOKINETICS.

Readily absorbed from GI tract and widely distributed in tissues. Accumulates in liver with slow release up to 2 mo after a single dose. Crosses the placenta.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.138.5 SPECTRUM.

Protozoa: *Coccidia*, *Giardia*, *Leishmania*. **Others:** some tapeworms.

108.138.6 INDICATIONS.

Giardiasis, alternative to nitroimidazoles, sometimes cutaneous leishmaniasis (except caused by *Leishmania aethiopica*, *Leishmania braziliensis*).

108.138.7 CONTRAINDICATIONS.

Hepatic dysfunction, pregnancy.

108.138.8 ADVERSE REACTIONS.

GI upsets, vomiting, diarrhea, CNS signs, fever, blood dyscrasias, dermatologic eruptions, yellow urine, skin, and sclera. Anorexia, lethargy, and pyrexia are common at the prescribed dosage.

108.138.9 INTERACTIONS.

Avoid use with other drugs that cause myelodyscrasias.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral tablets	100 mg	<i>Atabrine</i> HCl (Winthrop); not available in U.S. since 1992.

108.138.10 HANDLING.

More palatable if administered within gelatin capsules. Can add to liquids but is not stable in solution for more than 6 hr so should be used immediately in this form. Solution for intralesional injections in leishmaniasis is prepared by grinding three 100-mg tablets in a mortar to a fine powder. A solution of 30 ml 0.9% NaCl is added. This is filtered through coarse filter paper and rinsed with 0.9% saline. The mixture is filtered through a 5- μ m filter needle into a sterile empty vial. The final concentration is adjusted to 5%.

108.138.11 ADMINISTRATION.

For intralesional injections in leishmaniasis, has been mixed as a 5% solution given at intervals of 3-5 days.

1308

1309

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Giardiasis	50–100 mg/dog	PO	12	3 ^a
	6.6 mg/kg	PO	12	5
Cats				
Coccidiosis	10 mg/kg	PO	24	5

Infectious Diseases of the Dog and Cat, 3rd Edition

a Skip 3 days, then repeat again for one more course of therapy.

108.138.13 ADDITIONAL DOSAGES.

Enteric protozoal infections, [Table 78-2](#); coccidiosis, [Table 81-2](#).

108.138.13 DISPENSING INFORMATION.

Tablets can be crushed and placed in honey or ice cream to increase palatability by masking taste to animals that are difficult to medicate.

108.139.20 QUINUPRISTIN-DALFOPRISTIN

108.139.1 CLASS.

Streptogramin. Combined in the ratio 30 : 70 (w/w). The two components act synergistically.

108.139.2 ACTION.

Against bacterial 50S ribosomal protein synthesis.

108.139.3 MORE INFORMATION.

See QUINUPRISTIN-DALFOPRISTIN; [Chapter 34](#).

108.139.4 PHARMACOKINETICS.

After parenteral administration to people and rodents, they are metabolized in the liver and excreted predominantly in the bile into the intestine.

108.139.5 SPECTRUM.

Gram positive: Methicillin-resistant staphylococci and vancomycin-resistant enterococci, some penicillin-resistant *streptococci*, poor activity against *Enterococcus faecalis* but good against *Enterococcus faecium*. Differentiating between enterococcal species is important for this reason. **Gram negative:** *Moraxella*, *Legionella*, *Neisseria*. **Anaerobes:** *Clostridium perfringens*. **Others:** *Mycoplasma*, *Toxoplasma gondii*.

108.139.6 INDICATIONS.

Bacteremias, nosocomial catheter-related bacteremia, or valvular endocarditis caused by β -lactam or vancomycin-resistant gram-positive bacteria. Complicated cutaneous infections caused by resistant gram-positive organisms. Since this drug is reserved for restricted treatment in people with highly resistant gram-positive bacterial infections, its use in dogs or cats is discouraged.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.139.7 CONTRAINDICATIONS.

Drug clearance reduced with hepatic dysfunction; however, no adjustment for renal impairment.

108.139.8 ADVERSE REACTIONS.

Pain, inflammation, swelling and thrombophlebitis at the site of IV infusion can occur. Occasional arthralgia, myalgia, and hyperbilirubinemia.

108.139.9 INTERACTIONS.

Metabolized by cytochrome P-450 3A4. Potent inhibitor of CYP3A4 and must be used with caution in patients taking drugs that are substrates of 3A4. Will lead to increased serum concentrations of drugs such as nifedipine, midazolam, and cyclosporine. For broader coverage, can be used simultaneously with antimicrobials with gram-negative spectrum such as zatreonam, cefotaxime, ciprofloxacin, and gentamicin against Enterobacteriaceae and *Pseudomonas*.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	IV solution	500 mg (150 Q:350 D)	Synercid I.V. (Rhône-Poulenc Rorer) (Aventis Pharmaceuticals)

108.139.10 INTERNATIONAL PREPARATIONS.

Same

108.139.11 HANDLING.

Use caution to ensure drug is given IV. Never mix with normal saline, heparin, or other drugs. Use only 5% dextrose or sterile water for reconstitution and 5% dextrose for dose infusions. Should phlebitis develop, the dose should be further diluted for the next infusion.

108.139.12 ADMINISTRATION.

Given IV over 1-hr time period, beginning every 8 hr. Should infuse through a central line to avoid vascular or perivascular irritation.

Dosage				
(Human Extrapolation)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Enterococcal bacteremia	7.5	IV	8	prn
Complicated skin infections	7.5	IV	12	prn

Infectious Diseases of the Dog and Cat, 3rd Edition

108.139.13 **ADDITIONAL DOSAGES.**

None.

1309

108.140 **RIBAVIRIN**

1310

108.140.1 **CLASS.**

Nucleoside (guanosine) analog.

108.140.2 **ACTION.**

Antiviral; nucleoside analog that interferes with DNA and mRNA synthesis. Inhibits retroviruses; however, unlike other anti retroviral drugs, it allows DNA synthesis to occur but prevents formation of viral proteins by interfering with capping of viral mRNA. It has weak anticellular activity.

108.140.3 **MORE INFORMATION.**

Ribavirin in [Chapter 2](#); references: [Ch 2](#), ref. 165; 166; 167.

108.140.4 **PHARMACOKINETICS.**

Erythrocytes sequester large amounts of drug. Crosses blood-brain barrier, CSF concentration 50%-100% of blood levels.

108.140.5 **SPECTRUM.**

Virostatic against DNA and RNA viruses, including herpes-, orthomyxo-, pox-, paramyxo-, influenza-, arena-, bunya-, hanta-, and immunodeficiency viruses. Also feline infectious peritonitis virus ([Ch 2](#), ref. 9; 170), canine parainfluenza virus, feline calicivirus. Has not been as effective against feline calicivirus in vivo as in vitro studies suggest.

108.140.6 **INDICATIONS.**

Humans: aerosol therapy of infants with respiratory syncytial virus. IV or PO for adults with influenza A or acute viral hemorrhagic fever, for arthropod-borne encephalomyelitis. Not recommended for coronaviral infection in cats because of poor efficacy whether in aqueous or liposomal encapsulated form ([Ch 2](#), ref. 167).

108.140.7 **APPROVED USES.**

Humans for respiratory syncytial virus.

108.140.8 **CONTRAINDICATIONS.**

Preexisting anemia, leukopenia, thrombocytopenia, pregnancy.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.140.9 ADVERSE REACTIONS.

Toxic in cats when used alone at therapeutic dosages or higher (22 or 44 mg/kg) (Ch 2, ref. 166). Diarrhea, myelotoxicity (megakaryocytic hypoplasia, increased myeloid-erythroid ratio, anemia, leukopenia, thrombocytopenia), increased blood alanine transaminase, alkaline phosphatase, creatine kinase activities, enteritis, hepatocellular vacuolation or necrosis, fetotoxic, teratogenic, GI hemorrhage, and ulceration. Treated cats with calicivirus infection have had increased severity of illness, depressed bone marrow, weight loss, increased hepatic enzymes, icterus. Kittens treated for coronaviral infection had pronounced multifocal hemorrhages throughout body tissues (Ch 2, ref. 166). None of these abnormalities have been found in beagle dogs given 60 mg/kg of ribavirin for 2 weeks, although nonregenerative anemia develops in people and other animals given similar dosages.

108.140.10 INTERACTIONS.

For cats, use at lower dosages in combination with interferon- α . It antagonizes actions of AZT by inhibition of thymidine kinase such that AZT is not phosphorylated.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for reconstitution for aerosol	6g	Virazole (ICN)

108.140.11 HANDLING.

Vials of powder are stored in a dry place at room temperature. Do not mix with any other drug. Solubilize drug with sterile water at final concentration of 20 mg/ml. Reconstituted drug is stable for 24 hr at 20–30°C.

108.140.12 ADMINISTRATION.

Aerosol: dilute in reservoir and nebulize by a small particle aerosol generator. Deliver via face mask, ventilator, oxygen hood. Unfortunately, aerosols can leak and be inhaled by health care personnel. **IV:** relative toxicity and dose have been reduced by incorporation of the drug in liposomes but liposome-encapsulated drug was less effective than free ribavirin in treating coronavirus-infected cats (Ch 2, ref. 167).

Dosage				
INDICATIONS (Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Systemic infections viral	11	PO, IM, IV	24	7
Children	2.5	PO	6	7

108.140.13 ADDITIONAL DOSAGES.

None.

108.140.14 DISPENSING INFORMATION.

Can be given orally by placing powder in gelatin capsules.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.141 **1 RIFAMPIN (RIFAMPICIN)**

108.141 **1 CLASS.**

Ansamycin.

108.141 **2 ACTION.**

Binds to and inactivates bacterial DNA-dependent RNA polymerase while not affecting mammalian cells.

108.141 **3 MORE INFORMATION.**

Similar to rifabutin (*Mycobutin*, *Ansaticpine*); [Chapter 34](#).

108.141 **4 PHARMACOKINETICS.**

Rapid and almost complete absorption from GI tract. Food reduces rate and extent of absorption. High lipid solubility, penetrates most tissues, including CNS. Penetrates cells, including phagocytes, and organisms in extracellular cavitory spaces or caseous lesions, reaching therapeutic concentrations in abscessed tissues and discharges. Metabolized in liver and active metabolites excreted in urine (30%) and bile (70%), in the former as unchanged and metabolized drug.

108.141 **5 SPECTRUM.**

Gram positive: staphylococci, *Rhodococcus*. **Gram negative:** *Bartonella*, *Brucella*. **Others:** *Neisseria*, *Haemophilus*, *Mycobacterium*. Antiviral (adenoviruses, poxviruses) and antichlamydial at very high doses. Some mycobacteria resistant to rifampin may be susceptible to rifabutin.

1310

1311

108.141 **6 INDICATIONS.**

Resistance develops rapidly. Should always be combined with other drugs to improve efficacy and hinder resistance development. Chronic refractory pyoderma, bacterial abscesses, or granulomas. Resistant staphylococcal infections in difficult sites: osteomyelitis, endocarditis, CNS infections, infection of prosthetic implants. Rhodococcosis, granulomatous, mycobacterial infections, brucellosis, chlamydiosis. Can facilitate penetration of other antimicrobials, such as amphotericin B or flucytosine for fungal infections or isoniazid in tuberculosis. Facilitates metabolism and urinary excretion of bile acids, reducing pruritogenic substances.

108.141 **7 APPROVED USES.**

Human mycobacteriosis and *Neisseria* meningitis.

108.141 **8 CONTRAINDICATIONS.**

Reduce dosage in hepatic dysfunction or biliary obstruction. This drug induces its own accelerated metabolism and excretion. In pregnancy, can cause teratogenesis in laboratory animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.141 **ADVERSE REACTIONS.**

Hepatotoxicity: use lower dosages; vomiting, elevated liver enzymes, icterus, hemolytic anemia, thrombocytopenia. Urine, stool, saliva, tears may be discolored orange-red color by drug. CNS disturbances. Higher dosages (30-60 mg/kg PO daily) are more likely to be associated with side effects and should be avoided. Some cats have shown erythema, especially of the pinna, pruritus, dyspnea, and respiratory distress as a result of anaphylaxis, which may require dilute epinephrine and glucocorticoid administration. Pretreatment with antihistamines and reducing the dose has been beneficial in reducing this untoward reaction.

108.141 **INTERACTIONS.**

Accelerates metabolism and may reduce effectiveness of drugs metabolized by microsomal enzymes: glucocorticoids, cardiac glycosides, sulfonyleureas, benzodiazepines, chloramphenicol, doxycycline, digitoxin, ketoconazole, theophylline, barbiturates, verapamil. Hepatotoxicity increased when used with isoniazid or halothane. Inhibits assays for serum vitamin B₁₂ and folate.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral capsules	150 mg, 300 mg	<i>Rifadin</i> (Marion Merrell Dow), <i>Rimactane</i> (Geigy)
	Powder for injection	600 mg	<i>Rifadin IV</i>

108.141 **INTERNATIONAL PREPARATIONS.**

Diabacil, Eremfat, Fenampicin, Fimizina, Rifa, Rifagen, Rifaldin, Rifapiam, Rifcin, Rifocina, Rifoldin, Rimactan, Rimycin.

108.141 **HANDLING.**

Store at room temperature in moisture and light-resistant containers. Powder for injection reconstituted with sterile water. Stability best in 5% dextrose. After reconstitution can store for 4 weeks at room temperature or refrigerated. To make PO suspension (10 mg/ml), mix contents of four 300-mg caps with simple syrup and bring to 120 ml with syrup. Keep refrigerated, stable for 4 weeks. May have to reformulate into smaller dosage capsules for cats by adding cornstarch and placing it in new capsules. Compounding pharmacists can be used to produce optimal dosage formulations.

108.141 **ADMINISTRATION.**

Food interferes with absorption; administer to fasted animal 1 hr before or 2 hr after meals. *Always give in combination* with at least one other drug when treating mycobacteria or other persistent intracellular infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Pyoderma	10	PO	12	prn
	5–10	PO	8–12	prn
Brucellosis	5–10	PO	24	prn ^a
Systemic bacteremia ^b	10	IV, IM	8–12	prn
Cats				
Bartonellosis, mycobacteriosis ^c	5–10	PO	24	14
<p>a For brucellosis, used in combination with doxycycline and a fluoroquinolone (Ch 34, ref. 396a)</p> <p>b Maximum 8 mg/kg/day if hepatic function is impaired.</p> <p>c Use in combination with doxycycline for bartonellosis, see Chapter 54, and for other antimycobacterial drugs, see Chapter 50.</p>				

108.141 **14** ADDITIONAL DOSAGES.

Actinomycosis, Table 49-2; mycobacterial infections, Tables 50-4 and 50-6; *Bartonella*, Table 54-3; CNS infections, Table 92-5.

108.141 **15** DISPENSING INFORMATION.

Give to fasting animal. May cause harmless reddish-orange discoloration of body excretions and secretions.

1311

108.142 **16** RONIDAZOLE

1312

CLASS: Nitroimidazole.

ACTION: See METRONIDAZOLE.

MORE INFORMATION: See TINIDAZOLE, IPRONIDAZOLE.

SPECTRUM: *Tritrichomonas*.

INDICATIONS: Preliminary studies show effectiveness against *Tritrichomonas foetus* infection in cats. At recommended dosages, the drug was effective in clearing infected cats based on PCR and causing clinical resolution of diarrhea. Little or no improvement or clearing was noted in cats treated with lower dosages or placebo, respectively.

CONTRAINDICATIONS: Pregnancy.

ADVERSE REACTIONS: Not noted, although metagenesis is possible.

INTERACTIONS: See METRONIDAZOLE.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (Company)
Veterinary	Feed/water additive for trichomoniasis in birds	200-mg sachets	TRICHO PLUS (Oropharma)

HANDLING: Store at room temperature and away from light.

ADMINISTRATION: Mix amount in food or place in gelatin capsules for administration.

Dosage				
INDICATIONS (Cats)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
<i>Trichomonas foetus</i> infection ^a	30–50	PO	12	14

a For additional information, see [Chapter 78](#), Trichomoniasis, Therapy; Reference: [Ch 78](#), 49a.

108.143.1 ROXITHROMYCIN

108.143.1 CLASS.

Macrolide.

108.143.2 ACTION.

Bacteriostatic, interferes with bacteria protein synthesis.

108.143.3 MORE INFORMATION.

See ERYTHROMYCIN; reference: [Ch 34](#), ref. 215.

108.143.4 PHARMACOKINETICS.

Rapidly absorbed from GI tract after PO administration, and 50% bioavailable. Acid stable in stomach, better absorbed than erythromycin. Feeding increases absorption in dogs. High concentration in pulmonary, prostatic, tonsillar, and pleural fluid. Does not enter saliva, milk, or CSF in absence of inflammation.

108.143.5 SPECTRUM.

See ERYTHROMYCIN for bacteria; coccidia.

108.143.6 INDICATIONS.

Respiratory, prostatic, urethral infections.

108.143.7 CONTRAINDICATIONS.

Reduce dose in renal or hepatic dysfunction.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.143.8 ADVERSE REACTIONS.

See ERYTHROMYCIN.

108.143.9 INTERACTIONS.

See ERYTHROMYCIN.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral capsules	150 mg	<i>Rulide</i> (Roussel-Uclaf)

108.143.10 INTERNATIONAL PREPARATIONS.

Assoral, Claramid, Macrosil, Rossitrol, Rotesan, Rotramin, Rulid, Surlid.

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Soft tissue, respiratory, urinary infections	15 mg/kg	PO	24	prn

108.143.11 ADDITIONAL DOSAGES.

Coccidiosis, [Table 81-2](#).

108.143.12 DISPENSING INFORMATION.

May be administered with food.

1312

108.144 SARGRAMOSTIM (GRANULOCYTE MACROPHAGE COLONY-STIMULATING OR HEMATOPOIETIC GROWTH FACTOR, GM-CSF)

1313

108.144.1 CLASS.

Cytokine, Glycoprotein.

108.144.2 ACTION.

Stimulates myeloid progenitors in bone marrow and T lymphocytes. Affects both peripheral monocytes and tissue macrophages. Treated macrophages exhibit enhanced conidial phagocytosis and hyphal damage against fungi. GM-CSF given before glucocorticoids, blocked the immunosuppressive effect against *Aspergillus* infections in mice. Can act synergistically with TNF- α in experimental murine and clinical human infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.144.3 MORE INFORMATION.

Chapters 2 and 58; references: Ch 2, ref. 37; 37a; 124a; 3.

PHARMACOKINETICS: In people, following IV administration, drug is detected in serum from 3-6 hr. With SC injection, was detected up to 6 hr. Clearance was the same regardless of lyophilized or liquid preparations.

108.144.4 INDICATIONS.

To stimulate production and function of neutrophils and monocytes. In dogs, for short-term use in treating neutropenia from whole body irradiation, parvovirus and *Ehrlichia* infections, myelosuppressive drugs. Potential uses in cats are leukopenias associated with feline panleukopenia virus, FIV, and FeLV infections, myeloproliferative disease, lymphoid tumors, aplastic anemias. Best for short-term (≤ 21 days) use for treatment of neutropenia caused by infectious agents, chemotherapy, or total body irradiation. Neutropenia caused by toxins (e.g., cancer chemotherapeutics, estrogens, chloramphenicol, trimethoprim-sulfonamides) or infections (e.g., ehrlichiosis, parvoviral infections).

108.144.5 CONTRAINDICATIONS.

Treatment for longer than 3 weeks.

108.144.6 ADVERSE REACTIONS.

Bone discomfort or splenomegaly, allergic reactions. High doses of recombinant human GM-CSF in dogs (150 $\mu\text{g/kg}$) induces antibodies by 10-12 days of treatment that have been thought to blunt the leukocytosis. In cats, a majority of rhGM-CSF treated animals had similar increases in antibodies by 35 days of treatment; however, no blunting of the leukocytosis was observed (Ch 2, ref. 3)

AVAILABILITY	TYPE	SIZE	PREPARATION (COMPANY)
Human	Powder for injection.	250 μg vial	<i>Leukine</i> (Berlex)
	lyophilized		
	Liquid	500 $\mu\text{g/ml}$	<i>Leukine</i> (Berlex)

108.144.7 HANDLING.

Lyophilized drug is reconstituted with sterile water and used immediately as there are no preservatives. If reconstituted with bacteriostatic water (containing 0.9% benzyl alcohol, can be stored for 20 days. If newly and old stored solutions are mixed, the duration of storage prior to dosage is only 6 hours. The vial should not be frozen or exposed to sunlight. Storage of opened liquid and reconstituted solutions is by refrigeration at 2–8°C for 20 days.

108.144.8 ADMINISTRATION.

Can be given SC or IV. Should give along with supportive care such as concurrent blood transfusions for concurrent anemia or thrombocytopenia or antibiotics for leukopenia. For SC use, no further dilution is

Infectious Diseases of the Dog and Cat, 3rd Edition

needed. For IV use, should be further diluted to 5-15 µg/ml with addition of 0.9 % saline. Albumin is added (12 mg/ml) to prevent absorption to plastics when drug is diluted.

Dosage				
INDICATIONS (Neutropenia)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs	150	SC	24	≤21
Cats	5	SC	12	≤21

108.144.9 ADDITIONAL DOSAGES.

FIV infection, [Table 14-5](#): Reference [Ch 2](#), ref. 3).

108.145.5 TERRATIA MARCESCENS (BESM, IMUVERT®) IMMUNOSTIMULANT. SEE [CHAPTER 2](#)

108.146.3 SPECTINOMYCIN

108.146.4 CLASS.

Aminocyclitol related to aminoglycoside.

108.146.2 ACTION.

Usually bacteriostatic; inhibits bacterial protein synthesis by acting on 30s ribosomal subunit.

108.146.3 MORE INFORMATION.

Related to a new derivative trospectomycin, *Spexil* (Pharmacia & Upjohn).

108.146.4 PHARMACOKINETICS.

Minor (<8%) absorption from GI tract. When given orally, used to reduce intestinal microflora or treat enteric pathogens. Rapid absorption after IM injection. Tissue concentrations are lower than in blood. Like aminoglycosides, does not enter CSF or ocular tissues and only slightly with inflammation. Majority (70%-80%) excreted in urine as active drug.

108.146.5 SPECTRUM.

Gram positive: *Streptococcus*. Gram negative: *Proteus*, *Enterobacter*, *Salmonella*, *Escherichia*, *Klebsiella*. **Anaerobes:** little activity. **Others:** some *Mycoplasma*. **More effective:** most effective single agent for gram-negative bacteria in chemoprophylaxis of open bowel surgery. Used in people to treat gonorrhea. **Less effective:** *Chlamydia*, spirochetes, *Pseudomonas*.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.146.6 INDICATIONS.

Intraabdominal infections or prophylaxis for abdominal surgery. If used orally, for bacterial gastroenteritis or to reduce enteric flora in cases of hepatic encephalopathy.

108.146.7 APPROVED USES.

As single injection for penicillin-resistant human gonococcal infections.

1313

108.146.8 CONTRAINDICATIONS.

Pre-existing renal failure, hypersensitivity to this drug.

1314

108.146.9 ADVERSE REACTIONS.

Pain or irritation at injection site; elevation in blood hepatic enzymes and urea with repeated doses. Less ototoxic and nephrotoxic than aminoglycosides. Cholestatic hepatitis in people. Can cause neuromuscular blockade, reversible with IV calcium.

108.146.10 INTERACTIONS.

Effectiveness reduced when used with tetracycline or chloramphenicol. Can combine with lincomycin for increased efficacy against *Mycoplasma*.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection	2 g (as HCl)	<i>Trobicin</i> (Pharmacia & Upjohn)
	Powder for oral suppression	2 mg/m, 4g/ml	
Veterinary	Solution for injection (poultry approval)	100 mg/ml	<i>Spectam</i> (Sanofi)

108.146.11 INTERNATIONAL PREPARATIONS.

Kempi, Stanilo, Trobicine.

108.146.12 HANDLING.

Store at room temperature. Mix powder well after diluting. Stable 4 weeks at room temperature, although it is recommended to use reconstituted drug within 24 hr.

108.146.13 ADMINISTRATION.

Administer IM in large muscle.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Prophylactic for bowel surgery, peritonitis	10 mg/kg	IM, SC	8–12	^a
^a Immediately before and during surgery.				

108.146 ¹⁴ ADDITIONAL DOSAGES.

None.

108.147 ¹⁵ SPIRAMYCIN

108.147 ¹ CLASS.

Macrolide.

108.147 ² ACTION.

Bacteriostatic; inhibits bacterial protein synthesis; binds to 50 s ribosomal subunits.

108.147 ³ MORE INFORMATION.

See ERYTHROMYCIN, METRONIDAZOLE (interactions); Antiprotozoals, [Chapter 71](#); [Table 71-1](#).

108.147 ⁴ PHARMACOKINETICS.

Incompletely absorbed from GI tract, unaffected by food. Widely distributed except in CSF. Metabolized in liver to active metabolites with a majority excreted in the bile and 10% in urine. Enters milk. Persists in some tissues.

108.147 ⁵ SPECTRUM.

Anaerobic bacteria: *Campylobacter*, *Helicobacter*. Similar antibacterial spectrum as erythromycin but less active. **Others:** *Toxoplasma*, *Cryptosporidium*.

108.147 ⁶ INDICATIONS.

Toxoplasmosis, cryptosporidiosis. Combined with metronidazole for periodontitis and stomatitis.

108.147 ⁷ CONTRAINDICATIONS.

Preexisting hepatic disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.147.8 ADVERSE REACTIONS.

Irritating after IM injection. Vomiting and diarrhea (similar to erythromycin), allergic reactions, cholestatic hepatitis. Cutaneous irritation to veterinarians exposed to the drug during preparation or administration.

Coccidiosis, [Table 81-2](#); oral infections, [Table 89-4](#).

108.147.13 DISPENSING INFORMATION.

Do not break or crush tablets.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.148.1 STAPHYLOCOCCAL PHAGE LYSATE

108.148.1 CLASS.

Immunostimulant.

108.148.2 ACTION.

Increases immune response against *Staphylococcus*. Stimulates production of interleukin- γ , interleukin-6, tumor necrosis factor, and γ -interferon.

108.148.3 MORE INFORMATION.

[Chapter 2; Table 2-3](#); references: [Ch 2](#), ref. 26a; 78.

108.148.4 FORMULATION.

Bacteriologically sterile preparation containing cell wall components of *S. aureus*, a bacteriophage, and some culture media, in solution. Each ml of solution contains 120-180 CFU of *S. aureus* before phage lysis.

108.148.5 INDICATIONS.

Chronic or recurrent pyoderma in dogs caused by staphylococci.

108.148.6 CONTRAINDICATIONS.

Previous severe hypersensitivity reaction to the product.

108.148.7 ADVERSE REACTIONS.

Possible anaphylaxis. Rare fever, chills. Transient swelling, redness, and pruritus at site of inoculation.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Solution for injection	1-ml ampules, 10-ml multidose vials	<i>Staphage Lysate</i> (Delmont Labs)

108.148.8 HANDLING.

Store refrigerated (2–8°C). Do not freeze. Use entire contents when vial is opened. No preservatives, so must be handled aseptically. Should not use if solution is cloudy.

108.148.9 ADMINISTRATION.

Concomitant antibiotic therapy is recommended for the initial 4- to 6-week treatment period. Subcutaneous injection: to test for hypersensitivity, can perform intradermal skin test of 0.05 to 0.1 ml. Should precede

Infectious Diseases of the Dog and Cat, 3rd Edition

initial use. Observe animal and inoculation site for 1 hr for immediate reactions and 48 hr for delayed reactions. Allergic reactions may require epinephrine administration.

Dosage				
INDICATIONS	DOSE (ml)	ROUTE	INTERVAL (hr)	DURATION (days)
Canine pyoderma	0.1–0.2	SC	3–7	^a
	0.5	SC	Twice weekly	10–12 weeks ^b
<p>a *Increase dose in increments every 3–7 days until dose is 1.0 ml. Maximum dose in large dogs is 1.5 ml.</p> <p>b Then 0.5–1.0 ml every 1–2 weeks. The interval may be lengthened to the longest interval that maintains control of the disease.</p>				

108.148.10 ADDITIONAL DOSAGES.

None.

108.148.11 DISPENSING INFORMATION.

Observe the injection site for pain, swelling, or discharge. Should this develop, the dosage can be reduced.

1315

108.149 STAPHYLOCOCCAL PROTEIN A

1316

108.149.1 CLASS.

Bacterial extract, IgG binding reagent used for its affinity to purify mixtures of Ig.

108.149.2 ACTION.

Immunostimulant; activates antibody synthesis, interferon induction, lymphocytes; binds immune complexes. Binds the Fc portion of antibodies (IgG class) by a nonimmune mechanism, without disturbing antigen binding. Reaction is generally not species specific.

108.149.3 MORE INFORMATION.

See [Chapters 2](#) and [13](#), References: [Ch 2](#), ref. 13; 75; 83; 163; 102.

108.149.4 PHARMACOKINETICS.

Unknown.

108.149.5 INDICATIONS.

FeLV-viremic cats with clinical signs caused by immunosuppression.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.149.6 APPROVED USES.

Reagent grade chemical for experimental purposes.

108.149.7 CONTRAINDICATIONS.

Previous hypersensitivity to this compound or closely related compounds.

108.149.8 ADVERSE REACTIONS.

Anaphylaxis, low-grade peritonitis.

108.149.9 INTERACTIONS.

None.

AVAILABILITY	TYPE	SIZE	PREPARATION (COMPANY)
5 mg	Lyophilized powder (reagent grade)	3 ml volume dilutes	Pharmacia Biotech

108.149.10 HANDLING.

Powder (5 mg) is reconstituted according to manufacturer's recommendations in 3 ml sterile water using sterile technique. The resulting solution is filtered through a 0.3 μ filter and added to 500 ml of sterile saline to give 10 μ g/ml concentration. This is frozen (-20°C) in 5-ml aliquots, which can be frozen for several years. The solution should not be refrozen after thawing, and self-defrosting freezers with freeze-thaw cycles should be avoided.

108.149.11 ADMINISTRATION.

Clip fur from abdominal wall, scrub to remove surface bacteria with detergents. Give injection IP.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL	DURATION (weeks)
FeLV	10 mg/kg	IP	twice weekly	10 ^a
a Then once a month for the life of the animal.				

108.149.12 ADDITIONAL DOSAGES.

None.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.150.1 **STIBOGLUCONATE (SODIUM)**

108.150.1 **CLASS.**

Pentavalent antimonial.

108.150.2 **ACTION.**

Antiprotozoal: interferes with energy metabolism of *Leishmania* amastigotes.

108.150.3 **MORE INFORMATION.**

See MEGLUMINE ANTIMONIATE; [Chapter 71, Table 71-1](#); References [Ch 71](#), ref. 3.

108.150.4 **PHARMACOKINETICS.**

Rapid systemic availability after parenteral administration, attains high serum concentrations, most of drug is excreted in urine within 24 hr. Some accumulation and with delayed excretion occurs after multiple doses.

108.150.5 **SPECTRUM.**

Leishmania. Some increased resistance has been noted.

108.150.6 **INDICATION.**

Leishmaniasis.

108.150.7 **CONTRAINDICATIONS.**

Preexisting cardiac arrhythmias or renal dysfunction.

108.150.8 **ADVERSE REACTIONS.**

Musculoskeletal pain or injection, increased hepatic transaminases (usually reversible), pancreatitis, myocardial injury, hemolytic anemia, leukopenia, vomiting, diarrhea, cardiac arrhythmias, renal dysfunction, shock, sudden death. IV use can cause thrombophlebitis. In people, children tolerate the drug better than adults.

108.150.9 **INTERACTIONS.**

Has been combined with paromomycin or pentamidine for resistant leishmaniasis.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Solution for parenteral injection. Not available in U.S. for animal use, only for humans through CDC, Atlanta, GA, (404) 639-3670; available in other countries	100 mg antimony/ml in 100 ml multidose vials	<i>Pentostam</i> (Glaxo Wellcome)

108.150 ¹⁰ HANDLING.

Protect from ultraviolet light. Can sterilize solutions by autoclaving.

108.150 ¹¹ ADMINISTRATION.

Give IV or IM. If adverse reactions occur, can give on alternate days for longer periods. If given IV, should do it slowly (over 5 min) through a fine needle or catheter to avoid thrombophlebitis.

1316

1317

Dosage				
INDICATIONS (Human)	DOSE ^a (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Leishmaniasis (cutaneous)	10–20 antimony	IM	24	20
Leishmaniasis (visceral)	20 antimony	IM, IV	24	20–28

^a Doses are expressed as equivalent antimony.

108.150 ¹² ADDITIONAL DOSAGES.

Leishmaniasis, [Table 73-4](#).

108.151 ¹ STREPTOMYCIN

108.151 ¹ CLASS.

Aminoglycoside.

108.151 ² ACTION.

Bactericidal; interferes with bacterial protein synthesis.

108.151 ³ MORE INFORMATION.

See GENTAMICIN; Aminoglycosides, [Chapter 34](#); [Tables 34-5](#) and [34-6](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.151 ⁴ PHARMACOKINETICS.

See GENTAMICIN.

108.151 ⁵ SPECTRUM.

Gram positive: some *Streptococcus*. **Gram negative:** *Escherichia*, some *Pasteurella*, *Salmonella*, *Yersinia*, *Francisella*, *Brucella*. Bacterial resistance is common with this aminoglycoside. **Others:** *Mycobacterium tuberculosis*.

108.151 ⁶ INDICATIONS.

Brucellosis, tularemia, plague, mycobacteriosis. Should always be used in combination.

108.151 ⁷ CONTRAINDICATIONS.

Avoid use in cats because of toxicity. Avoid with renal insufficiency, myasthenia gravis.

108.151 ⁸ ADVERSE REACTIONS.

Ototoxicity, neuromuscular blockade, renal damage.

108.151 ⁹ INTERACTIONS.

Ototoxicity and nephrotoxicity increased with concurrent diuretics (mannitol, furosemide), cephalosporins.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Injectable solution	400 mg/ml	<i>Streptomycin sulfate</i> (Pfizer); discontinued in U.S.; available only for human use by CDC. Presently for investigational use by veterinarians in U.S. by Roerig, Division of Pfizer; Voice 800-254-4445; Fax 800-251-9445.

108.151 ¹⁰ INTERNATIONAL PREPARATIONS.

Cidan Est, *Novostrep*, *Solustrep*, *Streptocol*, *Strepto-Fatol*.

108.151 ¹¹ HANDLING.

Stored at refrigerated 2–8°C temperatures. If diluted in fluid for IV use, stable for 24 hr.

108.151 ¹² ADMINISTRATION.

IM use only. If insufficient muscle mass, may give dose in 100 ml of 0.9% NaCl or 5% dextrose and administer it over 30-60 min.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Brucellosis	10–20 mg/kg	IM	12	7 ^a
a Dose given for first and fourth week of treatment along with concurrent doxycycline (see Chapter 40 and Table 40-2).				

108.151 ¹³ ADDITIONAL DOSAGES.

Canine brucellosis, [Table 40-2](#); plague, [Table 47-1](#); musculoskeletal infections, [Table 86-4](#).

108.152 ¹⁵² SULFADIAZINE

108.152 ¹ CLASS.

Sulfonamide.

108.152 ² ACTION.

Bacteriostatic; inhibits bacterial folic acid synthesis.

108.152 ³ MORE INFORMATION.

TRIMETHOPRIM-SULFONAMIDE; [Chapter 34](#), Sulfonamides; [Table 34-10](#).

108.152 ⁴ PHARMACOKINETICS.

Rapid absorption after PO administration, 70%-100% absorbed, distributed through body tissues and fluids. Therapeutic levels achieved in eye, CNS, pleura, synovia. Enters placental and fetal tissues. Hepatic metabolism by acetylation. Pantothenic acid deficiency or “slow acetylating” animals may have increased risk of toxicity or accumulation of drug. Metabolites and active drug excreted in urine. Crystals are less soluble in acid urine and with restricted fluid intake.

108.152 ⁵ SPECTRUM.

Gram positive: *Streptococcus*, *Staphylococcus*, *Nocardia*. **Gram negative:** *Klebsiella*, *Proteus*, *Escherichia*, *Shigella*, *Salmonella*. **Anaerobes:** poor in vivo. **Others:** *Pneumocystis*, coccidia, *Toxoplasma*.

108.152 ⁶ INDICATIONS.

Urinary tract infections, meningitis, nocardiosis, otitis media-interna, toxoplasmosis (with pyrimethamine).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.152.7 CONTRAINDICATIONS.

Hypersensitivity to sulfonamides, thiazide diuretics, or local anesthetics that have similar chemical structure. Avoid with blood dyscrasias, renal or hepatic insufficiency.

108.152.8 ADVERSE REACTIONS.

High or overdoses can cause CNS signs or acute vomiting and abdominal pain. Hypersensitivity reactions (see TRIMETHOPRIM-SULFONAMIDE). GI irritation, dermatologic eruptions, polydipsia and polyuria, keratoconjunctivitis sicca. Resembles: goitrogens inhibiting T₄ production; diuretics causing polydipsia, polyuria; sulfonureas causing hypoglycemia.

1317

1318

108.152.9 INTERACTIONS.

Chronic administration results in reduced thyroid hormone synthesis. It may increase warfarin activity, phentoin concentrations, thiopental activity, sulfonurea concentrations in treated animals. Increases toxicity of methotrexate, which also affects folate metabolism.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Tablets	500 mg	Generic (various)

108.152.10 HANDLING.

Store in airtight containers at room temperature.

108.152.11 ADMINISTRATION.

Once daily suitable for urinary tract infections, but twice daily needed to maintain blood and tissue levels. Maintain hydration and adequate fluid therapy, especially in cats.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Soft tissue, urinary infections	30	PO	24	7–14
Cats				
Soft tissue, urinary infections	15	PO	12	7–14

108.152.13 ADDITIONAL DOSAGES.

Nocardiosis, [Table 49-3](#); hepatozoon (with trimethoprim), [Table 74-2](#); see also TRIMETHOPRIM-SULFONAMIDE for combined use in other infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.152¹³ DISPENSING INFORMATION.

Watch for vomiting, diarrhea, systemic illness, or reduced tear production.

108.153¹⁵ SULFADIMETHOXINE

108.153¹ CLASS.

Sulfonamide.

108.153² ACTION.

Bacteriostatic; inhibits bacterial synthesis of folic acid from para-aminobenzoic acid. Antiprotozoal.

108.153³ MORE INFORMATION.

See SULFADIAZINE; the SULFONAMIDES; [Chapter 34](#); [Table 34-10](#).

108.153⁴ PHARMACOKINETICS.

See also SULFADIAZINE. Rapidly absorbed from GI tract. High plasma protein binding allows for sustained blood levels, prolonged excretion, longer dosing intervals. Diffuses especially into tissues that are less acid and in those having high leukocyte concentrations. In the dog, because the drug is excreted unchanged, the potential for drug-induced nephrotoxicity is low.

108.153⁵ SPECTRUM.

Gram positive: *Streptococcus*, *Staphylococcus*. **Gram negative:** *Klebsiella*, *Proteus*, *Escherichia*, *Shigella*, *Salmonella*. **Anaerobes:** poor in vivo. **Others:** coccidia, some activity against *Cryptosporidium*. **Ineffective:** viruses and *Rickettsia*, *Pseudomonas*.

108.153⁶ INDICATIONS.

Treatment of bacterial respiratory, enteric, genitourinary tract, soft tissue infections. Coccidiosis.

108.153⁷ CONTRAINDICATIONS.

Dehydration. See SULFADIAZINE.

108.153⁸ ADVERSE REACTIONS.

Few in dogs, diarrhea at higher than therapeutic dosages. IM injections are too painful to be practical.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.153.9 INTERACTIONS.

Reduced thyroid hormone synthesis with chronic (6 weeks) treatment. See SULFADIAZINE.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Oral tablets (approved dogs and cats)	125 mg, 250 mg, 500 mg	<i>Albon</i> (Pfizer), <i>Bactrovet</i> (Schering-Plough)
	Liquid for injection (approved cats, dogs, horses, cows)	400 mg/ml	<i>Albon</i>
	Oral suspension (approved dogs, cats)	250 mg/5 ml 125 mg/ml	<i>Albon</i> <i>Bactrovet</i>

108.153.10 HANDLING.

Store injectable liquid at room temperature. If crystals form, dissolve by warming slightly.

108.153.11 ADMINISTRATION.

Parenteral liquid: IV or SC to obtain rapid blood levels or to treat anorectic, vomiting, fractious animal. IM route is very painful and should be avoided. PO suspension is custard flavored. Animals should maintain adequate water intake.

1318

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs and Cats				
Systemic infections, coccidiosis	27.5 ^a	IV, IM, PO	24	3–5
Cats				
Coccidiosis	50	PO	24	10
	27 ^a	PO	24	prn ^b

1319

a Give twice this dose the first day.

b Or 48 hr after signs resolve; usual course for coccidiosis may be 14–29 days.

108.153.12 ADDITIONAL DOSAGES.

Coccidiosis, [Table 81-2](#); pyoderma (with ormetoprim), [Table 85-3](#). For combination therapy, see also TRIMETHOPRIM-SULFONAMIDE, ORMETOPRIM-SULFONAMIDE, and BAQUILOPRIM-SULFONAMIDE for treatment of other infections.

108.153.13 DISPENSING INFORMATION.

Make sure animal has access to water at all times.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.154.1 SULFASALAZINE (SALICYLAZOSULFAPYRIDINE)

108.154.1 CLASS.

Sulfonamide.

108.154.2 ACTION.

Inhibits bacterial folic acid synthesis combined to salicylic acid. The salicylate component is believed to be the active moiety, mainly antiinflammatory.

108.154.3 MORE INFORMATION.

See [Chapter 34](#), Sulfonamides; [Table 34-10](#).

108.154.4 PHARMACOKINETICS.

After PO administration, one third of dose is absorbed from small intestine. The remaining two thirds pass to the colon, where it is hydrolyzed by resident microflora to 5-aminosalicylic acid and sulfapyridine; most of the latter is absorbed and metabolized. Within 3 days, 91% of drug and metabolites is recovered in the urine.

108.154.5 INDICATIONS.

Inflammatory large bowel diseases of dogs and cats.

108.154.6 CONTRAINDICATIONS.

Previous hypersensitivity to sulfonamides, intestinal, or urinary obstruction. Use caution in treating cats because of salicylate content.

108.154.7 ADVERSE REACTIONS.

Anorexia, vomiting, hypersensitivity reactions. Use of enteric-coated tablet may alleviate GI side effects in cats. CNS signs (ataxia, depression), polydipsia, polyuria may inhibit thyroid hormone and produce thyroid enlargement (goiter). Orange-yellow discoloration of urine or skin, reduced spermatogenesis; keratoconjunctivitis sicca. Folate-deficiency anemia, especially in cats on long-term treatment. See TRIMETHOPRIM-SULFONAMIDE.

108.154.8 INTERACTIONS.

Reduced thyroid hormone synthesis with chronic (5-6 weeks treatment).

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets ± enteric coating	500 mg	Azulfidine (Pharmacia & Upjohn), generic (various)
	Oral suspension	250 mg/5 ml	Azulfidine

Infectious Diseases of the Dog and Cat, 3rd Edition

108.154.9 INTERNATIONAL PREPARATIONS.

Colo-Pleon, Gastroprotetto, Salazopyrin, Salisulf, Sulazine, Sulfazine.

108.154.10 HANDLING.

Tablets should be stored at room temperature. Shake PO suspension before using and refrigerate after use; do not store longer than 14 days after reconstitution.

108.154.11 ADMINISTRATION.

Give with food if causes vomiting. Subdividing the dose or using enteric-coated tablets helps avoid GI irritation.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Colitis	10–15 ^a	PO	6–8	2–4 ^b
Cats				
Inflammatory bowel disease	10–20	PO	12	14–42
	25 ^c	PO	24	14–42

a Maximum of 1g daily.

b Then re-evaluate treatment response. After 4–5 weeks may reduce dose to 12- to 24-hr interval for 2–3 weeks before discontinuing.

c Maximum of 250 mg total dose (1/2 tablet) can be given every 24 hr.

108.154.12 ADDITIONAL DOSAGES.

Gastroenteric infections, [Table 89-16](#); colitis, [Table 89-19](#).

108.154.13 DISPENSING INFORMATION.

See SULFADIAZINE; watch for reduced tear production.

1319

108.155 SURAMIN

1320

108.155.1 CLASS.

Purine receptor antagonist that is a hexasulfonated naphthyurea.

108.155.2 ACTION.

Antiprotozoal, inhibits angiogenesis, and antitumor agent.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.155.3 MORE INFORMATION.

See SURAMIN; [Chapter 2, Table 2-2](#).

108.155.4 PHARMACOKINETICS.

Not absorbed from GI tract. Highly bound to serum proteins; therefore minimal penetration of the blood-brain barrier. Excreted slowly in the urine following each dose.

108.155.5 SPECTRUM.

Trypanosoma brucei, *Trypanosoma gambiense*, *Trypanosoma b. rhodesiense*.

108.155.6 INDICATIONS.

Treatment of African trypanosomiasis. Active against early stages (see [Chapter 72](#)). Has been used to treat FeLV infections without controlled studies (see [Chapter 2](#)).

108.155.7 CONTRAINDICATIONS.

Renal pathology as determined by the presence of urine casts or biochemical features. Avoid in pregnancy.

108.155.8 ADVERSE REACTIONS.

In people, cloudy urine, transient albuminuria, dermal paresthesias from peripheral neuritis, diarrhea, hypoglycemia, anorexia. Collapse and nephrotoxicity.

108.155.9 INTERACTIONS.

None reported.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human (Germany and South Africa)	Powder for injection	1g vials	<i>Metaret</i> (Bayer) Not available in U.S. or Canada

108.155.10 INTERNATIONAL PREPARATIONS.

Bayer 205, *Germanin*, *Moranyl*, *Fourneau 309*, *Belganyl*, *Naphuride*, *Antrypol*.

108.155.11 HANDLING.

Store in tightly capped container away from moisture at 4°C. Drug is a loose powder that dissolves in water and physiologic saline. Diluted to a 10% concentration. IV therapy is preferred as it can be irritating after IM use.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.155.13 ADMINISTRATION.

Best to give a test dose of 100-200 mg first time over 20-30 min and evaluated for any side effects.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION
Human infant dose for trypanosomiasis	10–15 mg/kg	IV	24 ^a	^b
a 24-hr interval is used for 2–3 days and then subsequent injections are at weekly intervals until a total dose is reached.				
b Administer until a total dose is up to 5g for adults. A second course cannot be repeated until at least 3 mo later.				

108.155.13 ADDITIONAL DOSAGES.

None.

108.156 TEICoplanin

108.156.1 CLASS.

Glycopeptide.

108.156.2 ACTION.

Bactericidal; binds to bacterial cell wall peptidoglycan.

108.156.3 MORE INFORMATION.

See VANCOMYCIN; [Chapter 34](#).

108.156.4 PHARMACOKINETICS.

Not absorbed from GI tract. Usually given IV or IM and 90% bioavailable. After parenteral administration, enters liver, pancreas, bone, mucosal tissues, and peritoneal, biliary, and blister fluids. Poor entry into CNS or CSF with noninflamed meninges. Longer plasma half-life than vancomycin, can give once daily. Little metabolism, most renally excreted unchanged. Slow elimination phase.

108.156.5 SPECTRUM.

Gram positive: Only against gram-positive aerobes and gram-positive obligate anaerobes; more activity and less resistance than with vancomycin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.156.6 INDICATIONS.

β -lactam-resistant gram-positive infections as a result of *Staphylococcus*, *Streptococcus*, *Enterococcus*, *Listeria*, *Corynebacterium*, *Clostridium*. Should be combined with aminoglycoside to treat staphylococcal endocarditis, septicemia, endocarditis, skin, soft tissue, and lower respiratory infections, osteomyelitis. For catheter-induced infections; has also been impregnated on IV catheters for prophylaxis. Orally is not absorbed but is given to treat enterococcal and clostridial enterocolitis.

108.156.7 CONTRAINDICATIONS.

Renal failure. Should monitor function during therapy.

108.156.8 ADVERSE REACTIONS.

Injection site pain (IM) or phlebitis (IV), urticarial rash, eosinophilia, neutropenia, thrombocytopenia, vomiting, diarrhea.

108.156.9 INTERACTIONS.

Synergistic with aminoglycosides, imipenem, and rifampin.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	200 mg, 400 mg	<i>Targocid</i> (Marion Merrell Dow)

1320

108.156.10 INTERNATIONAL PREPARATIONS.

1321

Targocid.

108.156.11 HANDLING.

Do not mix with other drugs in solution. See VANCOMYCIN.

108.156.12 ADMINISTRATION.

Can give over 5-min period compared with 60-min duration required for vancomycin.

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr) ^a	DURATION (days)
Skin, urinary, soft tissue infections	3	IV, IM	24	prn
Systemic infections	6	IV, IM	24	prn
Bacteremia with resistant organisms	12	IV, IM	24	prn

^a Often give twice the dose the first day.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.156 ¹³ ADDITIONAL DOSAGES.

None.

108.157 ¹⁴ TERBINAFINE

108.157 ¹ CLASS.

Allylamine.

108.157 ² ACTION.

Inhibits fungal sterol synthesis via enzyme squalene epoxidase. Antifungal and fungicidal against hyphal organisms such as dermatophytes, *Aspergillus*, *Sporothrix* and less effective against yeast or dimorphic fungi. Has activity against superficial yeasts that cause infections such as *Malassezia* (Ch 57, ref. 45).

108.157 ³ MORE INFORMATION.

Reference Ch 57, ref. 37; 124, 45; Ch 63, ref. 46.

108.157 ⁴ PHARMACOKINETICS.

In people, well absorbed (>70%) from the GI tract. Highly lipophilic and absorption increased when taken with fat; however can be given fasting. Remains in plasma for extended periods of several weeks. Distributed in high concentrations in tissues, skin, sweat, sebum, nail bed, hair. Low amounts in lung tissue which may preclude its use in pulmonary infections. Excreted into milk. Liver metabolizes drug. A majority of the drug (70%) eliminated in the urine. Topical preparations are minimally ($\leq 5\%$) absorbed.

108.157 ⁵ SPECTRUM.

Dermatophytes, some activity against *Sporothrix* and systemic fungi. In combination with itraconazole was somewhat successful in treatment of cellulitis caused by *Pythium insidiosum*. Low effectiveness against yeasts. Three species of dermatophytes from dogs and cats were highly susceptible in vitro to terbinafine (Ch 57, ref. 58). Terbinafine had greater activity than griseofulvin, and oral treatment of animals for up to 39 weeks had no effect on MIC values.

108.157 ⁶ INDICATIONS.

Onychomycosis, dermatophytosis, sporotrichosis, aspergillosis. Reduced treatment time, improved cure rates, and lower relapse rate compared with griseofulvin. Has been used in AMB and azole-resistant asperillosis in people. Poor activity against yeasts and systemic (dimorphic) fungal infections. Generally used in combination with azoles, especially for sporotrichosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.157⁷ CONTRAINDICATIONS.

Reduce dosage in renal failure or hepatic dysfunction. Does not have teratogenic effects and can be used in pregnancy.

108.157⁸ ADVERSE REACTIONS.

GI disturbances, vomiting, abdominal pain, diarrhea. Hepatotoxicity, intrahepatic biliary stasis, increase hepatic enzyme activities, neutropenia, pancytopenia. In people, alopecia and loss of taste sensation. In one evaluation, some of the dogs receiving 30 mg/kg once daily had mild to moderate elevations in serum ALT and ALP when treated for 3-18 weeks.

108.157⁹ INTERACTIONS.

Cimetidine increases blood concentrations while rifampin decreases it. There are very few interactions of this drug compared to those with the azole antifungal agents.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets (as hydrochloride)	125 mg, 250 mg	<i>Lamisil</i> (Sandoz)
	Topical cream (as hydrochloride)	1%	<i>Lamisil</i> (Sandoz)

108.157¹⁰ INTERNATIONAL PREPARATION.

Daskil.

108.157¹¹ HANDLING.

Store tablets at room temperature in an airtight, light-proof container. May have to crush tablets and recompound the drug in gelatin capsules to achieve low dose needed.

108.157¹² ADMINISTRATION.

Some increase in absorption is noted with administration of food. Must treat for extended periods in onychomycosis to become incorporated into nail surface.

1321

Infectious Diseases of the Dog and Cat, 3rd Edition

1322

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Onychomycosis, dermatophytosis	10 ^a	PO	24	42–84
Nasal aspergillosis	5–10	PO	12	42–84
<i>Malassezia</i> Infection	30	PO	24	218 ^b
Cat				
Dermatophytosis	30–40 ^c	PO	24–48	14–42 ^d
Dermatophytosis carrier ^e	8.25	PO	24	21
Sporotrichosis	30	PO	24	42–84

- a Extrapolated human dose. Tablets may have to be reformulated to achieve this dose.
- b Given with food it reducing levels of dermal yeasts (Ch 57, ref. 45).
- c Begin on daily regimen. Must use at least 30 mg/kg. Use 40 mg/kg in resistant cases. Lower dosages of 10–20 mg/kg were not different from untreated controls (Ch 57, ref. 72).
- d Treatment may be effective after 14 days (Ch 57, ref. 87). Higher doses =20 mg/kg were needed for a mycologic cure but this took 21 to 126 days (Ch 57, ref. 94a).
- e Effective for eradication of *Microsporum canis* spores from haircoat of carrier cats (Ch 57, ref. 16).

108.157 **ADDITIONAL DOSAGES.**

None.

108.157 **DISPENSING INFORMATION.**

This drug may cause GI upsets manifested by anorexia, vomiting, diarrhea.

108.158 **TETRACYCLINE**

108.158 **CLASS.**

Tetracycline.

108.158 **ACTION.**

Bacteriostatic; inhibits bacterial protein synthesis by binding to 30s ribosomal subunit. Has anti-inflammatory effects by suppression of leukocyte chemotaxis.

108.158 **MORE INFORMATION.**

OXYTETRACYCLINE; Tetracyclines, Chapter 34; Antiprotozoals; Table 34-7; Chapter 71; Table 71-1.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.158.4 PHARMACOKINETICS.

77%-80% absorption from GI tract (fasting). Unabsorbed drug appears in feces and may alter GI flora. Readily enters most body fluids and tissues. Crosses the placenta to accumulate in fetal bones and teeth. Reaches highest concentration in CSF than other tetracyclines except minocycline or doxycycline. Levels in the CNS and CSF may be therapeutic. Primarily (50%-70%) renal excretion by glomerular filtration. Highest concentrations reached in liver, kidney, urine.

108.158.5 SPECTRUM.

Gram positive: *Streptococcus*, some *Staphylococcus*, *Bacillus*. **Gram negative:** *Escherichia*, *Pasteurella*, *Klebsiella*, *Enterobacter*, *Brucella*, *Bordetella*, *Aerobacter*, some *Salmonella*. **Anaerobes:** *Clostridia*, *Actinomyces*. **Others:** *Rickettsiae* (*Rickettsia*, *Ehrlichia*, *Mycoplasma* (formerly *Haemobartonella*), *Chlamydia*, *Mycoplasma*, *Balantidium*. **Ineffective:** *Mycobacterium*, *Proteus*, *Pseudomonas*.

108.158.6 INDICATIONS.

Tick-borne diseases (Rocky Mountain spotted fever [RMSF], ehrlichiosis, borreliosis), leptospirosis, oral spirochetosis, gram-negative bacterial gastroenteritis, yersiniosis, pasteurellosis, campylobacteriosis, brucellosis, chlamydiosis, intestinal amebiasis. Urinary tract infections caused by *Staphylococcus* and *Escherichia*. Intrapleural administration of tetracycline as a sclerosing agent to treat recurrent spontaneous pneumothorax and lymphatic leakage (Ch 34, ref. 220). Intense chest pain is an undesirable side effect of this therapy. Has been used for other uses as an antiinflammatory agent and for treatment of autoimmune skin disease (Ch 34, ref. 418).

108.158.7 CONTRAINDICATIONS.

Pregnancy, lactation, and young (<6 mo); renal or hepatic insufficiency. Reduce dose or avoid in renal failure.

108.158.8 ADVERSE REACTIONS.

Fewer GI upsets than other tetracyclines. GI side effects are increased when coadministered with theophylline. Sometimes diarrhea from altered GI microflora. Yellow dental staining in young animals. Catabolic effect may exacerbate azotemia in renal failure. Esophagitis, anorexia, nausea, vomiting, occasional anaphylaxis, Fanconi-like syndrome if outdated drug given. Fever ($\leq 41.1^{\circ}\text{C}$ [106°F]) that resolves when treatment is discontinued. Cats very susceptible to these toxicities. Signs of GI irritation include depression, fever, anorexia, vomiting, diarrhea. Hepatotoxicity, hepatic necrosis, fever in cats (Ch 34, ref. 189). Nephrotoxicity has been associated with concurrent use of methoxyflurane anesthesia. Rapid IV injection may cause cardiac arrhythmias, presumably owing to chelation of calcium.

108.158.9 INTERACTIONS.

GI absorption reduced by iron, bismuth, aluminum hydroxide, sodium bicarbonate, cimetidine, calcium, magnesium, kaolin and pectin, milk products. May interfere with penicillin activity when coadministered.

1322

Infectious Diseases of the Dog and Cat, 3rd Edition

1323

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral suspension	125 mg/5 ml	<i>Achromycin-V</i> (Lederle), <i>Sumycin</i> (Squibb)
	Oral capsules, tablets	100 mg, 250 mg, 500 mg	<i>Achromycin</i> , generic (various), <i>Panmycin</i> (Pharmacia & Upjohn), <i>Sumycin</i>
	Powder for IV injection, also IM	100 mg, 250 mg, 500 mg vials	<i>Achromycin</i>
Veterinary	Oral liquid (chocolate-mint flavor)	100 mg/ml	<i>Panmycin</i> Aquadrops; <i>Actinomycin</i> , <i>Sumycin</i> , <i>Tetra-Vet</i>
	Oral capsules	250 mg	Generic (various)

108.158.10 INTERNATIONAL PREPARATIONS.

Acromicina, *Austramycin*, *Hostacyclin*, *Latycin*.

108.158.11 HANDLING.

Store capsules and tablets at room temperature in airtight, dry, light-resistant containers. PO suspension is stable at room temperature. Shake PO liquid well before administering. IV and IM products are stable at 12 and 24 hr, respectively, after reconstitution.

108.158.12 ADMINISTRATION.

Administer to fasting animal. Do not mix with dairy products or substances containing multivalent cations (e.g., Fe, Al, Mg, Ca). Usually does not cause vomiting but can be given with a *small* amount of food if necessary.

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION
Dogs				
Urinary infections	16 mg/kg	PO	8	7–14 days
Rickettsiosis, borreliosis	22 mg/kg	PO	8	14 days
Systemic bacteremia, brucellosis	22–50 mg/kg	PO	8	28 days
Cats				
Soft tissue infections	20 mg/kg	PO	8	21 days
Hemotropic mycoplasmosis	10–25 mg/kg	PO	8–12	21 days
Bacteremia, systemic infections	7 mg/kg	IV, IM	12	prn

108.158.13 ADDITIONAL DOSAGES.

Canine distemper, [Table 3-5](#); salmon poisoning, [Table 27-2](#); ehrlichiosis, [Table 28-4](#); RMSF, [Table 29-3](#); haemobartonellosis, [Table 31-1](#); salmonellosis and other enteric bacterial infections, [Table 39-2](#); helicobacteriosis (in combination), [Table 39-6](#); *Clostridium perfringens*-diarrhea, [Table 39-10](#); brucellosis (in combination), [Table 40-2](#); tetanus, [Table 43-2](#); leptospirosis, [Table 44-7](#); plague, [Table 47-1](#); enteric protozoa, [Table 78-3](#); musculoskeletal infections, [Tables 86-3](#) and [86-3](#); respiratory infections, [Table 88-8](#); oral

Infectious Diseases of the Dog and Cat, 3rd Edition

infections, [Table 89-4](#); gastrointestinal infections; [Table 89-16](#); hepatobiliary infections, [Table 90-5](#); urinary tract infection, [Table 91-10](#).

108.158.14 DISPENSING INFORMATION.

Give on an empty stomach.

108.159 THIAMPHENICOL

108.159.1 CLASS.

Acetamide, an antibacterial analogue of chloramphenicol.

108.159.2 ACTION.

Bacteriostatic. Binds to 50s ribosome of bacteria-inhibiting protein synthesis.

108.159.3 MORE INFORMATION.

See CHLORAMPHENICOL; [Chapter 34](#). Synonyms are vicemycetin, dextrosulfenidol, thiamphenicol, thiophenicol.

108.159.4 PHARMACOKINETICS.

Similar to chloramphenicol. High (90%) bioavailable after oral administration. Bioavailability after IM administration is 96% but absorption from the muscle is delayed ([Ch 34](#), ref. 65). Well absorbed orally, enters most tissues, with lowest concentrations in the CNS. High penetration with greater than serum concentrations in lung, kidneys, and mammary tissues. This drug has a sulpho-group instead of a nitro-group; consequently its metabolism is different than chloramphenicol. It is not a substrate for glucuronyl transferase in the liver so that 95% of the drug is excreted unchanged in the urine and feces ([Ch 34](#), ref. 64). In laboratory animals, 65% of the dose is eliminated in the urine by glomerular filtration, with the remainder in the feces.

108.159.5 SPECTRUM.

See CHLORAMPHENICOL. Gram-positive anaerobic bacteria such as *Actinomyces*, *Propionibacterium*, and *Fusobacterium*, are particularly susceptible. For most aerobic species, the MIC is >32 µg/g indicating ineffectiveness.

108.159.6 INDICATIONS.

See CHLORAMPHENICOL. Particularly indicated and highest therapeutic efficacy for treatment of anaerobic infections. Intermediate activity against *Escherichia coli*, *Streptococcus*, and *Bordetella*. Cross resistance between chloramphenicol has been observed. Consider for infections, such as pneumonia, urinary tract infections, mastitis and enterocolitis, caused by susceptible bacteria.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.159⁷ CONTRAINDICATIONS.

Pregnancy. Low fetal weights observed at high-dose ranges in rats and rabbits, possibly related to altered enteric microbial flora in the dam and not a direct toxic effect.

108.159⁸ ADVERSE REACTIONS.

The idiosyncratic irreversible aplastic anemia in people associated with chloramphenicol exposure or treatment has *not* been seen with thiamphenicol. In a 6-mo study on beagle dogs being treated daily, lethargy, tremors, and weight gain was observed at 60 mg/kg/day. Doses as low as 30 mg/kg/day were associated with decreased erythrocyte counts and hematocrits, reduced bone marrow cellularity, and testicular atrophy. These findings were reversible with withdrawal of the drug.

1323

1324

108.159⁹ INTERACTIONS.

See CHLORAMPHENICOL.

108.159¹⁰ INDICATIONS.

Systemic or localized anaerobic infections. Theoretically this drug offers a safety advantage over chloramphenicol with regard to human health risks.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary (pigs, cattle, sheep, poultry, fin fish)	Parenteral solution Capsules	750 mg 250 mg, 500 mg	<i>Urfamycin</i> , <i>Urfamucil</i> (Sanofi Pharma)

108.159¹¹ INTERNATIONAL PREPARATIONS.

Acobiotic, Ervin, Fluimicil, Fultrexin, Glitisol, Thiamcin, Thiophenicol, Tiofeniclin, Urfamycin, Urfamycine.

108.159¹² HANDLING.

Can be stored between 2–30°C, although refrigeration is not necessary.

108.159¹³ ADMINISTRATION.

Can be given PO, IV, IM or SC; the IM injection may cause pain and irritation.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Systemic infections	15–20 ^a	PO, IM, SC	12	3–5

^a Extrapolated from dosages for food-producing animals and toxicity data in dogs.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.159.14 ADDITIONAL DOSAGES.

None.

108.160.1 TICARCILLIN

108.160.1 CLASS.

Carboxypenicillin.

108.160.2 ACTION.

Bactericidal, inhibits bacterial cell wall synthesis.

108.160.3 MORE INFORMATION.

See CARBENICILLIN; Penicillins, [Chapter 34](#); [Table 34-1](#).

108.160.4 PHARMACOKINETICS.

Not absorbed after PO administration, so given parenterally. Reaches many extracellular fluids, soft tissues, and bone. Crosses blood-brain barrier, primarily with inflammation. CSF-serum ratio is 0.06 : 1 with noninflamed meninges and 0.4 : 1 with meningitis. Eliminated primarily by renal excretion.

108.160.5 SPECTRUM.

Gram positive: *Staphylococcus* (non β -lactamase producers), some *Streptococcus*, some *Enterococcus*. **Gram negative:** *Escherichia*, *Proteus*, *Salmonella*, *Enterobacter*, *Pseudomonas*, *Citrobacter*, *Serratia*. **Anaerobes:** *Clostridium*, *Peptococcus*, *Peptostreptococcus*, *Bacteroides*, *Fusobacterium*. **More effective:** more potent than carbenicillin against *Pseudomonas*. Because of low toxicity, can cause large doses to have activity against some resistant strains of *Pseudomonas*.

108.160.6 INDICATIONS.

Bone, joint infections, bacterial sepsis, skin, soft tissue infections, acute, chronic respiratory infections, genitourinary infections, intraabdominal, pelvic infections. Infections of these areas involving *Pseudomonas* or anaerobes. Has been used topically to treat otitis externa caused by *Pseudomonas*; see Handling below and under Dosage section of ticarcillin-clavulanate below for details.

108.160.7 CONTRAINDICATIONS.

Reduce dosage in renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.160.8 ADVERSE REACTIONS.

See CARBENICILLIN.

108.160.9 INTERACTIONS.

Often combined with β -lactamase inhibitor, clavulanate (see TICARCILLIN-CLAVULANATE). May also use with aminoglycoside (administered separately) for additional activity against gram-negative aerobes and facultative anaerobes in severe infections.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	1g, 3g, 6g, 20g, 30g	Ticar (SmithKline Beecham)

108.160.10 INTERNATIONAL PREPARATIONS.

Aerugipen, Tarcil, Ticarpen, Ticillin, Triacilline.

108.160.11 HANDLING.

Store powder at room temperature. **IM:** dilute with sterile water, 0.9% NaCl or 1% lidocaine solution. **IV:** dilute to 1 g/4 ml in 0.9% NaCl or 5% dextrose. Should refrigerate if not used within 1 hr because precipitation may occur. Stable for 24 hr at room temperature and 72 hr if refrigerated. Continuous drip required or intermittent pulse administration over 30 min to 2 hr. Never mix solutions with aminoglycosides because they become inactivated; however, they can be given separately at different sites. **For topical use in ears:** use the following protocol (Ch 85, ref. 42): First make a concentrated solution by reconstituting a 6-gm vial of ticarcillin with 12 ml of sterile water. Divide equally into 2-ml portions in syringes and freeze. This will remain stable for 3 mo. To make the final ear solution, thaw and mix a 2-ml aliquot of concentrate with 40 ml of normal saline. Divide this into four 10-ml aliquots and freeze. Clients should thaw one aliquot at a time and keep it refrigerated. This should be used over a week period and any remainder discarded.

108.160.12 ADMINISTRATION.

Often given IV for bacterial sepsis, in combination with an aminoglycoside.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Soft tissue, systemic infections	15–25	IV, IM, SC	6–8	prn
Septicemia	40–50	IV, IM	4–6	prn
Difficult, severe systemic infections	100	IV	6–8	prn
Cats (<i>Pseudomonas</i>)				
Soft tissue, systemic infections	15–24	IV, IM, SC	8	prn
Systemic, bacteremia	40–50	IV	6	prn

Infectious Diseases of the Dog and Cat, 3rd Edition

108.160.13 ADDITIONAL DOSAGES.

Gram-negative bacterial infection, [Table 37-3](#); otitis externa, topical, [Table 85-6](#); bacteremia and endocarditis, [Table 87-6](#); respiratory infections, [Table 88-8](#); hepatobiliary infections, [Table 90-5](#).

108.161 TICARCILLIN-CLAVULANATE

108.161.1 CLASS.

Carboxypenicillin and β -lactamase inhibitor in 30 : 1 ratio.

108.161.2 ACTION.

Bactericidal; ticarcillin interferes with bacterial cell wall synthesis; clavulanate inactivates plasmid-mediated β -lactamases; that cause resistance to penicillins and cephalosporins.

108.161.3 MORE INFORMATION.

See TICARCILLIN; Penicillins, [Chapter 34](#); [Tables 34-1](#) and [34-2](#).

108.161.4 PHARMACOKINETICS.

See also TICARCILLIN. Ticarcillin is not systemically available after PO administration. Parenteral dosages produces good concentration in tissues, bile, pleural and interstitial fluids; CSF in inflamed meninges. Mainly renal elimination, with 60%-70% ticarcillin and 35%-45% clavulanate excreted unchanged in urine. Dogs excrete clavulanate more rapidly than ticarcillin.

108.161.5 SPECTRUM.

Gram positive: *Staphylococcus*, *Streptococcus*, *Enterococcus*. **Gram-negative:** *Pseudomonas*, *Proteus*, *Enterobacter*, *Salmonella*, *Klebsiella*, *Escherichia*, *Citrobacter*, *Serratia*, *Acinetobacter*, *Pasteurella*, *Bordetella*. **Anaerobes:** *Bacteroides*, *Clostridium*, *Fusobacterium*, *Peptostreptococcus*, *Eubacterium*, *Peptococcus*.

108.161.6 INDICATIONS.

Nosocomial pneumonia, severe skin, soft tissue infections; septicemia; bone, joint, urinary tract, intraabdominal, gynecologic infections. Synergistic with aminoglycosides against some strains of *Pseudomonas*.

108.161.7 CONTRAINDICATIONS.

Reduce dose in renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.1618 ADVERSE REACTIONS.

Platelet dysfunction, hypersensitivity reactions, seizures, vomiting, diarrhea, myelotoxicity. Rarely hepatotoxicity in people.

108.1619 INTERACTIONS.

Synergistic with aminoglycoside for severe infections.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	3.1g (3.0g ticarcillin, 0.1g clavulanate)	<i>Timentin</i> (SmithKline Beecham)

108.16110 INTERNATIONAL PREPARATIONS.

Betabactyl, Claventin, Clavucar, Timenten.

108.16111 HANDLING.

Concentrated reconstituted solution (200 mg/ml) stable up to 6 hr at room temperature or 72 hr if refrigerated. Can be diluted to 10-100 mg/ml with 5% dextrose, 0.9% NaCl, lactated Ringer's, and is stable for 24 hr at room temperature 7 days refrigerated, and 30 days frozen. For 5% dextrose solution, storage is only 7 days at frozen temperatures. Incompatible with bicarbonate in solution.

108.16112 ADMINISTRATION.

IV slowly over 30 min. Administer any concurrent aminoglycosides separately. IM administration is effective but painful, therefore IV route is recommended for most uses.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Bacteremia,	20–50	IV	6–8	prn
<i>Pseudomonas</i> sepsis				
<i>Pseudomonas</i> Otitis externa	3–4 drops	topical	6–8	prn ^a
<i>Pseudomonas</i> Otitis externa	15–25	IV	8	prn ^a
Cats				
Bacteremia,	40	IV	6	prn
<i>Pseudomonas</i> sepsis				

^a For *Pseudomonas* otitis use the following regimen (Ch 34, ref. 280). Treatment with 1–2 mg/kg prednisolone PO, every 24 hr, and ear cleaning, every 8 hr, followed by 3–4 drops of topical reconstituted ticarcillin-clavulanate solution. If the ear drum is perforated, concurrent IV treatment is given until the ear drum heals. A new vial of drug is reconstituted each day. The prednisolone is tapered over 2 weeks. Topical treatment is continued for 14 days beyond clinical cure. The duration of treatment has been 14–36 days.

1325

Infectious Diseases of the Dog and Cat, 3rd Edition

1326

108.16213 ADDITIONAL DOSAGES.

Gram-negative bacterial infections, [Table 37-3](#); respiratory disease, [Table 88-8](#); intraabdominal infections, [Table 89-21](#).

108.16214 TINIDAZOLE

108.16215 CLASS.

Nitroimidazole.

108.16216 ACTION.

Bactericidal, antibacterial, also antiprotozoal; see METRONIDAZOLE, IPRONIDAZOLE.

108.16217 MORE INFORMATION.

See METRONIDAZOLE; [Chapter 71](#); [Table 71-1](#); references: [Ch 71](#), ref. 79a; 79b; 79c; 79d.

108.16218 PHARMACOKINETICS.

Almost complete absorption ($\geq 90\%$) from GI tract. Widely distributed in tissues and body fluids. Therapeutic concentrations also in gingival crevice fluid. Metabolized in liver to active metabolites. Repeated administration at the pharmacologic dose does not lead to drug accumulation. Elimination half-life 8.4 hr in cats, 4.4 hr in dogs ([Ch 71](#), ref. 79c). Unchanged drug and metabolites are excreted in urine and to lesser extent in feces. In people, half-life of tinidazole is longer than metronidazole, but there is no difference in dogs ([Ch 71](#), ref. 79c).

108.16219 SPECTRUM.

See METRONIDAZOLE. **Anaerobes:** Excellent activity against *Porphyromonas* spp in canine gingival crevice and most obligate anaerobes including β -lactamase-producing *Bacteroides*. **Others:** anaerobic protozoa *Giardia*, *Entamoeba*, *Trichomonas*. **Ineffective:** aerobic and facultative anaerobic bacteria. **More effective:** anaerobic bacteria and anaerobic protozoa. The MIC for most anaerobes is 2 $\mu\text{g/ml}$.

108.16220 INDICATIONS.

Gingivitis, oral ulceration, periodontitis, abscesses, anal sacculitis, chronic diarrhea of bacterial or protozoal (giardiasis, amebiasis, balantidiasis) association, osteomyelitis, peritonitis, hepatic abscess, pyothorax, pyometra, animal bite wounds. Invasive amebiasis. Used like metronidazole but has a longer duration of action. See also METRONIDAZOLE.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.162.7 CONTRAINDICATIONS.

No dosage modification in renal failure. Avoid in pregnant or lactating animals. Use with caution in animals with hepatic dysfunction as it is metabolized and eliminated by the liver.

108.162.8 ADVERSE REACTIONS.

Vomiting and diarrhea, cutaneous reactions, thrombophlebitis after IV use, stomatitis, glossitis, dry mucous membranes, neutropenia, neurologic signs (vestibular), metallic taste, urine discoloration.

108.162.9 INTERACTIONS.

See METRONIDAZOLE.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Oral tablets	500 mg	<i>Fasigyn</i> (Pfizer, Europe)
	Oral tablets	250 mg, 500 mg	<i>Tindamax</i> (Presutti Laboratoris)
	Parenteral solution	5 mg/ml	

108.162.10 INTERNATIONAL PREPARATIONS.

Amebysol, Ametricid, Aplium, Asiazole, Cartrax, Colpolase, Doxifen, Duozol, Dyzole, Estovyn-T, Famidal, Fasigyne, Fundia, Ginec, Idazole, Pletil, Simplotan, Sorquetan, Tinazole, Tinoral, Tonid, Tricolam, Trimonase.

108.162.11 HANDLING.

See METRONIDAZOLE.

108.162.12 ADMINISTRATION.

Advisable to give with food to minimize GI side effects. Food does not affect absorption. Often given as a single daily PO dose with or after feeding. It can also be given IV.

Dosage				
INDICATIONS	DOSE (mg/kg) ^a	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Stomatitis, anaerobic bacterial infections	15–25	PO	12	7
Cats				
Stomatitis, anarobic bacterial infections	15	PO	24	7

^a A dose of 15 mg/kg achieved therapeutic levels in plasma for 12 hr in dogs and 24 hr in cats (Ch 71, ref. 79c).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.162.13 ADDITIONAL DOSAGES.

Enteric protozoal infections (e.g., *Giardia*), [Table 78-3](#).

108.162.14 DISPENSING INFORMATION.

Drug can be given with or without food.

108.163 TOBRAMYCIN

108.163.1 CLASS.

Aminoglycoside.

108.163.2 ACTION.

Bactericidal; inhibits bacterial protein synthesis.

108.163.3 MORE INFORMATION.

GENTAMICIN, [Chapter 34](#), Aminoglycosides; [Table 34-5](#).

108.163.4 PHARMACOKINETICS.

See GENTAMICIN.

108.163.5 SPECTRUM.

See GENTAMICIN. Similar to gentamicin but more active against *Pseudomonas*.

108.163.6 INDICATIONS.

Classically used to treat severe infections caused by *Pseudomonas*, *Proteus*, *Klebsiella*, *Enterobacter*, and *Escherichia*.

108.163.7 CONTRAINDICATIONS.

See GENTAMICIN. Reduce dose in renal failure.

108.163.8 ADVERSE REACTIONS.

Ototoxicity and nephrotoxicity, see GENTAMICIN. May be more nephrotoxic to cats than gentamicin or amikacin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.163.9 INTERACTIONS.

See GENTAMICIN.

1326

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Solution for injection	10 mg/ml, 40 mg/ml	<i>Nebcin</i> (Eli Lilly)

1327

108.163.10 INTERNATIONAL PREPARATIONS.

Brulamycin, Gernebcin, Mytobrin, Nebcina, Obracin, Tobral, Tobrallex, Tobramaxin, Tobrex.

108.163.11 HANDLING.

Do not mix with other drugs before infusion. Store at room temperature. Do not use if becomes discolored.

108.163.12 ADMINISTRATION.

IM: inject deep into large muscle. **IV:** dilute in 0.9% NaCl or 5% dextrose; administer slowly over 30-60 min.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr) ^a	DURATION (days)
Dogs				
Soft tissue, systemic infections	1–1.7	IV	8	<7
Systemic infections	2	SC	8–12	<7
Persistent bacteremia	3–5	IV, IM, SC	8	<7
Cats				
Soft tissue, systemic infections	2	IV, IM, SC	12	<5
Persistent bacteremia	2	IV, IM, SC	8	<5

^a There is evidence that administration of higher dosages less frequently may reduce the toxic potential of aminoglycosides and increase therapeutic efficacy by giving higher peak concentrations. Thus with this regimen, the total daily dose calculated can be administered once every 24 hr.

108.163.13 ADDITIONAL DOSAGES.

Otitis externa topical, [Table 85-6](#); respiratory infections, [Table 88-8](#), local ocular treatment, [Table 93-4](#).

108.164.1 POLTRAZURIL

108.164.1 CLASS.

Triazinon.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.164.2 ACTION.

Antiprotozoal, anticoccidial.

108.164.3 MORE INFORMATION.

[Chapter 71](#); [Table 71-1](#). See also Ponazuril. Related drug available in some countries is Diclazuril (*Clinicox*), Janssen.

108.164.4 SPECTRUM.

Coccidia, *Hepatozoon*.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Veterinary	Oral solution 2.5%, 5%	100 ml, 1L bottle	<i>Baycox</i> , <i>Baycox Vet</i> (Bayer)

Dosage

INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Coccidiosis (<i>Dog</i>)	5–20	PO	24	2–3
Coccidiosis (<i>Cat</i>)	30	PO	24	2–3

108.164.5 ADDITIONAL DOSAGES.

Toxoplasmosis, [Table 80-3](#); coccidiosis, [Table 81-2](#). Reference [Ch 71](#), ref. 52.

108.165 TRIFLURIDINE (SEE [CHAPTER 2](#))

108.166 PRIMETHOPRIM-SULFONAMIDE

108.166.1 CLASS.

Pyrimidine and sulfonamide in 1 : 5 ratio.

108.166.2 ACTION.

Bactericidal, antiprotozoal; synergistic blockade of microbial synthesis of folic acid.

108.166.3 MORE INFORMATION.

See ormetoprim-sulfonamide above, and trimethoprim-sulfonamide, [Chapter 34](#); [Table 34-10](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

108.1664 PHARMACOKINETICS.

Well absorbed orally, rapid and complete. Wide distribution in body tissues. Most (60%-80%) excreted in urine of dogs as unchanged drug. Small amount metabolized by liver and renally excreted. Acetylated metabolites do not accumulate in dogs, which reduces risk of nephrotoxicity compared with cats and people.

1327

108.1665 SPECTRUM.

1328

Gram positive: some *Staphylococcus* (coagulase negative). **Gram negative:** *Escherichia*, *Proteus*, *Klebsiella*, *Enterobacter*, *Bordetella*, *Salmonella*, *Pasteurella*; *Nocardia* and *Brucella* at high doses. **Anaerobes:** *Fusobacterium*, *Clostridium*. Despite in vitro efficacy, in vivo effectiveness against anaerobes is poor. **Others:** *Pneumocystis*; weak against *Toxoplasma* (pyrimethamine-sulfonamide better); enteric coccidia; *Cyclospora*, *Acanthamoeba*. **Ineffective:** many *Pseudomonas*, *Mycobacterium*, *Leptospira*, *Erysipelothrix*, many anaerobes, including *Bacteroides*, *Mycoplasma*.

108.1666 INDICATIONS.

Uncomplicated urinary tract infection as a result of susceptible bacteria. *Pneumocystis* pneumonia, acute and chronic prostatitis, antimicrobial prophylaxis for immunocompromised host; bacterial CNS infections/meningitis in dogs and cats. Long-term, low-dose therapy for chronic urinary infections. Microsporidiosis.

108.1667 CONTRAINDICATIONS.

Reduce dose with renal dysfunction. Pregnancy: teratogenic at high doses to laboratory animals but safe at therapeutic dosages in dogs. Avoid use in dogs with reduced Schirmer Tear test values. Doberman pinschers have a decreased ability to detoxify sulfonamide hydroxylamine metabolites resulting in increased susceptibility to toxicity (Ch 34, ref. 83). Avoid use in dogs with congenital bleeding disorders because they have an increased potential risk of hemorrhage should thrombocytopenia develop (Ch 34, ref. 97; 98). Avoid in animals with preexisting hepatic parenchymal disease, anemia, or leukopenia.

108.1668 ADVERSE REACTIONS

1. Dogs: keratoconjunctivitis sicca (KCS), dogs weighing <12 kg appear more at risk. KCS can develop within 1 week of treatment and up to 7 mo after discontinuation (Ch 34, ref. 24; 94).
2. Hepatotoxicity—cholestatic hepatitis: anorexia, depression, icterus, hepatic necrosis, especially with pre-existing hepatobiliary disease (Ch 34, ref. 321; 370; 387). Dogs that develop persistent increases in ALT have a poorer prognosis (Ch 34, ref. 379).
3. Megaloblastic—folate acid deficiency anemia; more dramatic in cats after several weeks; large doses and longer treatment will affect dogs. Dietary supplement with folinic acid (Leukovorin) at 2.5 mg/kg/day can overcome the folate deficiency. Folic acid supplementation should not be used because its activation to folinic acid is blocked by trimethoprim. With folinic supplements, effectiveness against enterococci and some protozoa is reduced.

Infectious Diseases of the Dog and Cat, 3rd Edition

4. Immune-mediated polyarthritis, retinitis, glomerulitis, vasculitis, serum sickness, urticaria, erythema multiforme, toxic epidermal necrolysis, facial swelling, conjunctivitis and meningitis (Ch 34, ref. 361; 379). For skin reactions see cutaneous drug eruption, next. Seems more common in large-breed dogs; Doberman pinschers have shown a predilection for immune-complex complications. Samoyeds and miniature schnauzers were also prevalent in one study (Ch 34, ref. 379), signs usually develop 1-3 weeks (range 5-36 days) after first use of the drug or within 1 hr to 10 days after repeated usage. Laboratory abnormalities include hemolytic anemia, neutropenia, thrombocytopenia, and proteinuria. Reaction begins to subside within 24-48 hr of withdrawal of the drug and commencement of glucocorticoid therapy. Dogs with increased ALT or thrombocytopenia had a poorer prognosis for recovery (Ch 34, ref. 379).
5. Cutaneous drug eruption—erythema multiforme, erythroderma, exfoliative dermatitis, urticaria, toxic epidermal necrolysis, vesiculobullous disease, otitis externa, pemphigus, and pemphigoid-like disease (Ch 34, ref. 90; 248; 252; 239). Large-breed dogs, particularly Doberman pinschers and golden and Labrador retrievers, have been most affected (Ch 34, ref. 139). Although early observations suggested that sulfamethoxazole-induced immune reactions were less prevalent in causing cutaneous drug eruption than sulfadiazine-containing combinations, hypersensitivity risk was found to be equal in later reports (Ch 34, ref. 379).
6. Renal failure—sulfonamide nephromicrolithiasis, polydipsia, and polyuria primarily seen in cats.
7. Salivation, diarrhea, and vomiting—especially in cats given crushed or broken tablets. Cats may show consistent vomiting after PO dosing, which may necessitate parenteral therapy. Parenteral therapy can cause local irritation.
8. Ataxia has been observed in dogs and cats given higher therapeutic dosages. Signs usually disappear within 24-48 hr after therapy is discontinued.
9. Prolonged treatment with trimethoprim-sulfonamides interferes with thyroid hormone synthesis because of the sulfonamide (see ORMETROPRIM-SULFONAMIDE). Chronic (6 weeks-dosing) to euthyroid dogs results in decreased serum T₃, T₄ (Ch 34, ref. 146). Effect is dosage- and duration-dependent. Dosages of 60 mg/kg/day for 4-6 weeks, or 48 mg/kg/day for 10 weeks are in the ranges that could produce clinical hypothyroidism (Ch 34, ref. 134). Dogs given 26.5-31.3 mg/kg PO, every 12 hr developed neutropenia, reduced T₄, and increased TSH, concentrations after 1 to 4 weeks of treatment (Ch 34, ref. 422).
10. Hyperkalemia—interferes with renal potassium excretion. It can exacerbate hyperkalemia in animals with hypoadrenocorticism (Ch 34, ref. 323). This effect can be reversed by normal saline diuresis.

108.166.9 INTERACTIONS.

Prolongs effects of anticoagulants, diphenylhydantoin, increased blood levels or activity of dapsone, sulfonyleureas.

Infectious Diseases of the Dog and Cat, 3rd Edition

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Trimethoprim-sulfamethoxazole (1:5 ratio)		
	Oral tablets	480 mg, 960 mg	<i>Bactrim</i> (Roche), <i>Cotrim</i> (Lemmon), <i>Septra</i> (Burroughs Wellcome), generic (various)
	Oral suspension	240 mg/5 ml	<i>Bactrim</i> , <i>Septra</i> , generic (various)
	IV solution	480 mg/5 ml	<i>Bactrim IV</i> , <i>Septra V</i>
Veterinary	Trimethoprim-sulfadiazine (1:5 ratio)		
	Oral tablets (approved for dogs)	30 mg, 120 mg, 480 mg, 960 mg	<i>Delvoprim</i> (Mycofarm, UK), <i>Di-Trim</i> (Syntex), <i>Duphatrim</i> (Solvay-Duphar), <i>Tribrisen</i> (Schering-Plough Animal Health)
	Oral suspension (approved for dogs)	60 mg	<i>Tribrisen</i>

1328

108.166.10 INTERNATIONAL PREPARATIONS.

1329

Abactrim, *Antrima*, *Chemitrim*, *Comox*, *Coptin*, *Cotribene*, *Eusaprim*, *Fectrim*, *Isotrim*, *Polytrim*, *Resprim*, *Septin*, *Sulfatrim*, *Sulfotrim*, *Trimatrim*, *Ultrasept*.

108.166.11 HANDLING.

Store all products at room temperature in airtight containers. Cats should be given whole tablets or PO suspension to avoid hypersalivation. Crushing tablets or putting them on food has little influence on the absorptive process. Once-daily dosing should only be used for treatment of chronic urinary and skin infections, and prophylaxis for urinary infections. Twice-daily dosing is more effective in eliminating established infection.

108.166.12 ADMINISTRATION.

Concurrent treatment with folinic and (2.5 mg/kg/day) will reduce the potential of megaloblastic anemia in cats. Hemogram should be done weekly for the first 2 weeks to check for myelotoxic effects. Hematologic studies should be performed at least once a month thereafter if treatment is extended. Always provide plenty of drinking water. Parenteral solutions are used to treat severe infections and for use in comatose or vomiting animals.

Dosage				
INDICATIONS	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs				
Urinary, pyoderma	30	PO	24	14
Urinary, pyoderma, soft tissue infection	15	PO	12	14
Chronic pyoderma, acanthamebiasis	30	PO	12	21–42
Systemic, bacteremia	30–45	PO	12	3–5
Cats				
Urinary infections	30	PO	24	7–14
Urinary, soft tissue infections	15	PO	12	7–14
Coccidiosis (weight ≤ 4kg)	30–60	PO	24	6
(weight > 4kg)	15–30	PO	24	6

Infectious Diseases of the Dog and Cat, 3rd Edition

108.166.13 ADDITIONAL DOSAGES.

Canine infectious tracheobronchitis, [Table 6-2](#); enteric bacterial infections, [Table 39-2](#); plague, [Table 47-1](#), opportunistic mycobacterial infections, [Table 50-9](#); pneumocystosis, [Table 68-2](#); hepatozoonosis, [Table 74-2](#); toxoplasmosis, [Table 80-3](#); neosporosis, [Table 80-7](#); coccidial infections, [Table 81-2](#); canine pyoderma, [Table 85-3](#); bacteremia, endocarditis, [Table 87-6](#); respiratory infections, [Table 88-8](#); gastrointestinal infections, [Table 89-16](#); hepatobiliary infections, [Table 90-5](#); urinary infections, [Table 91-10](#); CNS infections, [Table 92-5](#).

108.166.14 DISPENSING INFORMATION.

Watch for systemic signs such as fever, lameness, vomiting, yellowing of mucosae, or lack of tear production.

108.167 TRIMETREXATE GLUCURONATE

108.167.1 CLASS.

Diaminoquinazoline.

108.167.2 ACTION.

Bacteriostatic, antibacterial, and antiprotozoal; inhibitor of enzyme dihydrofolate reductase.

108.167.3 MORE INFORMATION.

Reference: [Ch 71](#), ref. 99.

108.167.4 PHARMACOKINETICS.

Not absorbed well orally, must be given by IV route. Metabolized by liver and excreted in bile. Metabolites and some (10%-30%) unchanged drug excreted in urine.

108.167.5 SPECTRUM.

Pneumocystis, *Toxoplasma*.

108.167.6 INDICATIONS.

Pneumocystis pneumonia refractory or resistant to trimethoprim-sulfonamides or pentamidine. As an adjunct or second choice to clindamycin in treatment of toxoplasmosis.

108.167.7 APPROVED USES.

Human: *Pneumocystis* pneumonia refractory or resistant to trimethoprim-sulfas or pentamidine.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.167.8 CONTRAINDICATIONS.

Previous sensitivity. Pregnancy.

108.167.9 ADVERSE REACTIONS.

Dermatologic eruption, myelosuppression, stomatitis, increased hepatic serum transaminases, vomiting or diarrhea, folic acid deficiency anemia or leukopenia. Fetotoxic and teratogenic.

108.167.10 INTERACTIONS.

Co-administer with folinic acid (leucovorin) to minimize mammalian cell toxicity.

AVAILABILITY	TYPE	SIZES	PREPARATION (COMPANY)
Human	Powder for injection	25 mg vials	<i>Neutrexin</i> (US Bioscience)

108.167.11 HANDLING.

Store powder at controlled room temperatures away from light. Wear gloves while handling. Just before use, reconstitute by adding 2 ml of 5% dextrose or sterile water until powder is completely dissolved without opacity. Further dilute with 5% dextrose to 0.5-2 mg/ml. Solution stable for 24 hr at room temperature or refrigerated. Discard unused drug after 24 hr.

108.167.13 ADMINISTRATION.

Must be given concurrently with folinic acid for 3 days after last dose of trimetrexate. Give IV separately from the folinic acid through a flushed IV catheter. Give over 60 min every 6 hr. IV catheters must be flushed with 10 ml of 5% dextrose before and after administering drug.

1329

Dosage				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
(Human) Pneumocystosis or Toxoplasmosis				
Trimetrexate with folinic acid	45 mg/m ²	IV	24	21
	20 mg/m ²	IV	6	24
Dog				
Trimetrexate	10 mg/kg	IV	24	21

1330

108.167.13 ADDITIONAL DOSAGES.

Pneumocystosis, [Table 68-2](#).

108.167.14 DISPENSING INFORMATION.

Recheck hemogram and biochemical tests every 2 weeks.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.168.1 TYLOSIN

108.168.1 CLASS.

Macrolide.

108.168.2 ACTION.

Bacteriostatic, antibacterial, similar to erythromycin.

108.168.3 MORE INFORMATION.

[Chapter 34](#); reference: [Ch 34](#), ref. 337.

108.168.4 PHARMACOKINETICS.

Absorbed primarily in the small intestine. Excreted in urine and bile.

108.168.5 SPECTRUM.

Gram positive: *Streptococcus*, *Staphylococcus*, *Chlamydia*, *Mycoplasma*. **Gram negative:** *Campylobacter*, *Helicobacter*.

108.168.6 INDICATIONS.

Campylobacteriosis, helicobacteriosis, inflammatory bowel disease, chronic colitis, upper respiratory tract infections in cats owing to *Mycoplasma*, *Chlamydia*. Bacterial sensitivity often follows that of erythromycin.

108.168.7 APPROVED USES.

Food-producing animals.

108.168.8 CONTRAINDICATIONS.

Preexisting cardiac arrhythmia, cardiomyopathy, myocarditis.

108.168.9 ADVERSE REACTIONS.

Pain and irritation with IM injection. Inject no more than 1-2 ml/site. Nausea and vomiting with PO administration. Wide safety margin. High dosages (200-400 mg/kg/day, given for a 2-yr period) tolerated by clinically healthy dogs with no apparent side effects. Dosages as low as 5 mg/kg have increased the tendency of dogs to develop ventricular tachycardia after experimental myocardial ischemia. Contact dermatitis has developed in some veterinarians who handled the drug.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.168.10 INTERACTIONS.

Erythromycin, chloramphenicol, lincomycin, clindamycin have similar action and should not be used together.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Veterinary	Soluble powder astartrate	100g containers	<i>Tylan</i> Soluble (Elanco)
	Injection	(~3g/teaspoon) 50 mg/ml, 200 mg/ml	<i>Tylan</i> Injection (Elanco), generic (Fermenta, Lextron)

108.168.11 HANDLING.

Should not mix injectable product with other drugs. Store in airtight containers. Unstable at low pH forming an inactive degradation product, desmicosin.

108.168.12 ADMINISTRATION.

PO powder: measured amounts placed on food or in gelatin capsules, or diluted with water and given by gavage. Wear gloves when handling, especially when applying the powder to food. Powder can be mixed with dextrose or cornstarch in a 1 : 9 ratio to make it ~300 mg/teaspoon for more convenient dosing amounts in small animals.

Dosage				
INDICATIONS (<i>Dogs and Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL(hr)	DURATION (days)
Staphylococcal pyoderma	20	PO	12	15–35
	10	PO	12	17–35
Upper respiratory disease,	6.5–12.5	IM	12	prn
inflammatory bowel disease	5–10	PO	12	prn
<i>Clostridium perfringens</i> diarrhea	20–40	PO	12–24	5–7

108.168.13 ADDITIONAL DOSAGES.

Enteric bacterial infections, [Table 39-2](#); *Clostridium perfringens*-associated diarrhea, [Table 39-10](#); gastrointestinal infections, [Table 89-16](#); colitis, [Table 89-19](#).

108.168.14 DISPENSING INFORMATION.

Use gloves when administering capsules or placing on food.

1330

Infectious Diseases of the Dog and Cat, 3rd Edition

1331

108.169 VALACYCLOVIR (VALTREX, SMITHKLINE): SEE [CHAPTER 2](#)

108.170 VANCOMYCIN

108.170.1 CLASS.

Glycopeptide.

108.170.2 ACTION.

Bactericidal; interferes with peptidoglycan biosynthesis in cell walls of replicating gram-positive bacteria. Less effect on cytoplasmic RNA synthesis.

108.170.3 MORE INFORMATION.

See also TEICOPLANIN. [Chapter 34](#); references: [Ch 34](#), ref. 182.

108.170.4 PHARMACOKINETICS.

Not well absorbed orally. Given PO for treatment of bacterial enterocolitis. For systemic infections it is given parenterally (IV) because IM is painful. After IV injection, fair penetration into body tissues. Clinically useful concentrations in tissues such as heart, lung, kidney, bone, synovial and peritoneal fluids. Primarily eliminated by kidneys via glomerular filtration. Concentration in inflamed meninges may be too low for therapeutic effects so that intrathecal administration would be needed. Similar low concentrations in pleural and pericardial fluids and bile.

108.170.5 SPECTRUM.

Gram positive: some *Staphylococcus*, most *Streptococcus*, some *Enterococcus*, *Corynebacterium*. Some resistance to *Enterococcus* and *Staphylococcus* occurs. Combination with aminoglycoside increases activity against these organisms. Those with low-level resistance are still susceptible to teicoplanin; however, some *Enterococcus* have high-level resistance, but development of resistance during treatment is unknown.

Anaerobes: *Clostridium difficile*, other *Clostridium*, *Bacillus anthracis*, *Actinomyces*. **Others:** *Entamoeba*.

More effective: Gram positive. **Ineffective:** most gram negative bacteria except *Neisseria*, *Mycobacterium*.

108.170.6 INDICATIONS.

Bacterial cholangiohepatitis in cats ([Ch 34](#), ref. 182). Prophylaxis or treatment of staphylococcal or streptococcal septicemia or endocarditis, for clostridial enterocolitis, and for resistant of gram-positive bacterial infections. Resistant *Enterococcus* urinary infections. Prophylaxis for orthopedic surgery combined with aminoglycoside. Orally used to treat *Clostridium difficile*-associated diarrhea in people, a rare condition in animals; enterococcal or clostridial enterocolitis is more likely in dogs and cats that might require vancomycin.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.170.7 CONTRAINDICATIONS.

Reduce dosage in renal failure.

108.170.8 ADVERSE REACTIONS.

If too rapid IV inoculation, anaphylaxis-like or urticarial reaction may occur. Preadministered antihistamine (H₁ antagonists) prevents the problem. In toxicity studies, dogs receiving bolus IV infusion developed hypotension and bradycardia. Reversible neutropenia and thrombocytopenia. Nephrotoxicity (hematuria, proteinuria, urine casts, azotemia) is infrequent and rare. May cause auditory ototoxicity.

108.170.9 INTERACTIONS.

Concurrent administration of an aminoglycoside and sometimes rifampin potentiates the activity of vancomycin. Use with aminoglycosides may potentiate nephrotoxicity.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Powder for injection	500 mg; 1g; 5g	<i>Vancocin</i> (Lilly), <i>Lyphocin</i> (Lymphomed)
	Oral solution and capsules (<i>Pulvules</i>)	125-mg, 250-mg capsules; 1-g, 10-g solution bottles	<i>Vancocin</i>

108.170.10 INTERNATIONAL PREPARATIONS.

Vancocine, *Vancoled*, *Vancor*.

108.170.11 HANDLING.

Incompatible in IV solutions with chloramphenicol, glucocorticoids, aminophylline, methicillin, barbiturates, sodium bicarbonate, heparin. Parenteral solutions stable for 14 days if refrigerated as concentrated stock solution. In infusion bottles is only stable for 24 hr at room temperature but 60 days if refrigerated. The oral solution is reconstituted with distilled water and is stable in refrigerator for 2 weeks.

108.170.12 ADMINISTRATION.

IV slowly over 30-60 min in 5% dextrose or 0.9% saline or lactated Ringer's. Rate should be less than 15 mg/min. For CNS infections, 5 mg is placed in CSF by intrathecal injection to provide a concentration of about 25 µg/ml. Given orally, it is not absorbed and reaches high intraluminal concentrations for treatment of enteric bacterial infections.

Dosage				
INDICATIONS (<i>Dogs</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
<i>C.difficile</i> enterocolitis	10-20	PO	6	5-7
Skin, urinary, soft tissue infections	10-20	IV	12	7-10
Systemic infection, bacteremia	15	IV	6	10

Infectious Diseases of the Dog and Cat, 3rd Edition

108.170.13 ADDITIONAL DOSAGES.

Hepatobiliary infections, [Table 90-4](#); local treatment ocular infections, [Table 93-4](#).

108.170.14 DISPENSING INFORMATION.

The oral solution may be given with small amounts of food or both. Keep refrigerated.

1331

108.171 VIDARABINE (SEE [CHAPTER 2](#))

1332

108.172 VORICONAZOLE

108.172.1 CLASS.

Broad spectrum triazole (UK-109,496). Synthetic derivative of fluconazole.

108.172.2 ACTION.

Antifungal; inhibits sterol and cytochrome P-450 synthesis. Inhibits 24—methylene dehydrolanosterol demethylation explaining why it is more active against molds such as *Aspergillus* while fluconazole is not. More potent than fluconazole in this effect.

108.172.3 MORE INFORMATION.

See [Chapter 57](#); references: [Ch 57](#), ref. 53; 103; 63.

108.172.4 PHARMACOKINETICS.

Relatively high bioavailability (>90% systemic availability in people) after IV or PO administration. Food reduces absorption. Accumulates up to 8-fold in tissues following multiple dosing as a result of saturating its own metabolism. In dogs, repeated once-daily administration results in twofold clearance of the drug from 3.4 hr to a shorter interval. This is caused by autoinduction of cytochrome P-450 ([Ch 57](#), ref. 113). Distributes rapidly and extensively through tissues after IV use. Plasma protein binding in most species, including dogs ranges from 51%-67 %. In dogs, 61% of the drug is excreted in the urine, the remainder is excreted in feces. Of the 61% of excreted drug, 7% is unmetabolized. The drug is extensively metabolized in the liver to up to 9 different inactive compounds.

108.172.5 SPECTRUM.

Active against a broad range of yeasts and filamentous fungi including *Candida*, *Cryptococcus*, *Blastomyces*, *Histoplasma*, *Scedosporium*, *Pseudallescheria*, *Fusarium*, and *Aspergillus*. High activity against *Aspergillus* spp. is seen by the geometric mean MIC of 0.4 mg/L which is similar to that of AMB. In experimental animal models of aspergillosis, even in immunocompromized animals, drug is highly fungicidal in sterilizing tissues.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.172.6 INDICATIONS.

Systemic fungal infections with filamentous, yeast, or dimorphic fungi. Has been used alone in people as the first choice with invasive aspergillosis, scedosporiosis, and fusariosis. These filamentous fungal infections have previously only been responsive to treatment with AMB.

108.172.7 APPROVED USES.

Human: for treatment of invasive aspergillosis and infections with *Fusarium* spp and *Scedosporium apiospermum*, the asexual form of *Pseudoallescheria boydii*.

108.172.8 CONTRAINDICATIONS.

Teratogenic in rats, avoid in pregnancy. IV formation should be avoided in patients with impaired renal function because the solubilizing agent, a cyclodextrin, can accumulate in the body.

108.172.9 ADVERSE REACTIONS.

Dose-related photosensitization, visual disturbances, and photophobia have been observed in people. Also noted are hallucinations, increased ALT activity, and rare fulminant hepatic failure. With IV infusion, anaphylactoid reactions can occur.

108.172.10 INTERACTIONS.

Drugs that induce cytochrome P-450 enzymes such as rifampin, phenytoin, and phenobarbital will accelerate voriconazole metabolism. Drugs that inhibit these enzymes, such as quinidine, may increase serum levels of the drug. Grapefruit juice, a known cytochrome P-450 enzyme inhibitor, increases concentration and duration of the drug during treatment of experimental infections of mice (Ch 57, ref. 130).

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral tablets	50 mg, 200 mg	Vfend (Pfizer)
	Parenteral injection	200 mg single use vials	Vfend I.V.

108.172.11 INTERNATIONAL PREPARATIONS.

None.

108.172.12 HANDLING.

Keep tablets at controlled room temperature in airtight containers. Parenteral injection should be stored at room or refrigerator temperature.

108.172.13 ADMINISTRATION.

In people, loading dose is used initially and this is followed by maintenance dose, which is often switched to oral tablets. Give without food. High fat meals reduce the bioavailability of this drug.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dosages				
INDICATIONS	DOSE	ROUTE	INTERVAL (hr)	DURATION (days)
Dogs^a —For fungal infections				
Loading dose	6 mg/kg	IV, PO	12	2
Maintenance dose	3–4 mg/kg	PO	12	prn
a Extrapolated from human dose.				

108.172.14 ADDITIONAL DOSAGES.

In people <40 kg, 100 mg every 12 hr; >40 kg, 200 mg every 12 hr.

108.172.15 DISPENSING INFORMATION.

This medication must be given either 1 hr before or after a meal. Dosage should be reduced in half with liver insufficiency.

1332

108.173 ZALCITABINE: SEE ANTIVIRAL THERAPY, [CHAPTER 2](#)

1333

108.174 ZIDOVUDINE

Formerly AZIDOTHYIMIDINE, AZT.

108.174.1 CLASS.

Nucleoside (thymidine) analog. Missing OH group at 3'-position.

108.174.2 ACTION.

Antiviral; inhibits viral reverse transcriptase. Converted to triphosphate intracellularly; however conversion to the di- and tri-phosphate is slow and thus competitively inhibits enzyme leading to depletion of nucleoside pool for DNA production (anti-herpesvirus activity). Blocks retroviral reverse transcriptase by similarity to thymidine triphosphate. Becomes incorporated into DNA but missing OH causes strand termination. Prevents infection of new cells but virus replication may continue when existing cells are already infected.

108.174.3 MORE INFORMATION.

[Chapter 2](#), Zidobudine; [Table 2-2](#); references: [Ch 2](#), ref. 31; 53; 54.

108.174.4 PHARMACOKINETICS.

Absorbed rapidly and completely from GI tract, unaffected by presence of food. Has a short half-life. Widely distributed and penetrates well into CNS and CSF, crosses placenta. Metabolized in liver to inactive metabolites, and rapidly excreted in urine.

Infectious Diseases of the Dog and Cat, 3rd Edition

108.174⁵ SPECTRUM.

Retroviruses, FeLV, FIV, some herpesviruses. Some resistance by FIV strains has been noted in vitro (Ch 2, ref. 124). Some antibacterial activity against Enterobacteriaceae and synergistic with trimethoprim-sulfonamide.

108.174⁶ INDICATIONS.

Clinically affected cats with FIV. Has been used in combination with investigational drug PMEA (Ch 2, ref. 31). Reduces viral replication and delays onset of immunodeficiency when given prophylactically to FIV infected cats (Ch 2, ref. 60). Higher doses (30 mg/kg day) did not affect viremia in FeLV-infected cats but reduced FOCMA antibody titers (Ch 2, ref. 59). Does not cure retroviral infections but reduces the risk of opportunistic infections.

108.174⁷ APPROVED USES.

Human use: for clinically affected people with HIV infection. Use in human pregnancy to protect unborn child from HIV infection.

108.174⁸ CONTRAINDICATIONS.

Dose must be reduced or dosage interval increased with hepatic insufficiency.

108.174⁹ ADVERSE REACTIONS.

Myelosuppression, megaloblastic anemia at high dosages (30 mg/kg/day) in cats (Ch 2, ref. 59; 136). Hematocrit of treated cats declines within 3 weeks of initiating treatment to 60% of baseline (Ch 2, ref. 179; 180). Effectiveness at 50 mg/kg/day was greatest in suppressing viral replication but most toxic in causing myelosuppression and anemia. At 5 mg/kg every 8 hr, was effectively reduced clinical signs of FIV infection and less toxic (Ch 2, ref. 52). Neutropenia is less frequent than anemia. In people, fever, malaise, GI signs, myalgia, rash also reported.

108.174¹⁰ INTERACTIONS.

Additive effect on FeLV, FIV if given concurrently with PMEA. Delayed metabolism of drug if coadministered with sulfonamides, narcotics, nonsteroidal antiinflammatory drugs.

AVAILABILITY	TYPE	SIZES	PREPARATIONS (COMPANY)
Human	Oral gelatin capsules	100 mg	<i>Retrovir</i> (Glaxo Wellcome)
	Oral raspberry syrup	50 mg/5 ml	<i>Retrovir</i>
	Solution for injection	10 mg/ml	<i>Retrovir</i>

108.174¹¹ HANDLING.

Store capsules and syrup away from moisture and light. Store vials at 15–25°C away from light. Injection: remove calculated dose from vial and add to 5% dextrose for IV use in humans. For SC use in cats should add

Infectious Diseases of the Dog and Cat, 3rd Edition

to 5 ml NaCl instead. Should not add to biologic fluids (plasma or blood). Stable after reconstitution for 24 hr at room temperature, 48 hr if refrigerated.

108.174.13 ADMINISTRATION.

Oral capsules or syrup must be individually compounded to proper dose for each cat. Can begin with IV infusions over 1 hr, given every 4 hr. Switch from IV to PO when able to tolerate it. Doses 30 mg/kg/day are more effective in suppressing virus, but are more myelotoxic to cats.

Dosage				
INDICATIONS (<i>Cats</i>)	DOSE (mg/kg)	ROUTE	INTERVAL (hr)	DURATION (days)
FIV	5–10 ^a	SC, PO	12	prn
FeLV	5 ^a	SC, PO	12	prn

a At higher dosages, cats have more chance for myelotoxicity. Lower dosages are recommended for cats with FeLV infection as they are often already having myelosuppression. See Zidovudine, [Chapter 2](#), for details on monitoring and duration of treatment.

108.174.13 ADDITIONAL DOSAGES.

FIV Infection, [Table 14-5](#); FeLV, under Antivirals and Immunotherapy, [Chapter 13](#).

108.174.14 DISPENSING INFORMATION.

Return once weekly for physical examination and blood count evaluation.

Infectious Diseases of the Dog and Cat, 3rd Edition

¹⁰⁹ APPENDIX 9 Concentrations and Dosages of Locally Used Ocular Antibacterial Agents^a

Jean Stiles

AGENT	TOPICAL	SUBCONJUNCTIVAL	INTRAVITREAL

a For dosage recommendations for systemic administration, see Drug Formulary, [Appendix 8](#).

1334

Infectious Diseases of the Dog and Cat, 3rd Edition

110 Abbreviations Frequently Used Throughout the Text

ABD

amphotericin B deoxcholate

ABCD

amphotericin B colloidal dispersion

ABLC

amphotericin B lipid complex

ACT

activated clotting time

ADE

antibody-dependent enhancement

A:G

albumin-globulin (ratio)

AGID

agar-gel immunodiffusion syndrome

AGP

alpha-acid glycoprotein

AIDS

acquired immunodeficiency syndrome

AIHA

autoimmune hemolytic anemia

ALP

alanine transaminase, alanine aminotransferase

AMB

amphotericin B

APTT

Infectious Diseases of the Dog and Cat, 3rd Edition

activated partial thromboplastin time

ARC

AIDS-related complex

AST

aspartate transaminase, asparatate aminotransferase

AVP

arginine vasopressin

AZT

azidothymidine

BBB

blood-brain barrier

BCG

bacille Calmette-Guerin [vaccine]

BDV

Borna disease virus

BSP

Bromsulphalein

BUN

blood (serum) urea nitrogen

CAV

canine adenovirus (type 1 or 2)

CBC

complete blood (cell) count

CDC

Centers for Disease Control and Prevention

CDV

Infectious Diseases of the Dog and Cat, 3rd Edition

canine distemper virus

CEO

chicken embryo origin

CF

complement fixation

CFU

colony-forming unit

CHV

canine herpesvirus

CIC

circulating immune complex

CIE

countercurrent immunoelectrophoresis

CK

creatin kinase

CMI

cell-mediated immunity

CNS

central nervous system

COVP

canine oral papillomavirus

CPE

cytopathic effect

CPiV

canine parainfluenza virus

CPV

Infectious Diseases of the Dog and Cat, 3rd Edition

canine parvovirus (type 1 or 1)

CRFC

Crandell feline kidney cells

CRV

canine rotavirus

CSD

cat scratch disease

CSF

cerebrospinal fluid

CT

computerized tomography

DF-2

dysgonic fermenter-2

DIC

disseminated intravascular coagulation

DMSO

dimethyl sulfoxide

DNCB

dinitrochlorobenzene

DTM

dermatophyte test medium

ECG

electrocardiography

ECHO

enteric cytopathogenic human orphan [virus]

ECM

Infectious Diseases of the Dog and Cat, 3rd Edition

erythema chronicum migrans

EEG

electroencephalography

EF-4

eugonic fermenter-4

EFF

Elokomín fluke fever

ELISA

enzyme-linked immunosorbent assay

EM

electron microscopy

EME

equine monocytic ehrlichiosis

EMG

electromyography

ETDA

ethylenediaminetetraacetic acid

FA

fluorescent antibody

FAIDS

feline acquired immunodeficiency syndrome

FAVN

fluorescent antibody virus neutralization

5-FC

5-fluorocytosin

FCoV

Infectious Diseases of the Dog and Cat, 3rd Edition

feline coronavirus

FCV

feline calicivirus

FCY

flucytosine

FCZ

fluconazole

FDP

fibrinogen degradation products

FECV

feline enteric coronavirus

FeLV

feline leukemia virus

FeFV

feline foamy (syncytium-forming) virus

FeSV

feline sarcoma virus

FHV

feline herpesvirus

FIPV

feline infectious peritonitis virus

FIV

feline immunodeficiency virus

FOCMA

feline oncornavirus-associated cell membrane antigen

FPV

Infectious Diseases of the Dog and Cat, 3rd Edition

feline panleukopenia virus

FRV

feline rhinotracheitis virus (also FHV -1)

FUO

fever of unknown origin

G-CSF

granulocyte colony-stimulating factor

GFV

griseofulvin

GGT

gamma-glutamyl-transferase

GI

gastrointestinal

GM-CSF

granulocyte-macrophage colony-stimulating factor

GME

granulomatous meningoencephalitis

GMS

Gomori's methenamine silver [stain]

H & E

hematoxylin and eosin [stain]

HCT

hemtocrit

HDCV

human diploid cell (rabies) vaccine

HEP

Infectious Diseases of the Dog and Cat, 3rd Edition

high egg passage [virus]

HGE

hemorrhagic gastroenteritis

HI

hemagglutination inhibition

HIV

human immunodeficiency virus

HOD

hypertrophic osteodystrophy

ICH

infectious cyclic thrombocytopenia

ID

intra-dermal

IFN

interferon
